
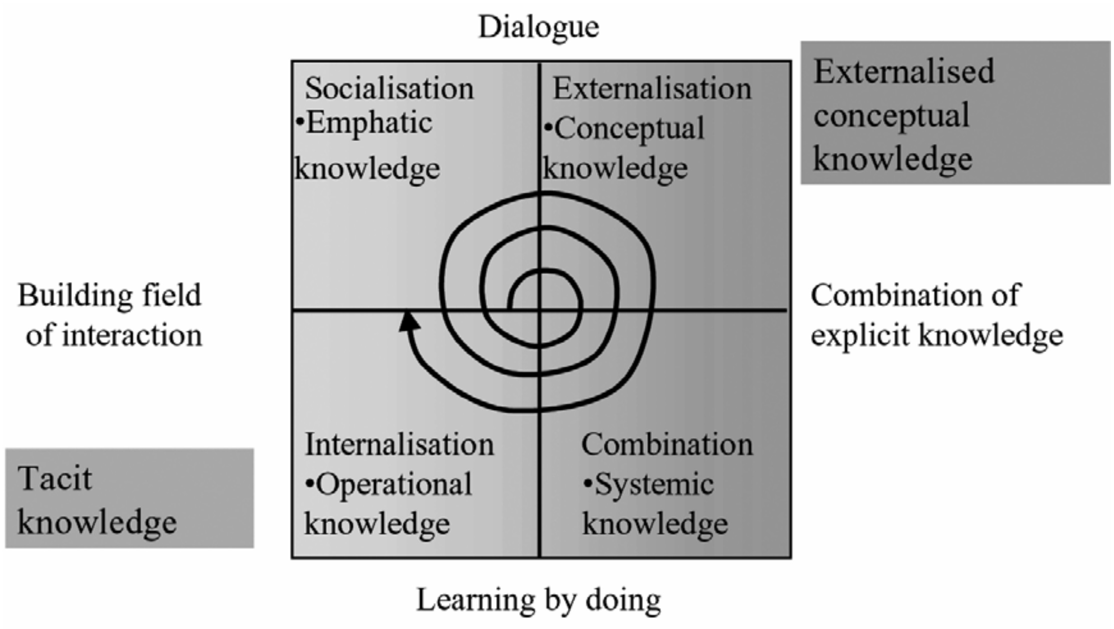

Figure 1 : The spiral of knowledge in the SECI model [8]

Thus the process of knowledge management begins with this knowledge creation and progresses to knowledge capture and storage, knowledge refinement, knowledge distribution, knowledge use, and monitoring of the entire process, which should then impact the beginning of the process [12]. In 1996, one view was that knowledge management involved knowledge creation, followed by knowledge interpretation, knowledge dissemination and use, and knowledge retention and refinement [13]. The American Productivity and Quality Center (APQC) [14] defined knowledge management as "the strategies and processes of identifying, capturing and leveraging knowledge" to enhance competitiveness. Miller considered that the knowledge management process is concerned with capturing an organisation's know-how and know-what through creation, collection, storage, distribution, and application [15]. Svieby [16] modelled the Create, Store Use, Reuse, Dispose cycle. In 2003, the Australian Standard in Knowledge Management clause 1.4.1 determined that the knowledge management process consisted of four activities: creating, discovering and acquiring knowledge; capturing and storing knowledge; presenting, distributing and sharing knowledge; and revising and disposing of knowledge [10]. Notably, clause 4.3.1 of the Australian Standard on Record Keeping details a similar process, being capture, registration, classification, classification of access, security and disposal, storage, use, and disposal [17]. Figure 2 presents a knowledge lifecycle model developed from this literature review.

.

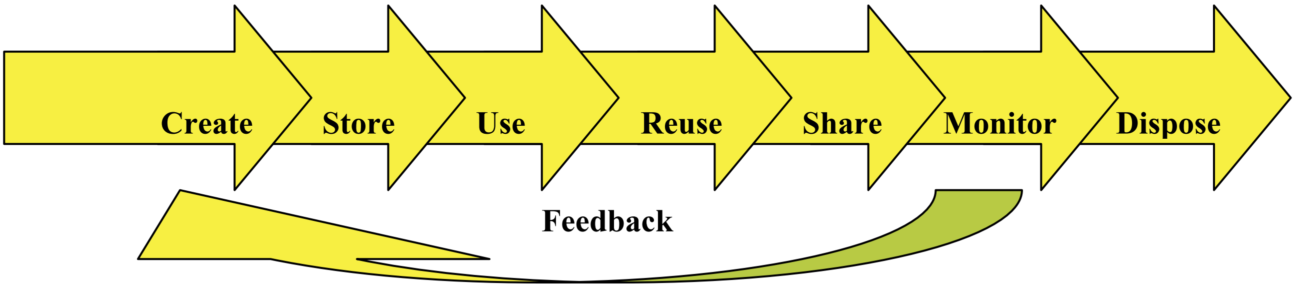

Figure 2 : Knowledge life-cycle model

1.1 Knowledge management

The key goal of knowledge managers should be to understand these knowledge management (lifecycle) processes and incorporate them into business activities. [12]. As Martin rationalises, the real point of efforts at understanding intellectual capital is not a matter of measurement or financial reporting but of management for creation of value. [18]. Knowledge management is the process of critically managing knowledge to meet existing needs, to identify and exploit existing and acquired knowledge assets and to develop new opportunities [19]. The two objectives of knowledge management are firstly to make the organisation act as intelligently as possible in order to secure its viability and overall success; and secondly for the organisation to otherwise realise the best value of its knowledge assets [20].

There are actually considered to be three major schools of thought on what knowledge management is [21]. One school suggests that knowledge management is primarily information technology enabling people to share knowledge. A second school suggests that knowledge management is more of a human resource issue with emphases on organisational culture and teamwork. A strong, positive organisational culture is critical to promoting learning, development and the sharing of skills, resources, and knowledge. The third school promotes the development of processes to measure and capture the organisation's know-how. Processes do not necessarily need to involve the use of information technology.

There has also already been three generations of knowledge management [22]. The first generation focused on defining knowledge management, investigating the potential benefits of KM for businesses, and designing specific KM projects [23]; [8]; [24]. The second generation of KM started to emerge around 1996 with many corporations setting up new jobs for KM specialists. The different sources of KM combined and expanded to touch frameworks [25], operations and practices [26] and advanced technologies [27]. Second-generation KM emphasised that KM is about systemic organisational change co-developed with management practices, measurement systems, tools and content management. Resulting from these new insights and practices, the third generation of KM emerged, according to [28] to integrate with the enterprise's philosophy, strategy, goals, practices, systems and procedures and how it becomes part of each employee's daily work-life and motivation. The third generation seems to emphasise the link between knowing and action [29].

The authors consider that in this dawn of a new millennium, a fourth generation of Knowledge Management is now evolving. This is supported by the recent 'third wave of environmentalism' as recognised by Holgrem [30]. This fourth generation seeks to integrate the synergistic philosophies of Quality and Knowledge Management, and apply wise decision making discipline to implement only the highest quality knowledge. This would support the principle of 'real quality' as proposed by Heeks [31]. Although Hawking dreams of a day beyond unified theory when we have a complete understanding of our existence and the mind of God [32], such a quest for such 'knowledge' is considered suicidal unless wisdom prevails. Multi-loop learning inevitably converges human knowledge to the wise practice of organic sustainability. The practice of fourth generation knowledge management is to enable that outcome. It is considered that this fourth generation evolution of knowledge management would therefore actually be more appropriately coined 'Wisdom Management'.

The most common objective of first adopters of those earlier generation knowledge management systems was implementing some sort of knowledge repository. The objective of this was to capture a particular type of knowledge (eg best practices, sales information, lessons learnt, competitive intelligence, plans etc) for later and broader access by others within the same organisation. [12]. Since the implementation of these early knowledge management systems, organisations have been better enabled to create, store, refine, distribute, use, monitor and feedback knowledge, as per the Figure 2 lifecycle.

However, as the human knowledge (and technology) further evolved forward, ongoing maintenance of the knowledge assets and the system itself is required to retain the asset in an optimised state to enable organisational competitiveness. Therefore, this raises a requirement for organisational knowledge condition monitoring and maintenance techniques.

2 MAINTENANCE OF KNOWLEDGE

This section considers 'familiar' maintenance principles being applied to knowledge assets. To discuss a maintenance system the object system must first be defined [33]. In this paper, the object system being maintained is 'knowledge'. With the rapid evolution of organisational knowledge, knowledge maintenance has become a challenging activity for most competitive organisations. There is growing recognition in the business community about the importance of knowledge as a critical resource for organisations [34], [35]. In this new economy, individuals and companies are obliged to focus on maintaining and enhancing their knowledge asset in order to innovate [22]. Organisational knowledge evolution (learning) is a result of an efficient and effectively designed and implemented Quality Management System [36]. Such knowledge evolution enables continuous improvement [37], and thus further knowledge evolution. As with technical processes and production capacities, the process of quality management is also liable to wear as parts of the system become ignored or go out of date [38]. Maintenance activities are necessary to "repair" the quality knowledge assets as discrepancies arise. The outcome of Knowledge Management is a continuous implementation of knowledge improvements.

The maintenance of the knowledge asset is considered by linking maintenance concepts [39], [40] with concepts of quality and knowledge management [41], [8], [42]. The maintenance of knowledge can be through either built-in or non-built-in maintenance. External and internal audits are examples of built-in maintenance. The results of 'built in' audits and inspections affect the performance of organisational knowledge development, in the sense that explicit operational process performance quality is reviewed, and changes introduced. Such built-in actions enable maintenance of the organisational knowledge. If the activity has been left to chance, performed in addition to the normal quality control activities, it is of the non-built-in type. Often, non built-in maintenance is performed to put right (or to prevent) the poor functioning of the maintenance management (control) system itself.

The maintenance system comprises both formal and informal elements. The formal elements include management systems and methods, organisational structures, information systems, and technology necessary to implement the generic maintenance tasks within an industrial enterprise. The formal management system essentially specifies when to deal with one or more of the maintenance tasks, what to do when a task is dealt with, and who should do it considering formal collective knowledge and know-how. Informal elements of a maintenance system include the actors of maintenance. These actors include the individuals performing maintenance functions (ie. technicians, operators, and managers) as well as the influence of the corporate culture. Individuals of a maintenance organisation act and decide using their knowledge, skills and know-how, their motivation and attitudes [33].

Analogous to maintenance models for technical systems and products, the notions of preventive maintenance and corrective maintenance can also be applied to the maintenance of knowledge [38]. Preventative-based maintenance includes condition based or user based maintenance. Condition based maintenance is applied if the result of an observation violates defined norms. The observations may be done on a continuous or periodical basis. Inspections, audits, and monitoring can trigger condition-based maintenance of existing organisational knowledge. User based maintenance can be applied if there exists a relation between the decrease in the condition of the system and the intensity of use. The intensity of use is somehow observed and on the basis of this observation it is decided if it is necessary to maintain the system (or its parts). This maintenance method is most applicable to the knowledge that is (at least in principle) liable to ageing. Knowledge loss (losing documents or staff) is one example, and knowledge relevance (referencing most up to date information) another. On the basis of the results of user observations, a “knowledge repair” can be implemented. Corrective, failure based maintenance can be applied when certain aspects of the quality management system do not work as they should. Maintenance takes place only after a failure occurs. For example, when a customer complaint indicates opportunity for knowledge system improvement, maintenance of the system to reduce similar complaints can be implemented. These knowledge maintenance methods are depicted in Figure 3.

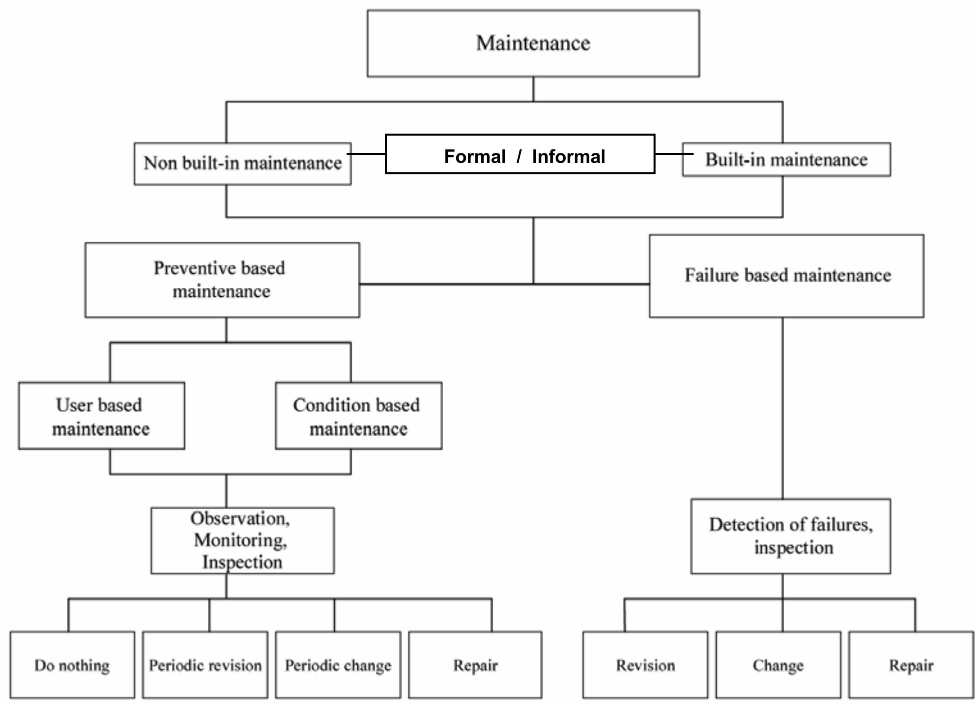

Figure 3: Knowledge Maintenance Methods

3 IMPLEMENTING TOOLS TO MAINTAIN THE KNOWLEDGE ASSET

Business involves competitive advantage [43]. Competitive advantage requires innovation [44]. Improvement and innovation play a crucial role in securing sustained competitive advantage [43]. The continual improvement of quality brings continual rise in productivity [45]. Innovation and continual improvement are a main outcome of knowledge management, which benefits competitive advantage. Therefore, it can be deduced that successful implementation of knowledge asset improvement positively influences business excellence. As organisations further appreciate these benefits of the knowledge asset on business competitiveness, engineers are kept striving to better maintain the knowledge asset.

The continuously changing and improving knowledge assets require implementing in order to deliver the competitive advantage capabilities and organisational excellence. It is vital that managers understand the issues that influence the implementation of these improvement changes, and how to offset any issues before they become dysfunctional. Successful knowledge management must ensure the balancing of the elements of People, Process and Product (Technology & Content) to fit with the organisation's capability and culture [10]. Likewise, it is considered that all three elements of people, product and process must also be considered to achieve successful implementation of a knowledge management change.

3.1 An emerging implementation model

Managers should be aware that these people, product and process issues can occur at any stage of the change implementation. Rogers recognised five stages of implementation; two stages prior to the decision to adopt the change, and three stages once that decision has been taken. The final stage occurs when everyone is using the new system and it has become routine [46]. The individual participation in the process of implementing change is also considered to follow a change curve from denial through to commitment [47]. The capability maturity model (CMM) provides a five-stage classification for describing and assessing the extent to which an organisation has become proficient in adopting a particular technology or system[48], and Satir has developed a change management philosophy [49]. These models – Rogers' stages, Gaffe's change grid, capability maturity and Satir's curve – are not in conflict but rather detail different aspects of the change implementation process. It is considered that by incorporating the best aspects of each model, as was done for the knowledge lifecycle in Figure 3, an improved change maturity model could be developed. This will be the subject of a later paper. In the meantime the existing four models provides the framework for implementation.

3.2 The need for agility

Both Rogers model of technology diffusion and the capability maturity model are constructed as processes ending in full integration [50]. It is noted however from the literature that the time to achieve the integration presumed by Rogers' routinisation or level 5 maturity may be significant. Rogers himself suggests that the cultural change may take years [51] and a recent survey found that best practice can take an average of 27 months to move from one part of the organisation to another, even in the best of companies [52]. This indicates a lack of organisational agility to change in some instances. The turbulence of the business environment reduces the response-time available to firms to cope with change and thus creates the need for agility. The key drivers of this need for agility are to be found in a company's business environment, such as change in the marketplace, technology, and competition [53, 54].

Agility is suggested as more than just the ability to respond to change; it is the ability to incorporate change as a way of managing the business. This implies that agile organisations should make change be felt at all the organisational levels and activities; should possess a continuous and improved ability to predict changes and should be open learning organisations with an important external focus [55]. However the literature also notes that the more agile [56] an organisation is, the more dynamic and adaptive [57, 58], better able to operate profitably in a competitive environment of continuous and unpredictable change [59, 60], and more capable of gaining competitive advantage by intelligently, rapidly and proactively seizing opportunities and reacting to threats [61, 62]. It is contented that if the agility performance of an organisation could be better measured, management science could be applied to further improve that agility. This should enable more rapid maturity rate of knowledge change, creating greater capability for competitiveness.

Agile organisations are knowledge intensive organisations and are characterised because intellectual capital is the main factor of production and because they innovate in response to changing environments. These organisations create new knowledge bases by converting tacit and explicit and individual and collective knowledge reservoirs following a dynamic spiralling process [8]. Learning organisations should then be skilled at creating, acquiring and transferring knowledge and at modifying their behaviour to reflect new knowledge and insights [63].

4 PRACTICAL CASE STUDY IN MAINTAINING KNOWLEDGE ASSETS

A case study example is discussed here to demonstrate the practical concept of maintaining knowledge assets. A large coal mining company, operating a number of sites, is actively striving to better maintain its knowledge assets. The operational departments are nested deep within the corporate structure of the parent company as depicted in Figure 4. Obviously, in large organisations, the complexity of knowledge management is compounded by the amount of knowledge to be managed, the number of individuals involved, and the geographical separation / remoteness. Any change implementation issues with people, process or product also become more complex. By designing and refining effective and efficient solutions to issues that arise in such larger organisations, the solutions are then transferable to small implementations.

Figure 4: Organisational context of this case study

As part of its effort to continuously improve its business quality management systems, the Chief Executive Office supported the strategic vision for a company-wide Knowledge Management Policy (KMP). This KMP aims to optimise corporate information and knowledge management practices. The KMP was resourced and developed in response to recognition of the corporate value of information recorded within the organisation's knowledge, information and document assets. This case study discusses the practical aspects utilised to implement this directive at the 'operational' Department level, by considering the implementation issues with product, people and process, as follows:

- Product: To assist achieve the KMP strategic directive, the mine is currently implementing an Enterprise Content Management (ECM) System across all departments. The ECM system selected offers the technology to electronically store all documentation and retrieve items by searching for document meta-data or specific name strings, in a similar way to a Google search. Other products implemented to achieve this KM directive included a rationalisation of all archived documentation, with some obsolete documents being disposed of, and long term archives moved of site. The introduction of improved short-term knowledge storage systems in the product form of compactus and lockable cabinets. By creating a better space for document storage, the knowledge could be more appropriately sorted for application.
- Process: The site included process activities when planning the response to the KMP directive, acknowledging that the product (and product-focused training) would not be sufficient to achieve the corporate goals. A range of activities is being undertaken to assist the implementation process, including planning and offsetting issues before they became dysfunctional. This included regular communication to all employees involved through meeting presentations, e-mails, flyers, and one-one training. Another process initiative was the parallel implementation,

rather than sequential. This required project management techniques of scheduling, critical path analysis, and regular monitoring/review of progress.

- People: Observation over a period of 6 months showed that the implementation of this product is following an implementation maturity curve similar to that of Gaffe [47], with initial denial and resistance, to exploration and commitment. However there a few individuals – the early adopters (Rogers 1995) – who became mature users of the system with a minimum of fuss. Further process-focussed training and one-one consultations with stakeholders were applied to overcome or reduce resistance. Whilst the ECM tool enabled greater access to the organisational knowledge, it was observed that implementation was greatly influenced by the personal knowledge management disciplines / habits of individual people.

Overall, the practical experiences of this case have assisted in refining the emerging 'implementation maturity model' concept. The change curve was observed, and the methodologies developed to assisted offset and overcome the above people, process and product implementation issues before they became dysfunctional. This demonstrated the usefulness of the product-process-people framework. This case was presented here to demonstrate these practicalities in maintaining knowledge assets.

5 CONCLUSION

This paper discussed the concept of knowledge, its maintenance, the management systems that have evolved to assist, and the implementation of those systems. It is recognised from case study experience that it requires considerable skill to successfully implement a knowledge system change through to maturity. Implementation of a knowledge system change to maturity will assist organisations to maintain knowledge asset. Through management of the people, process and product issues, knowledge asset change was implemented, and overall knowledge system effectiveness increasing competitive capabilities of the business.

By pro-actively foreseeing and resolving any people, product and process implementation issues that arise, managers can increase the agility of any necessary change implementations. This not only makes the change more effective by being competitively mature earlier, it is also more efficient as resources are not wasted trying to push change against great resistance. The modern manager must appreciate the create/store/use/refine/dispose knowledge lifecycle, the maintenance requirements, the people, product and process issues that can arise, and the various stages of implementation maturity.

Ultimately, it is through better implementation of information and knowledge management systems that managers can better maintain their knowledge assets. The objective of this paper was to present knowledge management models that assist managers maintain organisational knowledge assets. These authors continue to research and refine their understanding of the implementation maturity model so as to provide change agents with useful tools to guide them through the implementation process. Through the development of the science of Knowledge Management, the challenge of change implementation becomes more manageable, and the client business becomes more competitive.

Abstract: Human intervention in system operation has the potential to introduce degradation in system performance, or, total failure of overall service delivery . The consequences of these fault or failure modes will vary according to the significance and configuration of the system, or service that has been interrupted by the planned intervention. Organisations must develop strategies and tools that provide engineering and maintenance staff, operators and decision makers with better information when planning to interrupt services for routine maintenance, project installation work, or configuration changes. Airservices Australia, as an internationally recognised Air Traffic Management Service Provider, has initiated an improved means of assessing and mitigating the risks associated with project and maintenance activities on Key Systems and Sites. These are defined as systems which, if interrupted, could cause a significant loss of service capability, seriously impairing operational safety. Our solution involved the development and support, in-house, of a successful Key Systems Works Planning process to capture the risks associated with the planned intervention, the mitigators required to reduce the identified risks to As Low As Reasonably Practicable (ALARP), the rationale for proceeding with the intervention and the associated communication requirements. The success of this program has been aided by the roll-out of a Human Error Management program.

Key Words: Systems Integrity, Safety Management Systems, Human Error Management, Works Plans, Maintenance, Operational Risk Assessment

1 BACKGROUND

For as long as industry has operated and maintained systems, plant and equipment, the very action of undertaking routine maintenance, configuration change, or, project installation, has resulted in the unplanned likelihood of degradation in system performance , or, at worst, total system failure. The consequences to production and safety are dependent on the operational significance and configuration of the system, or, service being interrupted. Industry can mitigate the outcomes of abnormal and degraded modes of operation by ensuring such activities are performed during complete plant shutdown and restart processes. This may not always be achievable, particularly in Air Traffic Management industry where it is common to be working on live systems, albeit with a backup, or, bypass system in operation.

A recent article [1] reported Britain's Air Accident Investigation Branch as stating "Maintenance errors were not the result of wilful negligence, or any desire to perform a less-than-satisfactory job, but the result of a combination of systemic issues that had increased the probability of an error being committed." British Airways (BA) took the safety report "very seriously" and had addressed the problems in its maintenance processes. "British Airways prides itself on safety and recognises that we are always ready to learn from incidents and encourage open transparent reporting," said the airline's head of safety, Captain Rod Young.

From a global perspective, we are witnessing an increase in system integration and operational inter-dependence, creating increased opportunities for common mode failures, yet, our strategies and tools for managing interruptions to systems and services can be seen to be lagging this technological change. In the challenge to strike the appropriate balance between production and safety, while still staying in business, organisations must continue to develop and implement strategies, tools and cultural change to enable engineering and maintenance staff, operators and asset owners to become informed decision makers with improved, appropriate and timely information when planning to interrupt services for planned maintenance, or, system configuration change. If we are to minimise the likelihood of operational failures when interrupting systems and services, we need to adopt a proactive approach,. thereby ensuring operational safety and system availability,

Early attempts at reducing operational safety incidents focused predominantly on the technological aspects, increasing reliability through improved engineering, driven from reactive analysis of accidents and incidents. Regulation of civil aviation defining 'what to do' and 'how to do it ' is essentially driven from the International Civil Aviation Organisation (ICAO)'s use of Standards and Recommended Practices (SARPs). In Australia the Civil Aviation Safety Authority (CASA), as the regulator, ensures international compliance by Airservices Australia to these SARPs . Substantial improvements in safety were achieved and continue to be achieved through this ongoing program

The implementation and application of a safety management system, utilising the safety case process, enabled Airservices Australia to systematically identify and manage hazards to reduce the level of risk to the National Airways System (NAS), through a 'systems' approach to safety. Certification and compliance to ISO9001, ISO14001 and CASR171/172/139 ensured sound systems' practices and procedures are adhered to, but these remained effectively a reactionary mechanism to safety improvement. What was needed was a proactive approach to safety culture through awareness and alertness to the effects of human error in the workplace [2,3].

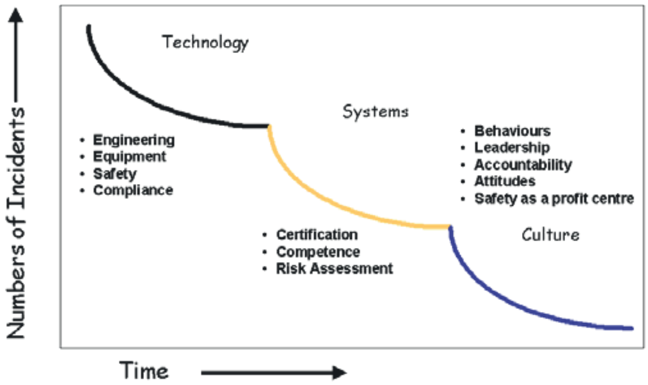

Figure 1 The Safety Management Evolution (11)

James Reason [4] describes a safety culture as the 'engine' that drives the organisation towards maximum attainable safety. Collectively it is the beliefs, attitudes and values of an organisation's approach towards safety. It includes the structures, practices, controls and policies the organisation possesses and employs, to achieve greater operational safety. Small incremental increases to safety have involved improvements to the safety culture of the organisation to better identify safety related hazards and risks, further reducers incidents, by instilling an 'intelligent wariness' [4], to expect the unexpected.

We were conscious of maintaining this "intelligent wariness" as a foundation for our safety improvement process. Airservices consequently developed a strong interest in human error identification, education and management in the engineering and maintenance group. Feedback from system performance reviews indicated that although we possessed highly skilled, knowledgeable and well trained staff, were a mature operator of a risk based Safety Management System, had embraced an integrated system safety philosophy, and had a comprehensive suite of support tools, we were incurring equipment failures that had the potential to impact on operational safety.

On several occasions Airservices Australia experienced a series of system failures arising from human errors by the engineering and maintenance group [5]. Subsequent investigation and analysis revealed a relative lack of human factors awareness, knowledge and capability within this group. This was identified as representing an ongoing risk to the safety and reliability of services. The Works Plan improvement program has been part of the safety culture journey, dovetailing with the roll-out of our engineering and maintenance Human Error Management program.

2 WORKS PLAN PROGRAM

2.1 Works Plan Concept

A Works Plan system facilitates the notification process and enables required actions when facilities/equipment forming part of the Australian national airways system are intended to undergo planned maintenance, configuration change, or, removed from operational service. The NAS includes facilities, equipment, [including Corporate Data Network facilities and privately owned facilities], used in the delivery of aeronautical telecommunications, radio navigation or air traffic services, as defined in Annex 10 and 11 to the ICAO Chicago convention.

"Works plans" are published descriptions of the intention to perform planned maintenance work. The nature of work and timing is proposed by technical staff and assessed and approved by operational staff. Once approved the execution of work is coordinated between Technical Customer Interface and Air Traffic Operations Managers.

The objectives of the original paper-based Works Plan system included:

- A mechanism for Operational, Technical and Engineering staff for planning the safe, efficient and effective removal and restoration of systems and facilities; this included works performed by internal and external service providers and where Airservices maintained assets for external owners, public and private sector
- Air Traffic Management (ATM) Facility Coordinators with advanced notice of equipment maintenance/configuration change activities that will affect their operations;
- The aviation industry to be advised of a temporary loss of a facility or a service, or, degraded level of service; (NOTAM action required);
- The ability for consultation among service users, prior to planned maintenance works;

- Formal advice of tasks that are considered high risk which may affect the provision of ATM services; and
- Increased level of visibility across the operational divisions of both scheduled and unscheduled maintenance, project and fault rectification activities.

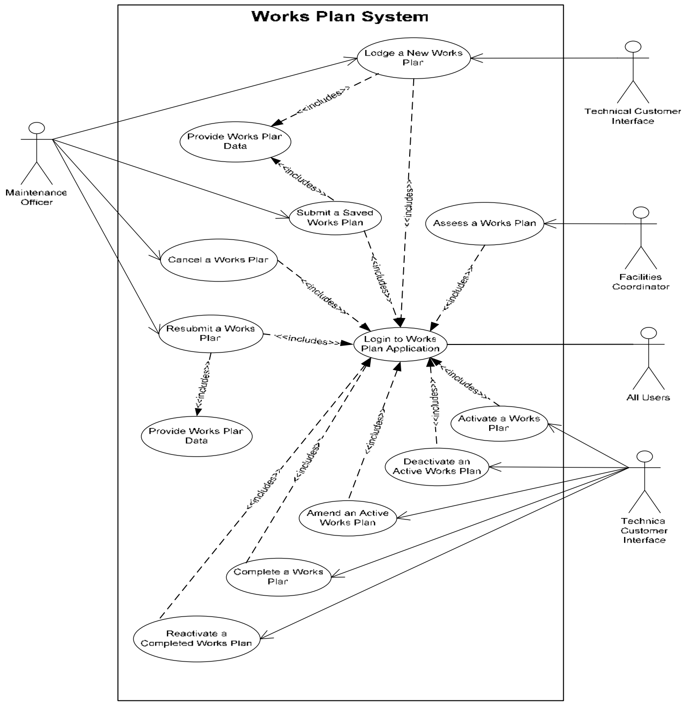

Figure 2 A Use Case Model that illustrates how various actors use the system by performing system functions (12)

The guiding principle for the use of works plans was defined as when routine maintenance, installation activity or testing will directly affect the ATC operating environment. Some examples included activity that:

- Required the operator to change their method of operation eg maintenance to a console where it required transfer of functionality to other consoles;
- Required the operator to be without a secondary or back up system or service for an extended period eg link path, secondary or tertiary frequency;
- May have a critical impact on multiple operational services; (testing of UPS static switches, satellite trunks)

Works Plans were not required for tasks on the airways system which were non intrusive, or, did not directly, or indirectly affect the facility user.

2.2 Intranet Works Plan

Performance audits revealed variations in use of the paper based system that had the potential to erode the safety requirements of the organisation in the face of constant socio-technological change, eg.

- Occasions where the works plan process was not used in accordance with agreed procedure
- Limitations of a paper based system in providing a uniform approach to daily management of Airways Systems works
- Inconsistency of information provided to decision makers eg- identifying hazards for risk determination
- Lack of visibility of both proposed & active works on an Flight Information Region, or, on a national basis
- Lack of Lessons learned Knowledge management engine

Airservices' solution involved implementing an intranet based Works Plan system to facilitate a uniform approach to the safe management of equipment maintenance activities. The system was developed "in-house" as a replacement for a paper based equipment maintenance process, previously used in isolation across all locations in Australia. This development strategy was driven by the lack of a commercially available "off the shelf" product at the time of need, significant internal programming knowledge and skills and a desire to maintain the safety and security around the propriety operational knowledge of the NAS.

Since the initial release of the "live" system, there had been many enhancements to the Works Plan application, in order to improve functionality and meet vital emerging safety and operational requirements. These were identified through regular feedback as well as planned consultations with stakeholders, including, asset owners, operators, maintainers, engineering and operational authorities.

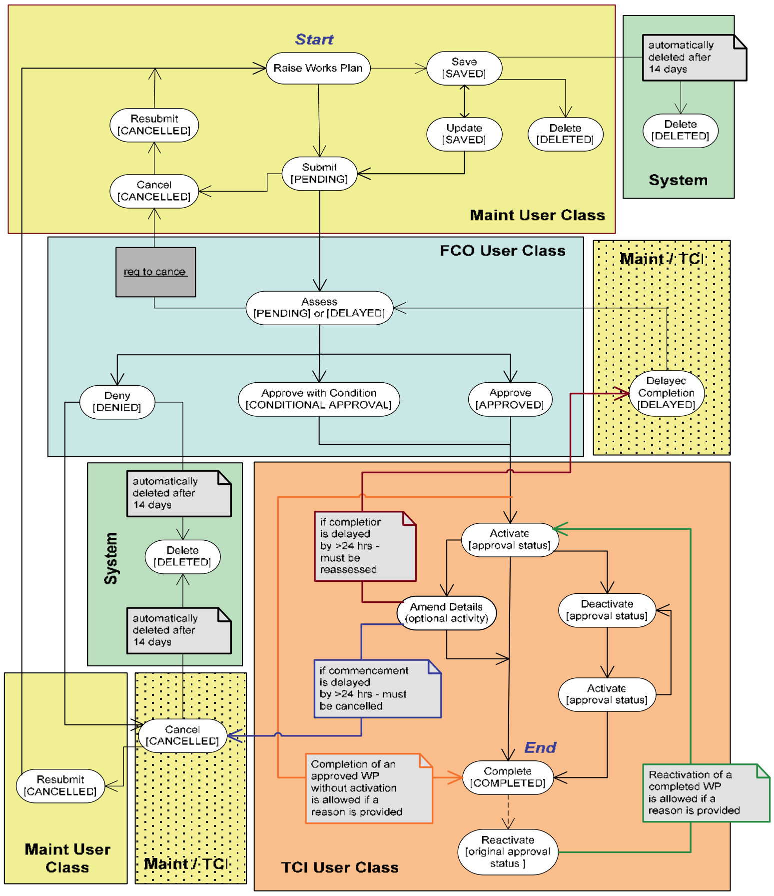

Figure 3 Illustration of the actions various user classes perform during the lifecycle of a works plan. (12)

Although the modifications have served the purpose at the time of implementation, the application had become inadequate in the changing operational environment. From a socio-technological perspective the existing system was deemed inefficient and expensive to maintain.

2.3 Enhanced Works Plan

The functionality of the existing intranet Works Plan application required improvement in order to maintain organisational missions of 'Keeping Safety First' and adopting world's best operational practices and safety requirements. A project was established to implement an Enhanced Intranet based Works Planning tool that would provide strategic and tactical planning capability for actual and potential service interruptions. A key requirement that emerged was the visibility of proposed maintenance, project activities, and system operational status with pre-existing conditions, such as degraded modes and known fault conditions. This required a mapping of systems to services, in a way that clearly showed the functional interrelationships. With this information, it would be possible to apply a risk based approach to service interruption based upon AS4360 – 2004, utilising the knowledge and expertise of the respective domain experts to identify and assess the technical and operational risks associated with maintenance activities and their potential impact on service levels. The Enhanced intranet based Works Planning Tool would provide a mechanism for effective communication and liaison between operational, engineering, technical work areas and relevant stakeholders. The solution would facilitate a means to capture knowledge of known adverse system interactions and interdependencies to minimise unintended adverse outcomes.

Initially there were difficulties enacting the mapping of systems to services, given the complexity of the operational environment. There was and still is, a reliance on the tacit knowledge of engineering and operational authorities to draw together the "big picture' of the operating environment when works plans are lodged for approval to proceed. With the continued use of the application, this tacit knowledge is being converted to explicit knowledge, retained within the application and through interfaces to SAP and the Document Management System.

In summary, the immediate benefits of the Enhanced Intranet Works Plan redevelopment project have included:

- Improved visibility of proposed maintenance activities to alert operational and maintenance staff on planned concurrent site activity and activity at other dependent sites enabling safe and efficient removal and restoration of systems;

- The identification of Key Systems providing a greater understanding of the technical and operational risks associated with system and site maintenance; this has lead to the development of Key Systems Works Plans and coordination with the Operational Risk Assessments (ORA). Figure 4 details the structure for ORA development. The top level encapsulates the delivery of an integrated service to the aviation industry. Underpinning the delivered services are airways systems and service delivery functions. Service delivery functions include system operation, maintenance and life cycle management

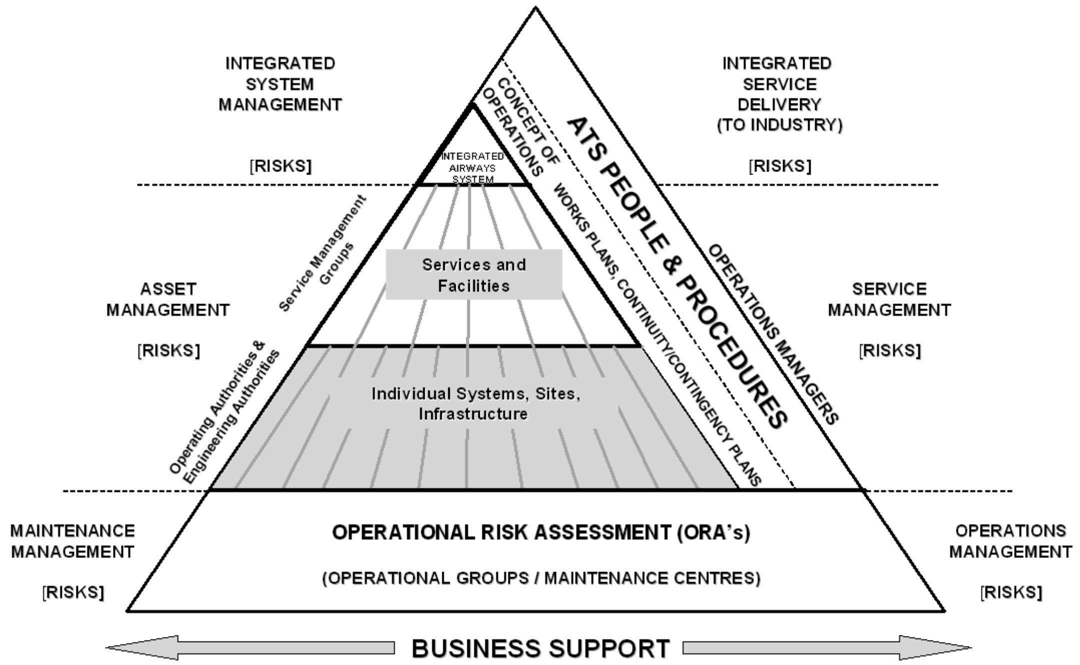

Figure 4 Operational Risk Assessment Pyramid (12)

- Data synchronisation with SAP PM to provide maintenance staff access to up to date information on equipment, systems and services when planning maintenance activities.
- Regular data uploads from SAP PM on faulted services to alert maintenance staff on known fault conditions when planning equipment maintenance activities;
- Links from Works Plan system to Key Systems Works Plan documentation and online system overview site diagrams to enable maintenance and operational staff make informed decisions relating to activities that may interrupt service delivery; and
- Enhanced screen layouts and modifications to existing system functionality greatly improved the efficiency and usability of the application; User training courses tailored for different user groups
- An Airservices wide, user friendly integrated approach, with a level of accountability for works plan activities across Operational, Engineering and Technical domains

2.4 Key Systems Works Plans (KSWP)

As part of our continual safety improvement program, Airservices Australia has developed an improved means of assessing the risks associated with periodic maintenance activities on Key Systems, determining appropriate mitigators to reduce the risk to ALARP, the rationale for proceeding with the maintenance and the associated internal and external communication arrangements. Key Systems are defined as those systems which, if interrupted, could cause a significant loss of service capability. That is, services that are critical to the organisation's mission. Soon after commencing this activity the group realised that periodic maintenance at Key Sites could also cause a significant loss of service capability. Key Sites are those sites which, if disrupted, could cause a significant loss of service capability. Key sites include those sites upon which multiple other sites have a high dependency for the integrity of service delivery, or those which support mission critical systems. These may include sites that contain a significant number of facilities, or that support a key system eg. A hub link site that feeds a number of other sites which, individually, present a low risk to service delivery, but, if all sites were not available on-line due to the failure of the hub link site, the risk to service delivery is greatly increased. The hub link site might then be considered a key site. If one of these sites supported a key system it too could be considered a key site.

The KSWP program was facilitated by the development of Key System Risk Management Reviews. These reviews recorded the outputs of a structured process that captured the risks associated engineering and maintenance activities at Key sites. Awareness by the facility co-ordinators of the growth in system integration and operational inter-dependence, with increased opportunities for common mode failures was an early milestone. An immediate need was flagged by the engineering and operational authorities to prepare simplified block diagrams, from the abundance of existing detailed schematics. These would be available to the Technical Customer Interface and Air Traffic Operations Managers, as an aid to clarification of the operational impact of intrusive maintenance on Key Sites and services before a decision was made to proceed or defer maintenance activity. An example simplifying the power supply to a major control centre is shown in Figure 5 .

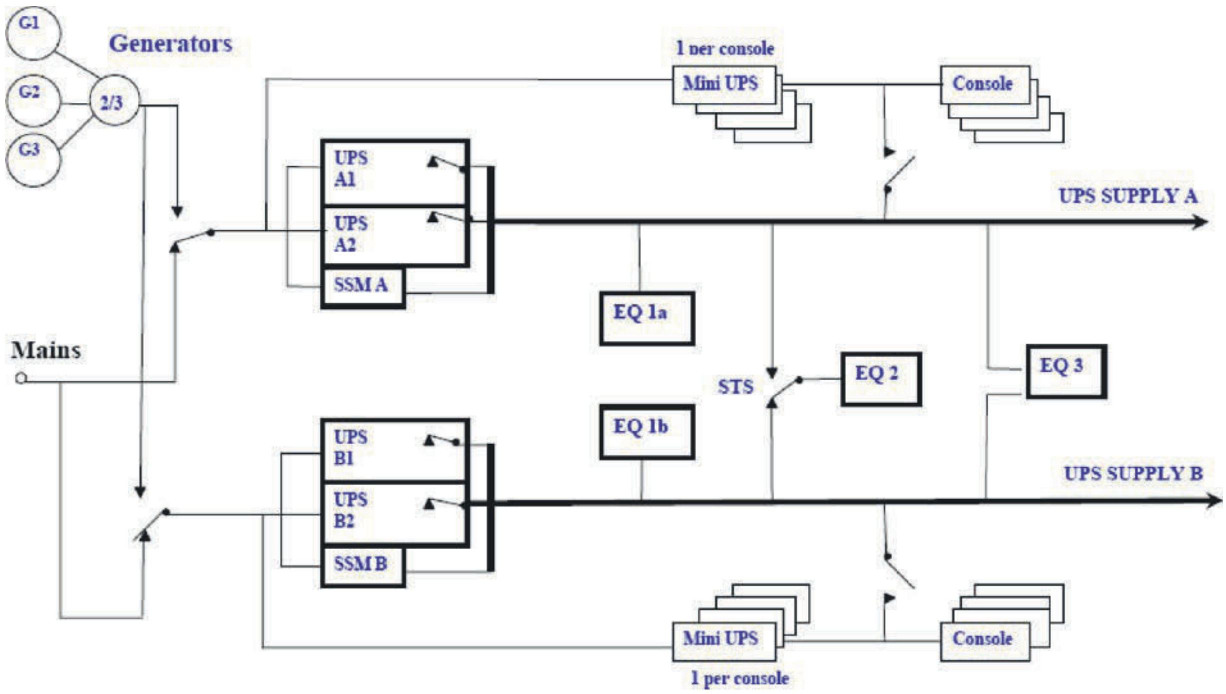

Figure 5 Basic UPS configuration for Major Air Traffic Control Centre (12)

Numerous benefits have flowed from this work, some of which include:

- Greater understanding of the technical and operational risks associated with Key System/Site maintenance
- Enhanced defences in reducing both the likelihood of failure and operational preparedness should a failure occur
- Improved communications with operations leading to improved decision making and a streamlined approval process for key system maintenance
- Improved definition of the system baseline uncovering potential improvements in system configuration to cater for system degradation

2.5 Works Plan categorisation

Key System Works Plans are included in Works Plan method, and are the top level category of Works Plan. Other categories of works plans would be required, with categories such as:

- Moderate (Written Consultation)
- Minor (Verbal Consultation)
- Nil Ops Consultation Required (eg data backups, non-operational equipment)

Decision support criteria for operations and maintenance decision makers have been developed for each category, based on the "significance" of the proposed works. These criteria can be expressed in descriptive terms, using examples of types of systems to be maintained, or, using the consequence categories, or a combination of both.

2.6 Threat Alert Management

The Threat Alert Management concept is meant to forcefully interrupt the "chain of causation" leading to an operational safety incident/accident by alerting engineering, maintenance and operators to lessons learned and potential hazards in the execution of the planned activities[6]. In figure 6 we see an adaptation of James Reason's accident causation/ "Swiss Cheese"

Model [4] that serves to highlight the process of error creation, capture and management, or, if all the “holes line up”, system safety failure.

Table 1 Criteria for Works Plans categories

Category	Consultation	Description	Consequence Criteria
Key System	Written	Potential for major loss of service provision, such as multiple frequency failure, multiple radar/display failure or a combination of system failures leading to a major degradation of service	The ability to maintain an air traffic service may be severely compromised within one or more airspace sectors without warning for a significant time.
Moderate	Written	Potential for moderate degradation of service provision (but no loss of service), handled through normal contingency arrangements	The ability to maintain an air traffic service may be impaired within one or more airspace sectors without warning for a significant time.
Minor	Verbal	Monitored by Ops SS	No affect on the ability to maintain an air traffic service in the short term, but the situation needs to be monitored and reviewed for the need to apply some form of contingency separation measures if the condition prevails.
Insignificant	Nil Ops Consultation	Technical Notification only (TCI monitoring), non-NAS related maintenance	No possible affect on aircraft or ATC operations

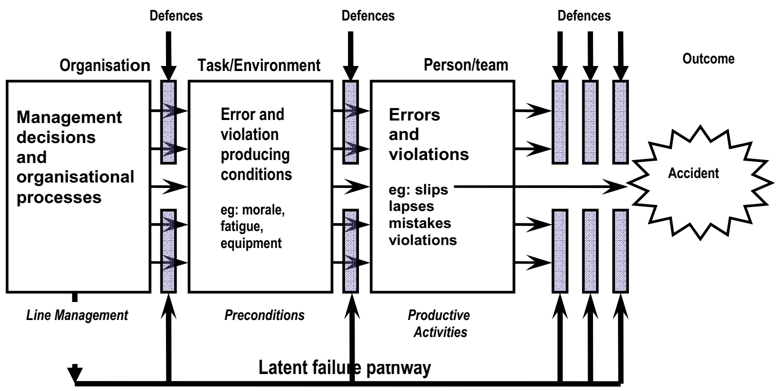

Figure 6 Adapted from Reason Model of Accident Causation [4]

The Threat Alert Management concept involves identifying and capturing potential threats to system integrity, that, if not properly considered, could adversely influence the outcome of a particular maintenance or project activity. Threats are the “ Traffic Lights” of potential hazards. Threats can, if not properly identified and considered, add to workload, distract, or force staff to do something different to the way one would normally act. These situations can increase the likelihood of human errors and could lead to undesirable outcomes. Threats to Works Planning include:

- Inter and intra-site dependencies (work at other “dependent” sites)
- Concurrent works (other active works plans on related facilities)
- Other works that, if combined with planned works could have an undesirable outcome (including external or contractor works)
- Air Traffic congestion; weather conditions
- Technical and operational staffing constraints
- Known equipment / system degradation or performance issue; lack of operational system bypass
- Undesirable times of day for particular work
- Duration of work

- Free lessons and near misses that capture relevant "things to watch-out for"

A threat may prevent engineers, maintainers, or, operators from planning and executing their job correctly. It may have the potential to impact on safety or efficiency. Maintenance and engineering staff, together in consultation with operations staff have the knowledge, skills and abilities to identify the types of threats. The Threat Alert Management Concept provides an approach that would improve situational awareness for both operations and maintenance staff, enable improved decision making for system or service interruptions, and reduce the likelihood of undesirable outcomes. Threat management will be incorporated into the Works Planning process, creating a database for capturing threats enabling the information to become visible for those involved in the Works Planning process.

2.7 Just Culture and the Blindness to Unidentified Risks Norms and Threats (BURNT)

Our ability to minimize, capture and mitigate operational error relies on our personal competencies, supported by an external systems and process that are error tolerant. A baseline essential requirement is an effective system of reporting errors that is supported through an organizational commitment to "Just Culture". Airservices commenced the rollout of this program in 2004, with firm commitment from our CEO and Executive and commenced development of a Human Error Management Program (HFHRO), in conjunction with an international expert in the field [6]. important goals of this program were to:

- enhance Airservices Australia's safety culture by establishing a "Just Culture", where staff willingly and openly report human errors, near misses and free lessons, without fear, or, intimidation and
- reduce instances of human error, by promoting an understanding of contributors that lead to making errors, and an awareness of the safety nets that can be applied to negate these contributors.

Feedback from staff who participated in the program has proven to be extremely valuable in identifying issues which may otherwise have remained undetected in the workplace. In recognising that we were on a journey, Airservices Australia's management subsequently endorsed the BURNT (Blindness to Unidentified Risks, Norms and Threats) training program.

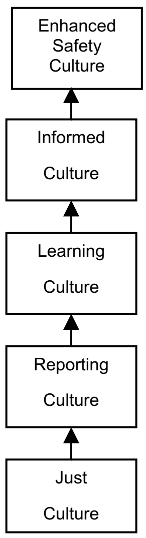

Figure 7 Managing Human Error through enhanced Safety Culture (12)

BURNT provided participants with a range of skills to identify norms and risks in the work place. There are many healthy norms in the workplace that contribute positively towards safety but are undocumented and not well known. The program provided staff with the techniques to identify these norms, so the benefits could be more widely distributed. Conversely, there may be norms that have a negative impact on safety and system integrity and therefore present a risk to staff, customers and our business. Through this program, these norms continued to be identified for appropriate attention by staff and management, working together. The overall theme being one of risk management and awareness.

BURNT workshops were of two days duration and presented in our workplace. The workshops were highly interactive and examined a number of case studies from multi-national High Reliability Organisations. An Operational Risk Assessment (ORA) concluded the workshops. Here, issues in our workplace that represent threats or opportunities to the way we do business are identified, discussed and actions planned, to ensure that the maximum benefits are obtained from the program The enhanced Works Planning process was reinforced and tested.

Our organisation has utilised information gathered from the BURNT Workshops to increase our understanding of the risks to our business operations. This process will continue to enhance our existing internal risk management processes and the growth of the safety Knowledge management system that is part of the Enhanced Works Plan tool.

In addition, the recent application of a tailored Human Error Investigation and reporting system, based on the error producing drivers, identified as local factors and maintenance factors as shown in figure 8 [5], has emerged as a significant diagnostic intervention in the journey to an enhanced safety culture

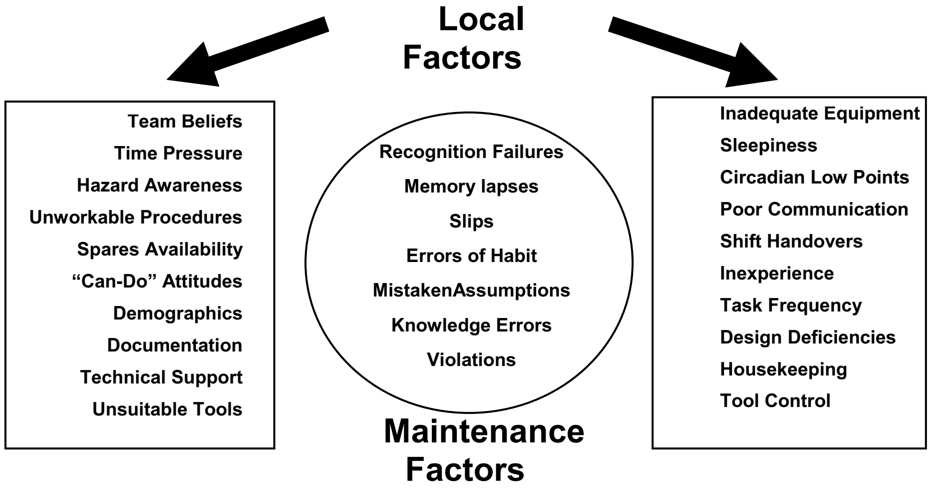

Figure 8 Adapted from Reason, J & Hobbs, [5] pg 63

3 NEXT STEPS IN THE SAFETY JOURNEY

In the daily challenge to balance production and safety imperatives, organisations are focussed on navigating the rocky path between catastrophy and bankruptcy [4,7]. In order to survive and grow, we continue to seek out strategies for best practice to enable optimal performance while ensuring safety of our employees and the travelling public.

Maintenance anomalies constitute one of the most common failures leading to system breakdowns, outages and accidents in a range of industries. Errors can be seen as mismatches between the demands of the task and the capabilities and limitations of the human. With appropriately targeted interventions, the probability of error can be reduced [8]. However, even in an ideal environment, a low background rate of human error is inevitable. For this reason, a maintenance error management program not only requires interventions to reduce the probability of error, but also requires the organization to continually increase the resilience of the system in the face of error [5,9,10] Airservices Australia has identified the following improvements in its safety management journey:

Enhanced Key Systems and Sites Works Plans

- Continued review and Integration of KSWP's into business operations
- Review service continuity consequence criteria against both recovery time and the interruption duration
- Continued Development of the threat and error concept; technical benefits/concurrent site activity alerting
- Existing system faults degraded/abnormal operation modes visibility in works plans
- Verify and validate historical reasons for customer rejection of works plans
- Verify and validate coordination agreements with external agencies and service providers

Implement operational safety measures into outage tasks

- Identifying tasks with high incidence of error
- Dissemination of best practices and safety guidelines to staff
- Analysing task management to determine best practices
- Continue development and application of Human Error Management Programs

Identifying and defining key areas of focus for employee performance and safety

- Establishing an ongoing (re)training programme to maximise operational efficiency and minimise incidents; Decreased incidence of injury and loss of workforce; increased equipment reliability;
- Asset manager, operator and maintainer training needs analysis

4 CONCLUSION

An intranet Works Plan system facilitates the notification process and enables required actions when facilities/equipment forming part of the Australian national airways system are intended to undergo planned maintenance, configuration change, or, removed from operational service. Works plans are published descriptions of the intention to perform planned maintenance work. The nature of work and timing is proposed by technical staff and assessed and approved by operational staff. Once approved, the execution of work is coordinated between Technical Customer Interface and Operations Manager*s*

Improvements in the delivery of operational safety and service availability can be achieved through an enhanced worksplan process. The intranet worksplan process facilitates the notification of intended work on the Airservices National Airways System including planned maintenance, configuration changes, projects or any work which may affect an operational service. Worksplans are categorised into Key System\Site, Moderate, and Minor. Improved decision making can be achieved by providing improved understanding of service to system mapping, analysing and prioritising the risks of human interaction, and determining contingency procedures on key systems and at key sites. The benefits are reduced unplanned service interruptions and in the event of a failure, a reduced impact on key systems and sites.

The worksplan process on systems with the potential for a moderate degradation of service provision include an analysis of the affect on operations and a risk assessment of the potential of an unintended outcome from the work.

.[b] *School of Computer and Information Science, University of South Australia, Mawson Lakes, Adelaide 5095, Australia.*

Abstract: Radio frequency identification (RFID) is a powerful data capturing technology that provides electronic identification, tracking, and storing of information contained on tags attached to or embedded in items, such as products, cases, or pallets. However, main trust of businesses in adopting this technology has been on logistics and warehouse management. RFID has particular significance for industries like defence where inventory consists of a variety of items; in order to alleviate capacity constraints, flow of materials in reverse direction is high; supply and demands factors are not as stable as compared to some other supply chains; and geographic end points of supply chain are not stable. RFID technology takes workforce mobility to a higher level by enabling eliminating the human computer interaction in tasks such as inventory tracking and management, and even condition monitoring, thereby allowing for reduction in data entry errors, speed of data flow, and real time access to information. This paper presents the results of an evaluation study undertaken for the Cooperative Research Centre of Engineering Asset Management to explore the efficiency of RFID technology for Asset Management. It identifies the major initiatives taken by different industries to use the technology; discusses current trends; and provides an evaluation of three technologies used to investigate the potential and limitation of RFID technologies. Drawing upon the conclusion it provides further insights into areas where RFID technologies could be used in the area of asset management.

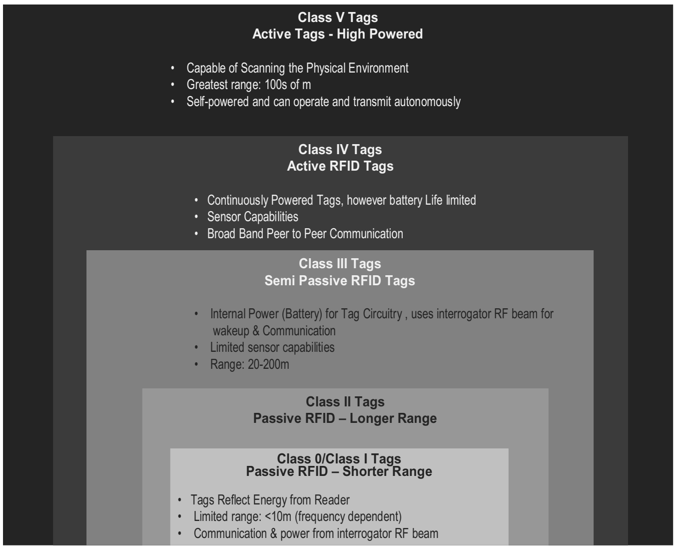
Key Words: Asset Management, Asset Maintenance, Performance Evaluation, Information Systems.

1 INTRODUCTION

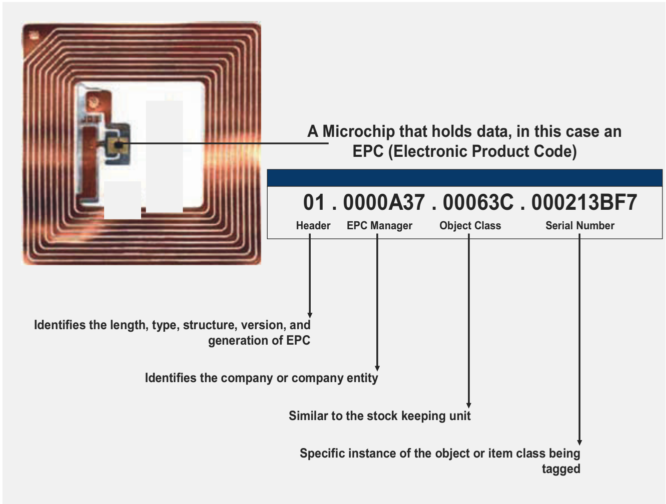
Radio Frequency Identification (RFID) has gained enormous popularity in the recent past, even though the technology has been around for considerable period of time. Reasons for this trend is the ease with which RFID technology provides for item tracking and thereby inventory management, logistics management, and supply chain management. Wal-Mart’s and US department of defence have been leading the race in this regard, and in so doing are realising a novel relationship between items and information. Major advantage of RFID technology over bar code technology is that with RFID technology information exclusive to the item travels with the item throughout the life cycle of the item. For example, at any time it is possible to find out the current location of the item; its origin, such as supplier and date of manufacture; its existing use and intended use; and its future destination. This functionality provides for real time visibility of end to end supply chain. RFID has particular significance for defence supply chains where inventory consist of a variety of items; flow of inventory from consumer to supplier is high; and supply and demands factors in this situation are not as stable as compared to some other supply chains, and geographic end points of this supply chain are continuously moving. However, this is just one area where RFID technology offers potential benefits; in fact it has the potential to address diversified issues concerning asset health management. Nonetheless, the proliferation of RFID technology is subject to the development of technology to overcome some of the issues such as, lack of standards, cost, data/infrastructure/systems implementation issues, data sharing and security. This paper presents an assessment of RFID technology, its applications and implications, and future research directions with particular significance to engineering asset management. Although RFID technology is convincing, as yet it is far from being pervasive. Nevertheless, we conclude that this technology is here to stay and its capabilities provide excellent grounds for various wireless applications in asset management.

2 UNCOVERING RFID TECHNOLOGY

RFID technology consists of three components, an RFID tag, a reader, and a Tag/Reader management systems or a middleware [1]. RFID tags are made up of a small microcontroller and antenna available in many different packages. They provide a contact free form of identification through the use of radio frequencies. Each tag has an electronic product code (EPC) or an identification number embedded into the tag microcontroller that is used to uniquely identify each tag, which can also be termed as the RFID’s version of a bar code [2]. When an RFID tag is placed close enough to the reader it is powered up through a magnetic field emitted by the reader thus powering the microcontroller of the tag, such that it transmits the EPC to the reader. RFID tags do not require line of sight between tags and readers for them to be detected and therefore make it possible for tags attached to items to be identified from a single point [3] [4]. An RFID reader is a mobile or fixed device, comes in a variety of shapes such as hand held or fixed mount, and emits electro magnetic waves. An RFID reader activates the tags by sending tags out encoded interrogation signals. This signal creates a magnetic filed that the tag uses to power itself, the tag then sends its EPC to the reader. The EPC is decoded by the reader and sent to the middleware. An RFID middleware represents the hardware and software that is necessary to process data coming from the tags, coordinate communication to and from multiple readers, and sends the captured information to legacy systems. It also segregates the vast amount of data before sending it onwards to legacy systems. In simpler terms it works as a traffic regulator and to some extent it also works a communication moderator. Nevertheless, unlike bar codes that are only capable of identifying a class of items, EPC identifies each item uniquely. The EPC identifies the manufacturer, product, version, and serial number or a product or item. There are two types of EPCs in common use, one that supports 64 bit on board EPCs and second the ones that support 96 bit EPCs. A 96-bit EPC provides unique identifiers for 268 million objects [2]. Figure 1b illustrates the taxonomy of an EPC.



a. RFID Tag Classification



b. Electronic Product Code

Figure 1

RFID tags can be active, passive, or semi-passive tags, and are classified into five classes according to their capabilities and functionalities (Figure 1a). However, there are commonly referred to as either passive or active. Passive tags are interrogated by the reader for information contained in them, whereas active tags themselves transmit the data streams to the reader, hence the name passive and active. Passive tags are powered via the reader thus they do not require batteries to operate, whereas active tags have an onboard power. Passive tags can be detected from a distance ranging from a few centimetres to a few metres, whereas active tags, on the other hand, have an on-board battery, and therefore, have a far longer read/ write range and memory size. Class 1 and 2 tags are the most common and can be easily found in operation today. These tags are mostly used for item tracking and inventory management purposes. Class 3 tags are semi passive, which means that they are on board power available, but that power needs to be activated by the magnetic filed that the sensing beam of the RFID reader creates. They have relatively smaller read range, which means that the reader has to be placed in close proximity to the tagged item. Class 4 and 5 tags have on board continuous power available (usually a life span of 10 years) as they are fitted with a battery, in most cases have a microcontroller available on board, support on board memory, and also have sensing capabilities. These tags are usually able to sense the temperature or light. Table 1 summarises typical characteristics of active and passive tags.

Table 1

Typical Characteristics of RFID Tags

	Passive tags	**Semi passive tags**	**Active tags**
Power supply	external (from reader)	internal battery	internal battery
Read range	up to 20 feet	up to 100 feet	Up to 750 feet
Type of memory	mostly read-only	read-write	read-write
Cost	$.20 (US) to several dollars	$2 (US) to $10 (US)	$20 (US) or more
Life of tag	up to 20 years	2 to 7 years	5 to 10 years

Source: [5]

Active tags have external interface available that allows for interfacing additional sensors and devices. On the other hand, major advantage of the passive tags is their small size; consequently they can be used for many applications where size and weight are limiting factors. Extra features on a tag, however, do increase the size and cost of each individual unit. Table 2 summarises the characteristics of passive tags and indicates application areas for each segment of tags.

Table 2

Common RFID Operating Frequencies for Passive Tags

	Frequency	Typical read range and rate	Examples of use
Low frequency	125 KHz	~1.5 feet; low reading speed	Access control, tracking, point of sale applications
High frequency	13.56 MHz	~3 feet; medium reading speed	Access control, smart cards, item-level tracking
Ultrahigh frequency	860-930	MHz up to 15 feet; high reading speed	Pallet tracking, supply chain Management
Microwave frequency	2.45/5.8 GHz	~3 feet; high reading speed	Supply chain management

Source: [6]

3 RFID APPLICATIONS

There are numerous applications of RFID technology currently being developed and a plethora of applications are envisaged by prospective users. At the moment major advantages that businesses gain from RFID are item tracking, warehouse management, reduced obsolete inventory, reduced material handling costs, supplier identification, authenticity of items, end to end visibility of materials flow, and supply and demand management support. Among these are applications like tracking a box, web luggage, smart shelves for pharmaceutical products, smart toolbox, and smart box etc [7], [8], [9], [10], [11]. With regards to asset management, there are a range of applications for RFID technology spanning asset management particularly maintenance management. Active RFID technology can be of significant use for condition monitoring of an asset; the sensing capability of RFID technology is further discussed later in the paper. The tracking capability of RFID could be used for tracking assets such as railway tracks, and pipelines. Table 5 presents the some of the RFID related initiatives under way in different agencies.

Table 3

Reported or Planned Use of RFID Technology

Industry/Service	Application
Defence	Logistics support; Tracking shipments ; Tracking and identification; Monitoring weapons
Energy	Detection of prohibited articles; Tracking the movement of materials
Health and Human Services	Physical access control
Homeland Security /Immigration and customs	Border control location system; Smart containers; Tracking and identification of assets Tracking and identification of baggage on flights
Law and order	Tracking offenders and prisoners
Transportation	Fleet management, Electronic screening
Finance and Treasury	Physical and logical access control; Records management (tracking documents)
Environment Protection	Tracking hazardous material
General Service Administration	Tracking and routing carriers along conveyor lines; Identification of contents of shipments; Warehouse management

Source [12]

4 MAKING USE OF THE UNIQUENESS

Figure 2 illustrates a framework that was used for developing different applications to investigate the potential of RFID technology for asset management. In this framework each item is tagged with an RFID tag; either active or passive, depending upon the nature of application. When the tag comes near the reader, the radio frequency field generated by the reader powers up the tag and causes it to continuously transmit its EPC by pulsing the radio frequency. The reader passes the EPC to the middleware, or what is also termed as a savant. A savant acts as a buffer between the reader and other organisational information systems, and consists of various modules or sub programs with each module performing specific functions.

The savant remains connected to the readers, and behave as a router of the RFID network with the primary functions of EPC related data smoothing, data forwarding and data storage; along with reader coordination, and task and event management. These savants use algorithms that take care of the reader collision, such that each tag is identified uniquely and is read each time it is attempted to be read.

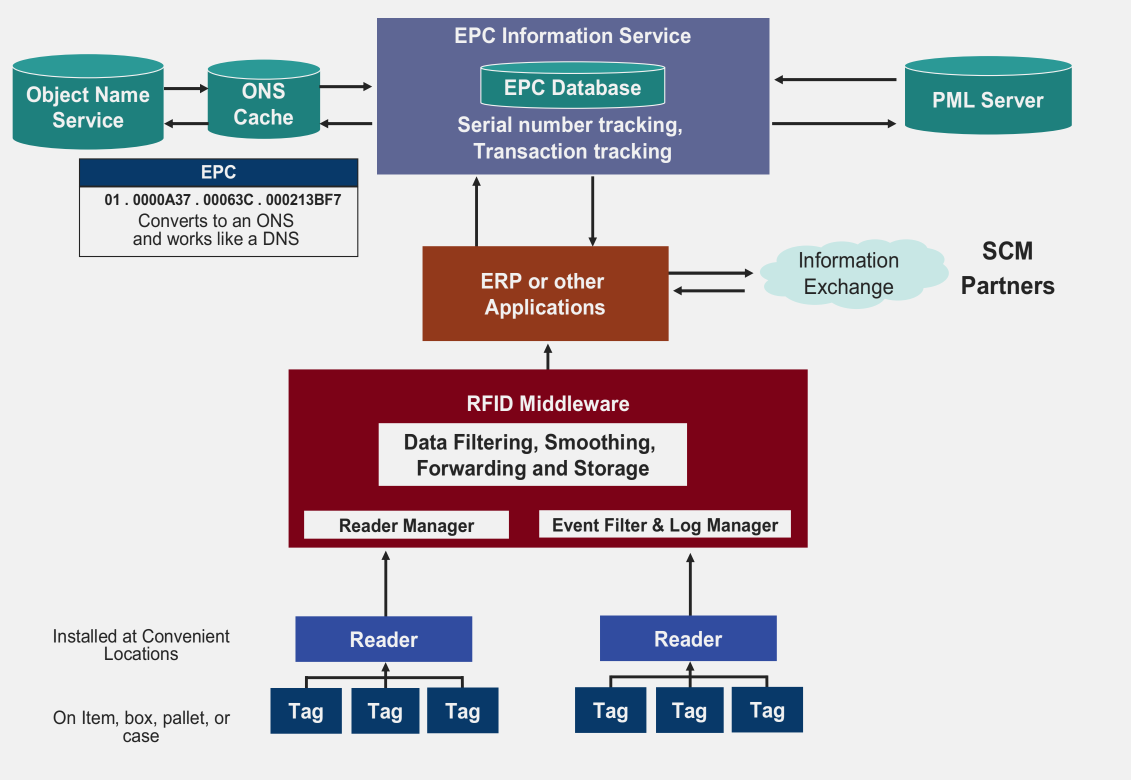


Figure 2 –Framework for RFID Based Prototype Applications for Asset Management

Since the EPC is the only information stored on the tag, it has to be used in such a way that it provides additional information about the item that the EPC is attached to. The savant interprets the EPC into a unique address of an object naming service (ONS), which points to a physical mark-up language (PML) server. PML is a version of the popular XML meta-data language. The server stores PML files that contain information about the item that the RFID tag is attached to. The whoel process works like a user access a website on the Internet, where a user types in the unique url (in this case the EPC), this url is interpreted into a DNS, which points to the service that is hosting the website pages and associated information. Using this framework, any amount of information exclusive to an item can be stored and retrieved in real time.

5 EVALUATION OF RFID TECHNOLOGIES FOR ASSET MANAGEMENT

In our evaluation we examined three RFID Technologies, for configuration management, item tracking, and for condition monitoring. We chose Texas Instruments Midrange Evaluation kit and Chipcon CC1010, since both these technologies offer valuation packages which include all the hardware and software required to begin developing specific applications. This also allowed us to explore both the passive and active tags. Even though the scope of this evolution was provide the proof of concept of RFID utilisation for configuration management, nevertheless, we were able to demonstrate tracking capabilities of RFID technology as well as sensing capabilities. Examination of active tags led us to believe that RFID technology could be used of a much enhanced scope of applications in engineering asset management.

5.1 RFID for Configuration Management

The Texas Instrument midrange evaluation kit is equipped with one reader and a selection of Tags in different packages. It operates at 13.56MHz capable of reading tags at a range of 7 inches from the reader. The reader unit is a similar size to a paperback novel (13cm*3.5cm*18cm), the unit is encased in a black plastic box which roughly doubles the necessary size of the unit. A variety of tags are supplied with the reader unit they can be categorized into two different types which come in different sizes. The Tag-it transponder inlays with 256 bits user programmable data, the estimated data retention time is 10 years and can be programmed typically 100 000 times. The evaluation kit also comes with Tag-it ISO transponder inlays also available in a range of different sizes the main difference is they have 2000 bits of programmable memory and a larger unique identification number for future expansion. The inlay style tags are a cost effective solution for tracking and inventory control type applications. As this technology becomes used on a larger scale it is expected the tags will be available for (USD) $0.10

each or less. However they are limited in the fact that they can only provide location information in conjunction with a software application.

5.1.1 Description

We developed a simple application as an introduction to the hardware components and how to collaborate between software applications and RFID tags. The purpose of the application is to provide a management system which can locate assets and record their current location and keep a record their history. This information can then be displayed to the user through a software application (software flow shown in Figure 3).

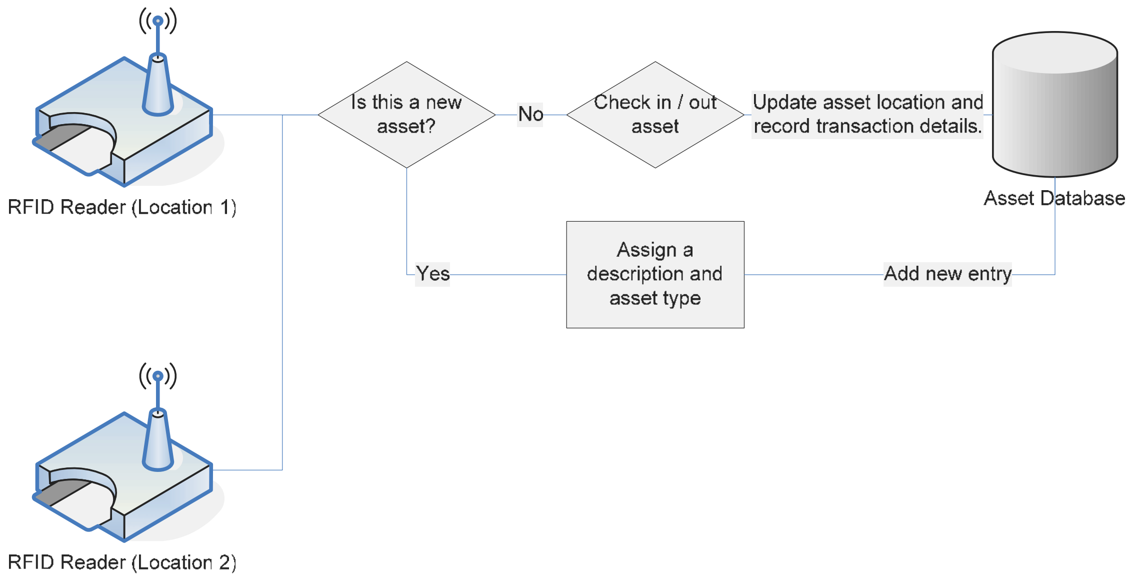

Figure 3: Software flow for Configuration Management

Tags were attached to a box (Figure 5), and the box was assumed as an asset, with the contents of box as the configuration or the constituents of an asset. Our aim is to monitor the location of each configuration item as well as that of the asset. In the application that we developed, when an asset is first read at a location the user is asked to enter a description and define the type of asset. There are two types of assets we have used in our design, items (configuration items) and containers (assets). An item is the lowest level of the two and only has knowledge of its own existence. Containers on the other hand can hold items within themselves. When an item type is selected this asset is added to the database and is now ready normal use. Now as an asset leaves and enters a room it is read by the reader which in turn adds transactions to the database. Each transaction records the location of the tag and the time it occurred. When a container type is selected the operation is the similar to that of an item with the exception an item may be placed within a container (Figure 4). This allows us to keep track of groups of related objects as one entity or asses when querying the database.

Figure 4: Inlay RFID Tag attached to container using a stick on plastic envelope.

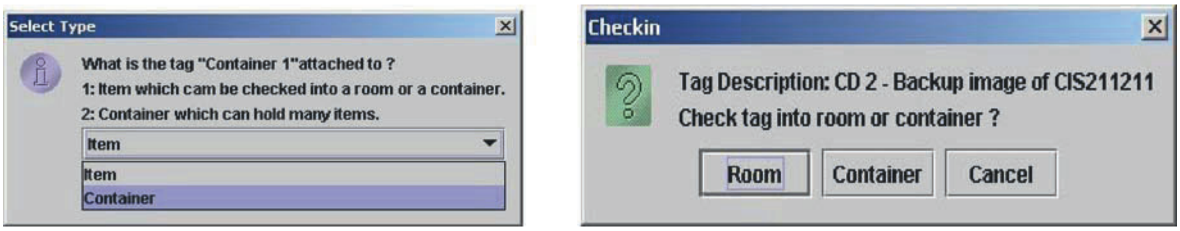

Figure 5

Figure 6 illustrates the snapshot of the user interface that describes the containers and the items contained in there.

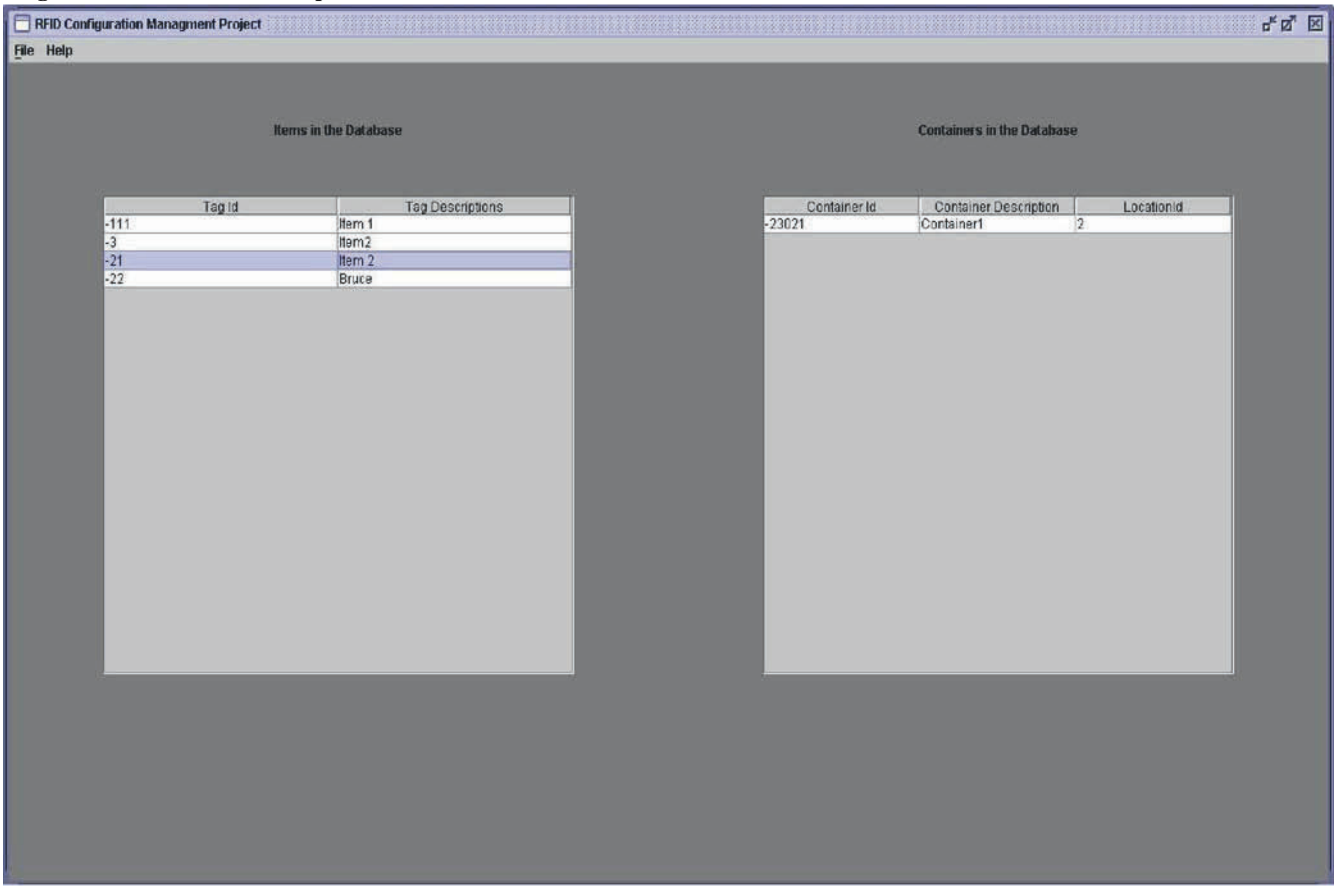

Figure 6: Demo Application Snapshot

One of the issues in configuration management is that of change management. Therefore it was necessary to capture the history of configuration. An example of each of this query is shown in figure 7.

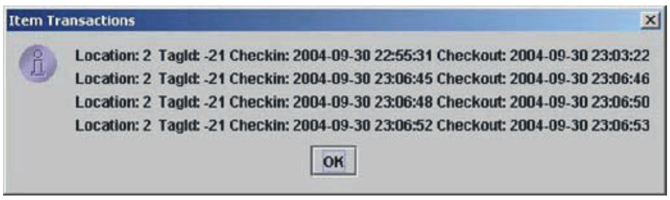

Figure 7: Configuration item history details

5.1.2 Issues

One of the limitations which should be considered is the material in which tags are attached to as well as the materials in the environment. When the tags are attached to metallic surface the tag malfunctions. Texas Instruments have released a range of tags designed to be mounted on metallic surfaces. However their reading range is reduced by 30% and their size is much larger than the inlay variety.

5.1.3 Future Directions

It appears that in highly metallic assets such as railway tracks, rolling stock, or military hardware existing RFID tags, especially the inlays, may not function. It is therefore, necessary to investigate how a robust tag can be developed that is able to provide the same functionality in a variety of environments. In addition to this, the issues regarding RFID technology working on different frequency spectrum will remain, particularly when assets are moved between international borders.

5.2 RFID for Supply Chain Management

Using the same methodology, as described above, we examined the Texas Instruments Series 6000 - HF-I Midrange technology. The midrange evaluation kit consists of one reader and a selection of tags in different packages. It is a high frequency kit, which operates at 13.56MHz. The reader is capable of reading tags at a range of 7 inches and its plastic housing integrates an antenna and an RS232 interface board. The reader is able to communicate with Tag-It as well as any ISO 15693 compatible tags. We used two readers in this scenario, with the other reader being S251B, which is a low frequency reader operating at 134.2 kHz and is able to communicate with TIRIS Low Frequency tags. It automatically tunes a standard antenna to resonance and keeps it tuned during operation. It is able to communicate with tags at ranges up to 1m (using a large size gate antenna). The reader decodes the signals emitted from transponders into identification numbers, performs error checking and translates the signals to standard serial interface protocols (RS232, RS422/485). It also contains a buffer, which can store up to 909 reading transactions. Communication with a PC can be performed over a serial interface (RS232) using ASCII commands.

5.2.1 Prototype Application

The prototype asset inventory management application developed using the Series 6000 - HF-I Midrange technology, mimics the scenario of movement of assets or items between a field forces distribution centre (FDC) and field supply depot (FSD). The application displays two warehouses i.e. of FDC and FSD, each containing six sections. If each section was equipped with a reader, we could easily locate the section containing an item at any time. The two readers are installed at the entrances to the warehouses, thereby allowing for tracking movement of tagged items, Figure 11.

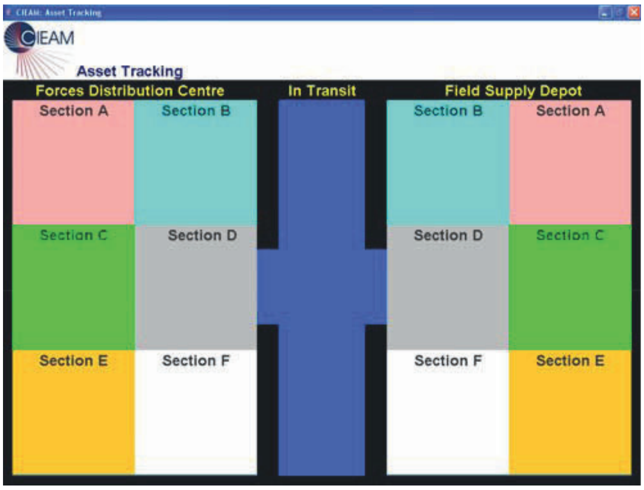

Figure 8: Asset Tracking Application Interface

When an item enters Forces Distribution Centre for the first time, the user is asked to enter item details figure 9. After entering item details, the item is displayed in the system, shown in figure 10.

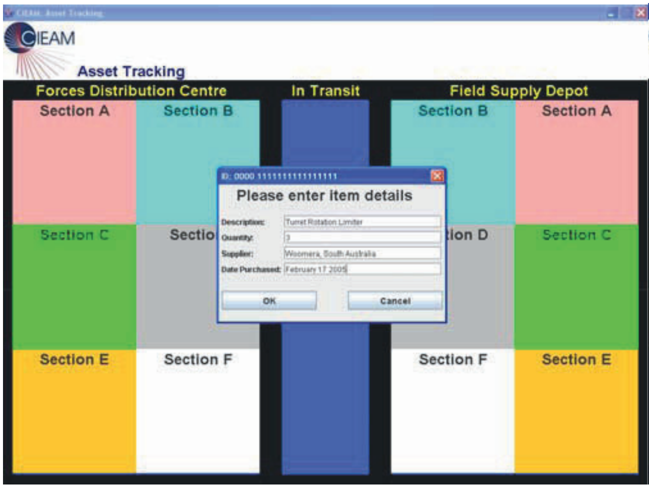

Figure 9:

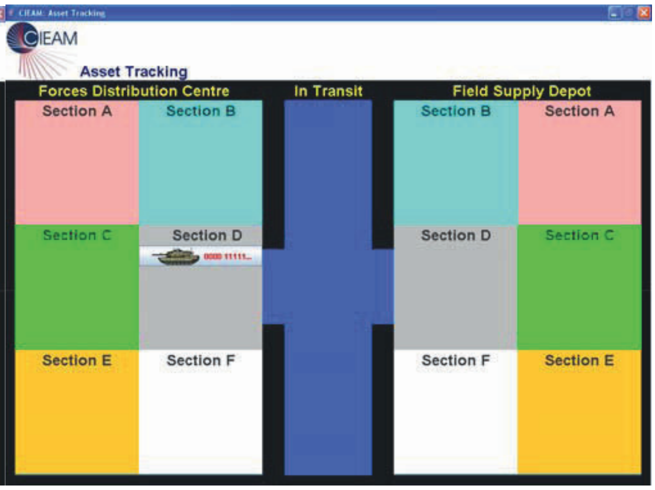

Figure 10:

When an item is moved out of the warehouse, it displays the status of the item as in transit, till the time it is checked in another warehouse. (Figure11). Figure 12 illustrates that history of an item's movement along with the time and date of each movement.

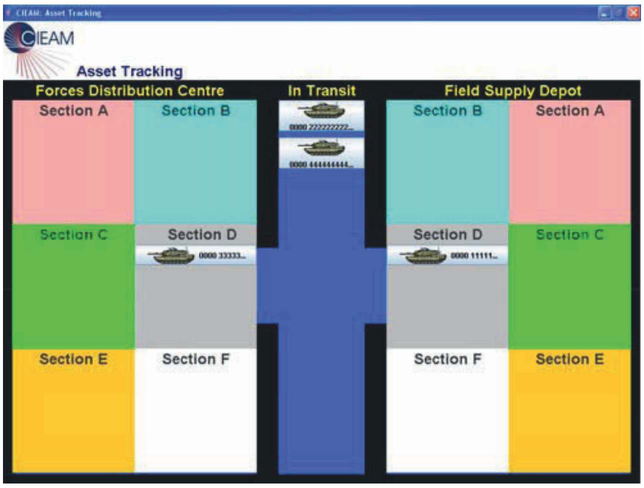

Figure 11:

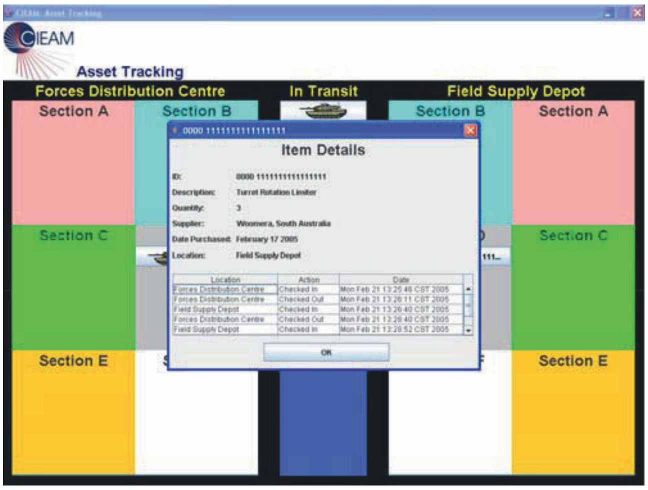

Figure 12:

However, it must be pointed out that the prototype was tested in laboratory only and did not have the chance to test it in field. Nevertheless, some of the issues that we faced using this technology were the malfunctioning of the technology in high magnetic fields, and in environments where other high frequencies based equipment was in operation.

5.2.2 Future Directions

Apart from the issues identified for configuration management, a major issue that we encountered for item tracking was the real time monitoring of an item when the same is in transit. RFID tags have a limitation and require the reader to be in close proximity of a tag, which means that they work well in the warehouse or a defined space, however cannot be used to track items moving out of the range. We considered GPS tags; however GPS technology cannot work in in-door environment. Therefore, in its existing state RFID technology can be used for item tracking between different staging sections and within those staging section; however it cannot be tracked in real-time when the item moves out of the staging sections. Further research is required in resolving this issue.

5.3 RFID for Condition Monitoring

Chipcon's CC1010 evaluation kit includes an evaluation board (CC1010EB) and two evaluation modules (CC1010EM). CC1010EB provides access to all of the analogue and digital pins on the CC1010, along with two serial ports, a parallel programming port, RF network analysis ports, and other peripherals. Each evaluation module features CC1010, an antenna port, and an analogue temperature sensor. CC1010EM includes an RF transceiver that can run from 300 MHz through to 1GHz. It has an onboard 8051 8-bit microcontroller with 32Kb of flash for code and non-volatile data, 2K of RAM. CC1010EB supports three ADC (analogue-to-digital converter) channels, a Universal Asynchronous Receiver Transmitter (UART), and 26 I/O pins. An important feature of CC1010 is that it can be read and written from distances in excess of 100 meters. At the same time, the tag supports a serial peripheral interface, and a hardware Data Encryption Standard chip for secure communication. Its flash RAM is divided into 256 pages with programmable protection flags that prevent unauthorized downloading of internal programs and data. All these features make the CC1010 a versatile platform for applications where we want to add external sensors to the modules. The general purpose I/O pins can be connecter to temperature, humidity, pressure and a whole range of external sensors. The two hardware UARTS are used to communicate between serial devices, this may be a PC other RFID modules or and hardware device using serial communications.

Figure 13: Left CC1010 module, Right CC1010 development board with module attached used for debugging purposes.

We envisioned the framework presented in figure 14 that utilizes CC1010 tags. In this framework each asset is attached with a CC1010 tag or a collection of it, such that all tags collectively form a wireless mote network with the provision of a gateway tag that provides for communication of data captured by the network. The gateway tag serves as the liaison between the database server and sensor network and delivers data captured to condition monitoring database. Apart from unique identification of the asset, the availability of serial ports in CC1010 provides for interfacing digital as well as analogue sensors. This means that it allows a connection with the any amount of sensors used for condition monitoring of an asset. This framework highlights continuous streaming of data without having to have any human intervention for data logging or recording. Obvious advantages of this type of CM are reduced labour cost, better fault detection, and identification of dangerous or hazardous areas without incurring risks to maintenance crew. Most significant advantage of this framework is that it makes possible economical remote condition monitoring. The framework captures data from different channels simultaneously and processing the same immediately, thereby by achieving greater accuracy in failure prediction. At the same time, it is also useful in isolating the area where the fault may be developing.

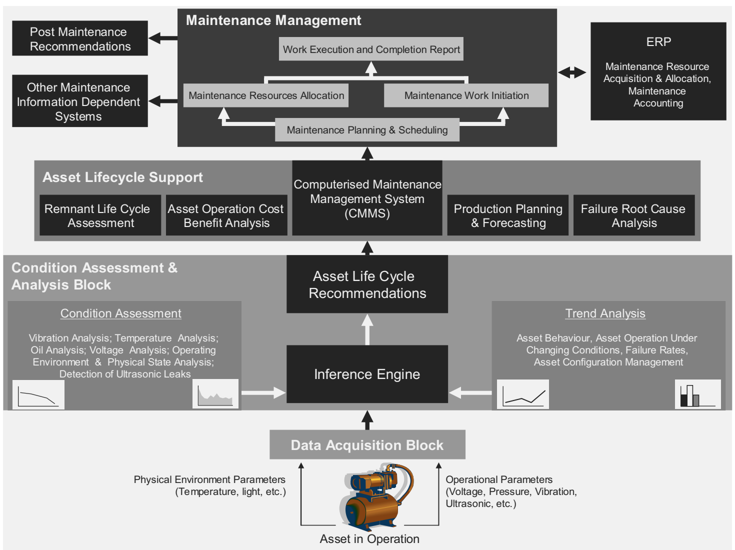

Figure 14: Integrated Condition Assessment Framework

In this proposed framework, the condition assessment block represents a series of decision support indicators, analyses and trend projections of assets operation. Using these comparisons and behavior assessments of asset operation useful deductions could be drawn for asset lifecycle support. The inference engine acts like a watch dog and compares the probabilities and possibilities before generating recommendations concerning asset life cycle support and other associated processes. Using RFID for prognostics poses significant advantages for engineering enterprises, and proves to be an important building block towards e-intelligence based maintenance and asset management. This framework allows for a technologically convergent and miniaturized device that bears most of the features of a SCADA systems at a fraction of its price.

For proof of concept we used the technologies presented in figure 15, and an external humidity sensor and the temperature sensor that is embedded in CC1010. The raw information captured from the sensors was communicated through the gateway to a transition database. The interface allowed for viewing this information as graphs or simple readings over a period of time. However, this information could easily be fed into a condition database with time stamp and tag ID, where it could be analysed further. The TCP/IP based connections allowed for a distributed server model, which means that using this framework remote condition monitoring is also possible. Apart from providing advances such as consolidation of condition information and single channel communication, another advantage of this framework is fault detection. An essential characteristic of RFID tag is ability to identify itself, therefore when the information captured from each asset is analysed, it provides important indication on exact location of the asset under investigation. For example in case of a failure condition developing or any malfunctioning it can point that at site number 1, pump no 2's vibration pattern is unusual. At the same time, this information together with information on other variables will provide for the exact nature of the fault and indications on its maintenance demands. The onboard memory provision of CC1010 could be used to store information, such as asset health and maintenance record, which could be updated after each maintenance execution.

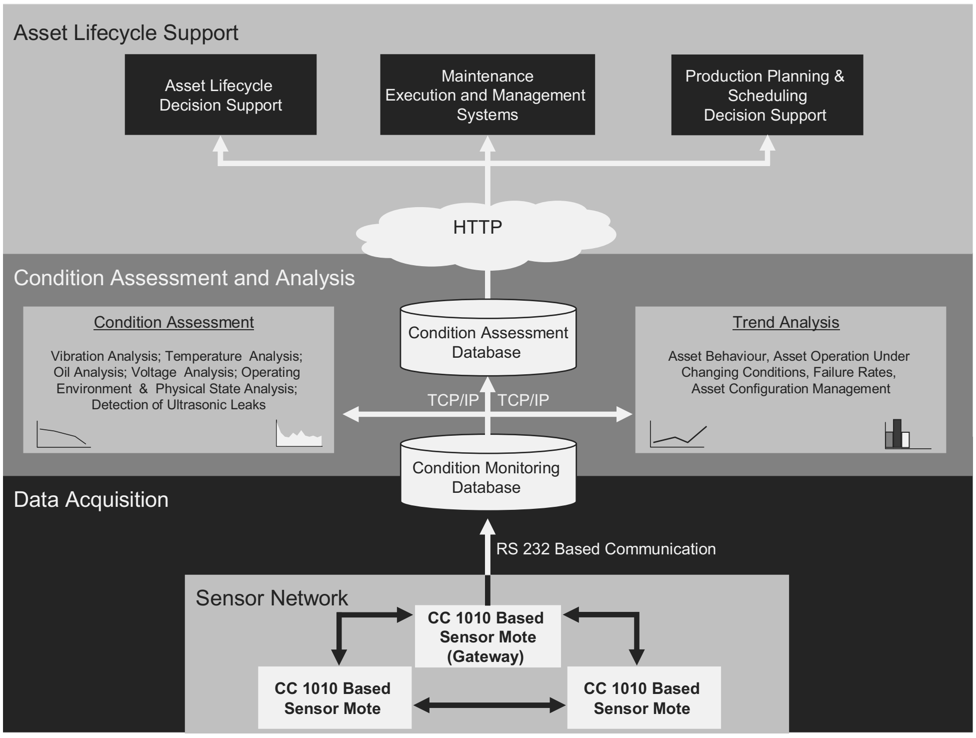

Figure 15: Integrated Condition Assessment with CC1010

Using RFID for prognostics poses significant advantages for engineering enterprises, and may prove to be an important building block towards e-intelligence based maintenance and asset management. This methodology allows for development of a technologically convergent and miniaturized device that could easily be mounted on an asset and realise centralized data acquisition. It reduces monitoring costs significantly and improves asset reliability through efficient prediction of asset failures.

5.3.1 Future Directions

We tested the technology for two sensors; it will be interesting to see how the RFID tag behaves when more sensors are attached. Other area of research is of making the technology more efficient, as the on board power supply of CC1010 has limited life span. Once these issues are resolved, it will be worth while to investigate the ways of integrating the inference engine on the gateway sensor mote.

6 CHALLENGES POSED TO RFID

Since the modern wave of RFID technology is still evolving and the technology can best be described as emergent, there are many issues and challenges associated with the technology. As mentioned before, one of the issues associated with RFID is the lack of uniform frequency spectrum. Different standards organisations and governmental legislations are under way to address this issue. Standards development efforts also include developing standards for hardware and software used in RFID technologies. However, there is another issue that emerges from standards development, which is regarding the multiple efforts towards developing standards for RFID operation. This means that in the presence of multiple standards there is no guarantee that the technology will embrace uniformity at a global scale. A corollary to the issue of multiplicity of standards is interoperability. This is, however, not to say that this problem does not exist at the moment. The issue of interoperability includes readers as well as tags, as presently the tags and readers have fixed operations and it is not possible to read high frequency tags with a low frequency reader. Acceptance of RFID technology will require it to be of low cost, and to be of low cost this issue of interoperability needs to be resolved. Cost effectiveness of RFID technology is actually an issue that small business and SMEs are facing at the moment, as they have limited budgets and limited expertise available at their disposal. Security and privacy are other two issues that are catching the attention of consumers as well as general public worldwide. With the existing nature of technology (primarily passive RFID tags) it is possible to read tags without any problem, which means that anybody could identify tagged items and could track their movement. A solution often proposed to address this issue is to encrypt the message, however as yet there is no solution on market that could provide this functionality and security.

7 CONCLUSION AND RECOMMENDATIONS

The primary aim of this evaluation study was to test RFID technology for configuration management; however we were able to successfully test and demonstrate the same for three different applications. During the course we also uncovered the potential of RFID technologies with regards to asset maintenance. Nevertheless, the proliferation of RFID technology is subject to the development of technology to overcome some of the issues identified in the paper. These issues and challenges include robustness of technology, operation of technology in different environments, lack of standards, cost, data/infrastructure/systems implementation issues, data sharing and security. Nevertheless, with further research into these areas it is anticipated that large scale implementation of RFID will occur in the next five years.

INTELLIGENT MAINTENANCE SYSTEM APPLICATION TO GLUE DISPENSING MACHINE

J. W. Chen, J. N. Jeng, Z. C. Chou, T. K. Yang and H. H. Li

RTC/ITRI and MSL/ITRI, Industrial Technology Research Institute (Taiwan)

Abstract: The tiny hole at the needle distal of the LCD (Liquid Crystal Display) Dispenser is frequently blocked due to the impure glue or clotted glue. Although many research studies have been performed for Intelligent Maintenance System (IMS), few of them are relevant to the discussion on the result of the process in this respect. For the most part, the downtime of a packaging production line occurs in the glue dispensing process. This paper is related to the feasibility study for the IMS application on the glue dispensing machine. It not only possesses the capability of self-diagnosis and self-improvement by employing effective data learning, but also ensures the equipment works safely for a long time. To implement such a diagnosis system, the raw data is collected directly from the images with the cameras on the equipment, and these data provided for the Back-Propagation Neural Network system to learn. The Back-Propagation Neural Network system is applicable to predicate these kinds of failure problems. The feasibility study of forming a knowledge exploration and intelligent decision-making system by making use of the theory of the Back-Propagation Neural Network system, it can be discussed through a case study.

Keywords: Glue Dispensing, Glue Path, Back-Propagation Neural Network, Nearest Neighbor Decision Rule, Vision Assistant

1 INTRODUCTION

The automatic industry fluids process is often intricate and expensive. Its applicative scope includes fluids to strong creams. These kinds of materials need to handle carefully and to reach the quality of consistency in the assembling process [1]. In order to make perfect for spreading fluid glue, it can control by atmospheric pressure or mechanical power device or desktop automatic Dispenser equipment, its application is very extensive. In generally, the state of syringe needle depend on the quality of glue, with spreading fluid glue in succession will bring some glue on the needle become the dregs of glue, then it is blocked the needle distal as shown in Fig. 1.

Fig. 1. Glue syringe needles with incomplete glue

The hardened dregs of glue will influence gradually the state of glued normally, so it is apt to trouble phenomenon of syringe needle blocking, skewing or out of shape, etc. The caused of failure phenomenon produced is even probably a bad needles distal. It is not to conform to the automatic and production line increasingly required, about deciding when they need to change the glue needles distal by human eye, and it is unable to control question which is an individual judgment subjectively about the glue quality determining with operator's experience of glue states determining when the suitable for glue needles distal change. In order to improve the quality of dispensing process, and improving the competitiveness for the products in the market, this paper is focal point on comprehensive quality of glued determining.

Recently the machine vision components are using for product inspecting include image acquisition card, CCD camera, CCD lens, and auxiliary light source, etc. Artificial Neural Network has already become one of the important researches of artificial intelligence (AI) themes in the field in recent years. The main reason is the Artificial Neural Network is possessed of learning ability, memory ability, summing up ability, fault-tolerant ability, and high-speed computing capability, etc [2, 3].

In order to determine the occasion for changing glue needle distal, this research use Back-Propagation Network and nearest neighbor decision rule to combine the vision system and measure a flaw glue to achieve the automatic vision and measure to replace the human eye estimated.

2 STRUCTURE AND PROCESS

The purpose of this paper employs Back-Propagation Network and nearest neighbor decision rules to measures flaw glue for determine the occasion to change glue needle distal. This structure includes four parts: system equipment, image process, Back-Propagation Neural Network and nearest neighbor decision rule.

Fig. 2. Dispensing machine platforms

The system hardware configurations are included dispensing machine platforms of desktop on PC-based that production line environment, CCD camera, auxiliary light source and image acquisition card as shown in Fig. 2. Image process is used by NI Vision assistant software. The CCD camera is set up on a column base beside the glue needle; through the glue of glue needle process, the camera can successively take a picture passing on glue dispensing path. Then utilize NI Vision Assistant to deal with the picture of feature. Because there is no real working environment of production line, therefore an experiment goes on by way of simulate a real factory and working for a long time. In order to reach quickly the situation about glue needle distal of failure, the experiment adopts one gluing process to finish and then shut down experiment for one hour later; that will accelerates the glue of needle distal clotted. This process is repeating until glue needle distal is clotted, finally the tiny hole at the needle distal of the dispenser is blocked by the glue clot and unable to glue.

Adjusting auxiliary light source and contrast for making image edge obviously while taking a photograph. The photograph taken will be dealt with the tool of package software of Vision assistant and subsequently threshold process to separate foreground from background. Therefore, to employ Low Pass Filter to eliminate noise mixed point and unnecessary border. These pictures were photographed by camera can regarded as input patterns for recognized. Use the conventional back-propagation model to train those patterns that have previous took photographs by camera. As a result, the search model can respond quickly the desired results whenever similar photograph have applied to the dispenser. Not only the designing procedures have been discussed but also the simulation results are presented to validate the effectiveness of this research. There are many phenomenon of glue needle blocking and its photo patterns include normal, skew, thin, width and out of shaping type, etc. The result of back-propagation model inferred will be given nearest neighbor decision rule to decision whether change glue syringe needle.

The nearest neighbor decision rule is a commonly used for classification algorithm in statistical pattern recognition. Each class is given as a set of sample prototypes, a training set of pattern vectors from that class. When an unknown vector is to be classified, its closest neighbors are found from among all the prototype vectors, and the class label is decided based on a majority rule. This rule is simple and elegant, and yet the error rate is small in practice. The block diagram of the Intelligent Maintenance System for Glue Dispensing Machine is depicted in Fig. 3.

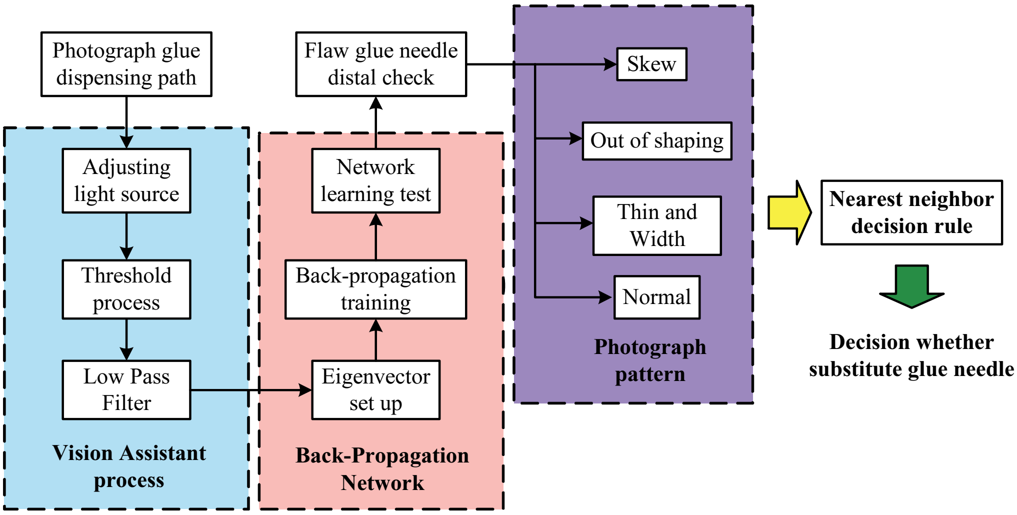

Fig. 3. Block diagram of intelligent maintenance system for glue dispensing machine

3 THE IMAGE PROCESS FOR CHECK FLAW IN GLUE PATH

Fig. 4. The result of threshold process

In practical application of image process, if the main object can be deal with a background which is not necessary to separate, the later process will more easily. It is easier to design Back-Propagation Network algorithms on binary images than on gray-level images. A binary image can be obtained by threshold a gray-level image. For preventing possible information losses in the threshold process, it may be natural to design Back-Propagation Network algorithms directly on the original gray-level images. The gray-level image is a binary image constructed by bright background and dark object. Thus, the bright background and gray main object have been divided into two parts. The best way to extract main object from background image is choosing one critical value T that can obviously separate it into parts. In this paper, the critical value T is 80 and user decides that. A binary image can be defined as g(x, y):

$$g(x,y) = \begin{cases} 1 & f(x,y) > T \\ 0 & f(x,y) \le T \end{cases}$$

These marks are correspondent to the background for the picture pixel of 1 and the other mark is correspondent to objects for the picture pixel of 0. The result of threshold process of image glue path is depicted in Fig. 4. It is clear to discern when the value T be set up suitable, the glue path will be separated obviously from background.

Fig. 5. With noise picture

The photograph noise means that the image structure to the true scenery does not exist in fact. The noise will influence the judgment on the true signal. For example in the one-dimensional image is shown in Fig. 5., nearby signal on the left of the glue path is fuzzy, that is to say that the noise is very strong, we will infer that the authenticity of the signal in pictures, perhaps it is only protruding higher noise of a coincidence. In Fig. 5., through the threshold process is unable to strengthen this signal directly because the raw data signal with a low credibility and noise will be enhanced at the same time. In Fig. 6, after filter process, edge value comparatively obvious, and treatment in follow-up will be more convenient comparatively and result of value can comparatively perfect, too. It can reduce the situation of judging by accident.

Fig. 6. After noise filter process

The noise influence image process that limits the image to deal with deepness. It is impossible for this restriction to disappear. However, it can enhance to the image process by some methods then the enlarged noise image is not obviously to keep the image intact. This method is regarded as reduce the tiny noise of structure in the image which is not significant at the cost of losing precision order of image [4].

Fig. 7. The raw data of image picture

4 EXPERIMENT AND RESULT

In this research, it is using the Vision Assistant 7.1 of National Instruments of package software [5], image acquisition (IMAQ PCI-1405) device, SONY XC-ES50 (CCD) camera, 1x65 extending camera lenses, and STDR 67/36R auxiliary light source. In the course of experiment, utilize CCD lens and extending lens to take an image picture that is glue path as shown in Fig. 7. After storing the image in the computer, use Vision assistant as the follow-up to deal with image process and analyze.

Open the image by Vision assistant, using Brightness option adjusts the brightness and contrast of image as shown in Fig. 8. This is easily to make the edge of picture obviously and facilitates the follow-up image process. The gray-level image is threshold processed by Gray Morphology, as shown in Fig. 4. The main objects will be separated with background which is not needed existing. Choosing a critical value T = 80 that can obviously separate it into parts and makes the mark correspondent to the background for the picture pixel of 1 and other marks are correspondent to main objects for the picture pixel of 0. When the critical value T is proper set up, the glue path will be separated from background clearly. In order to provide better picture quality and measure glue path easily, it must to reduce image noise and unnecessary edge. In this paper, it uses FFT Filter function of Vision Assistant Package software to improve the middle weighting value, as shown in Figs. 5, 6. The filters function as:

$$\begin{bmatrix} 1/10 & 1/10 & 1/10 \\ 1/10 & 2/10 & 1/10 \\ 1/10 & 1/10 & 1/10 \end{bmatrix}$$

4.1 Pattern parameter

Picking image of image process module makes the standard pattern parameter and flaw pattern parameter to treat as studying the module group in the pattern. This is the eigenvector needed to use that training study for the setting up type neural network. The pattern parameter mode is:

(1) Input the eigenvector of the parameter:

a. $\dfrac{\text{width of glue path}}{\text{width of picture}}$, determine whether the glue path is too width or thin.

b. $\dfrac{\text{skew of glue path}}{(\text{average width of glue path})^{1/2}}$, determine the skew of the glue path.

c. |prior slope of invert – posterior slope of invert|, determine the out of shaping of the glue of path.

(2) The eigenvalue of output parameters are 6 determined results as follows by:

a. left skew
b. right skew
c. left out of shaping

d. right out of shaping
e. thin
f. width

There are 13 picked points of the type parameters of glue path, which one of them is as shown in table 1. Table 1 is the normal case of glue path pattern and others case are omitted from here. The way of picked type parameters is:

A: $\dfrac{\text{width of glue path}}{\text{width of picture}}$, B: $\dfrac{\text{skew of glue path}}{(\text{average width of glue path})^{1/2}}$

C: left side |prior slope of invert – posterior slope of invert|

D: right side |prior slope of invert – posterior slope of invert|

4.2 Back-Propagation Network Learning

After getting parameters of the glue path types, that then going on the Back-Propagation Network learning, which will recall the network weighting value, needed to use while inferring by receiving the network. The measuring project of this system is divided into four types, such as normal, width, thin, skew of glue path and out of shaping, etc. Therefore, building the network of constructional learning which necessary learning parameters is every type of glue path to pick up 5 pictures and a picture is divided apart into 17 partitions that are 15 lines and using among of 13 lines have 26 points, as depicted in Fig. 8. Since there are 6 eigenvalues of output parameters, the total learning patterns are 390. Because of it is too huge to show training data of the parameters, there are 13 data among them as shown in table 2.

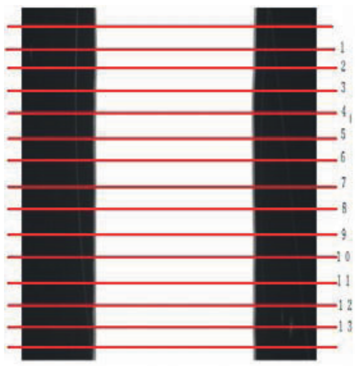

Fig. 8. Normal pattern

Table 2 Training data

	A	B	C	D	left skew	right skew	left out of shaping	right out of shaping	thin	width

11	0.5239	-0.3184	0.0222	0.0167	0	0	0	0	0	0
12	0.5240	-0.3374	0.0177	0.0228	0	0	0	0	0	0
13	0.5242	-0.3415	0.0203	0.0022	0	0	0	0	0	0

The constructional learning data can input Back-Propagation Network learning module to learn and then obtain a network link weighting value that support follow-up spend as what has been inferred to come. In this study, the Back-Propagation Network adopt input layer, two hidden layers and output layer altogether 4 structures and their states set up as follows:

1. Input layer nodes are the input parameters that is the mentioned 3 eigenvalues previously.
2. Output layer nodes are the network-outputted layer to output several nodes that is the 6 kinds of glue path types mentioned previously.
3. There are 390 training patterns to learn in the network. The more network train epochs, the more convergences disappear. In the experiment, training epoch is setting 100 times and disappears of that exceed the number of times, but increasing the time to train instead.
4. The hidden nodes are the process numbers of hidden layer, too much or too few affect the convergence result. The result of the hidden layer cannot reflect this problem and input the reciprocation among their units. Therefore, there are more errors. One or two hidden layers can overcome this more complex problem and reciprocate among their units of the response. Too more hidden layers make the network excessively complicated instead and more some minimums that will make also falls into some minimum of an error function even more while revising the weighting value of the network, it is unable to convergence. According to experience, the hidden layer of general problem is one layer and the more complicated problem is two layers. In this system, we take two hidden layers and the nodes of two layers are 10 respectively. The error convergence figure of after the network finishes learning is depicted in Fig. 9.

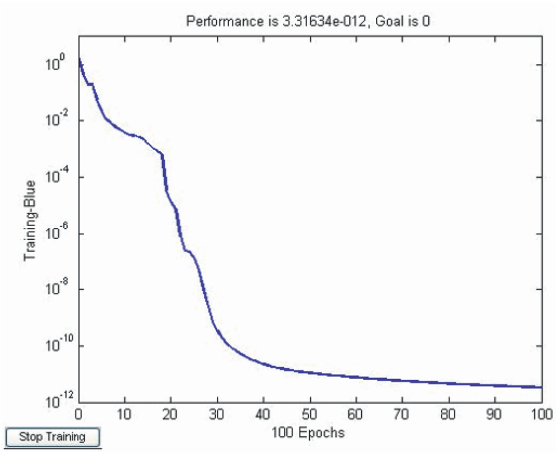

Fig. 9. The error of network learning

After 100 epochs of training, the root mean square error is converged to below 3.316×10^{-12} and the result of training network weighting value is as follows table 3 and table 4. The result of example training test is as shown in Fig. 10.

4.3 Glue path check

The final neural network learning is checking process. According to these link-weighting values of networks, it determines the output type of that will be measured event. This approaches to determine the failure type of glue path and replace the glue needle decision. The following each measure sample, the result of regular output is between 0 and 1. This is significant of it is closer to 1 and then the features of classified are more obvious. On the contrary, it is closer to 0 and the features of classified aren't obvious. According to experiment, while the network infers for some types that exporting values are very close to 1 and others are 0.

4.4 Nearest neighbour decision rule

The nearest neighbour decision rule itself has not included too many foundations of theorem [6]. It depends on intuition way to decide that how to classify who is the neighbour and who is closest to decide one's own classification. If there is a vector v of sample of an unknown classification, then we find out the closest point v_k to v in all sample data and use v_k to decide the v to classify which category. It is satisfied as following conditions that v and v_k can include in the same category and the mathematics form can express to:

$$dist(v-v_k) \leq dist(v-v_i),\ i = 1 \ldots n,\ i \neq k$$

Where $dist(v-v_k)$ is any way to distance measure, for example Euclidean distance.

The case of Fig. 11 is the Prototype of test pattern and its result of Back-Propagation Network training is as shown in table 5. The normal state position is defined x=0 and others failure state skew, out of shaping and thin-width are defined x=1, x=2 and x=3 respectively. Fig. 12 is shown 13 sample points distribution state. It indicate that the sum of Euclidean distance It calculate sum of Euclidean distance between the failure position and 13 sample points then it can find that the position skew x=1 is the sum of minimum distance. Therefore it can infer that the most possibly failure type is a skew state and advised to change glue needle distal.

5 CONCLUSION

In this research, it is using Back-Propagation Network, nearest neighbor decision rule and Vision assistant system to develop an intelligent equipment maintenance system for the diagnostic research. The main diagnostics is to diagnose with the automatic vision process that can reduce the careless mistake from human eye and subjective experience. According to much of the sample test, this diagnosis system is base on Back-Propagation Neural Network has already a precise distinguished. In the future, more reference data can even enhance the height ability.

Abstract: During tight financial times, and since the resources dedicated to the maintenance and operation of school buildings infrastructures come mainly from the state budget, the maintenance and operation budgets are frequently among the first cuts. Public schools infrastructures often resent themselves from this philosophy, presenting in some cases precocious degradation, generally as the result of the priority on allocating funds to items that directly affect education. It is important to focus on areas such as maintenance, building systems, safety improvements and technology, leading managers to improve maintenance performance of these organizations, if possible anticipating in time problems and opportunities. In this scenario, maintenance audits provide a framework for organizations to systematically review, analyse and recommend improvements in performance.

This paper presents the results of a study regarding the Portuguese Educational Buildings, specifically the ones concerning Secondary Schools. It identifies some areas needing improvements, as well as the suggestions made to improve maintenance management, regarding management decision making, human resources, information systems and strategies employed in maintenance management, among others.

The paper contains the analysis of the information about the Portuguese Secondary Schools maintenance management that was collected in 2004, with the help of a questionnaire answered by 279 Portuguese Secondary Schools administrations. Along with the information regarding maintenance management, it was also asked school administrations to provide information about the building characteristics and security, both inside and in surrounding areas of the school.

Key Words: Strategic asset management, maintenance audit, maintenance management, educational organizations, maintenance strategies in asset management.

1 INTRODUCTION

According to the Portuguese law for the Educational System, published in 1986, the dimensions of educational buildings must provide the possibility to receive a reasonable number of students, in order to guaranty the necessary conditions for a good pedagogical practice and to promote a true scholar community. Simultaneously, the management of spaces, installations and equipments, human and material resources, as well as financial and administrative management, should contribute for the educational and scholar success of each student [[1], [2]].

Despite the importance of building and infrastructures maintenance and its role in cost control, savings in materials and lifetime enlarging of equipment and facilities, maintenance in service organizations is often still regarded as a disturbing factor only. Since the resources dedicated to the maintenance and operation of school buildings infrastructures come mainly from the state budget, during tight financial times the maintenance and operation budgets are frequently among the first cuts. Public schools infrastructures often resent themselves from this philosophy, presenting in some cases precocious degradation, generally as the result of the priority on allocating funds to items that directly affect education [[1], [3]-[6]].

Bad conditions of equipments may interfere directly not only in the organization economics, but also by reducing the overall availability of buildings while simultaneously interfere with occupants' security. This is why both installations and equipments associated with the operation of school organizations must be maintained in good conditions. In order to accomplish that, fundamental areas such as Fixed Equipments, Building Structure, Safety, Technology and Maintenance must be considered in a well-balanced way [[7]].

2 PORTUGUESE EDUCATIONAL SYSTEM

Portuguese educational system has been changed significantly over the last three decades. The thought of generalising the access to all levels of education appears at the beginning of the seventies (XX century), yet, the growing number of students has not been followed by the necessary investments in installations and equipments nor in teaching staff competency until the end of the following decade. The publication of a new law for the educational system in 1986 [[2]], and the almost simultaneous integration of Portugal in the European Union, helped to change the scenario. The first introduced a new perspective of decentralisation in the educational system and the second one gave the economical support needed to invest in educational building renovation, new constructions and equipments [[3], [8]-[10]].

Paradoxically, and as a result of pressures in order to enlarge the educational offer, the significant growth of new constructions tends to coexist with spare or non-existent budgets available to maintain schools in good state of conservation, resulting in functional expenses restraint [[3], [5], [6]].

The growing amount of funds dedicated to education until the end of the last century conducted to a significant development and improvement of human and material resources. As a result, Portugal presents a public expenditure in education that overtakes the average of the countries members of the Organization for Economic Cooperation and Development (OCDE). However, the national effectiveness does not come to the pattern of OCDE and Portugal must reduce significantly its public expenditure [[3], [8]].

Education is one of the most resource absorbing sectors and thus it is becoming more and more important to improve its efficiency [[8], [11]]. Despite the complexity of the educational sector, it is obvious the need to review management and administration models, applying the principles of the law for the educational system published in 1986, in particular the principle of institutional autonomy [[3], [8], [10]].

It is important for managers to improve maintenance performance of school organizations, focusing on areas such as maintenance, building systems, safety improvements and technology, if possible anticipating in time problems and opportunities [[7]]. To accomplish all of those goals these organizations must be determined to manage their available resources effectively and to seek improvements for increased efficiency, while they must implement a regularly scheduled detailed maintenance plan for all building systems [[5]].

3 INTERNATIONAL OVERVIEW

In countries such as the United States of America, the United Kingdom, Canada and Australia several reports related to state buildings' maintenance have been published [[1], [12]-[16]]. Those reports enhance the relationship between budgeting plans and maintenance activities for both equipments and buildings.

The British Standard Guide to Building Maintenance Management is an example of a standardization document whose structure allows its application both in more complex organizations and in domestic properties. This document emphasises the importance of health and security in buildings maintenance, both by the perspective of the building user and the maintenance management work executants [[17]].

The development of databases with information about frequent problems and maintenance global costs as well as long-term maintenance plans and inspections, are some of the several methodologies used to improve buildings maintenance [[5], [12]]. Among the considered requirements are [[1], [12], [13], [18]]:

- Regular inspections for assessing equipment and structures current state;
- Regular inspections for assessing equipment and structures evolutionary state;
- Long time planning for maintenance operations;
- Preventive Maintenance Plans;
- Periodic Audits of the organizational structure of maintenance management personnel;
- Computerized Maintenance Management Programs or similar;
- Data bases with the most common problems;
- Records of all maintenance activities;
- Data bases with all maintenance costs;
- Energy management.

The development and implementation of suitable maintenance plans, for the full range of building systems, equipments and components, is systematically referred. It is also pointed out that such maintenance plans must be the result of a real and participative commitment of each organisation [[5], [13]-[15]].

Both operation and the implementation of the abovementioned requirements involves funding. One of the mentioned approaches to budgeting for preventive maintenance needs considers 5% of the operating budget to be adequate. Another one sets the budget based on 5% of the buildings present value [[13]].

4 MAINTENANCE POLICY FOR PORTUGUESE SCHOOLS

In the mater of building's maintenance, the legislation published in Portugal is vague and sometimes even not existent, which contributes for the precocious deterioration of some buildings. As an example, Portuguese Laws 38382/51, 555/59 and 177/2001 only state that "*(...) at least one time every eight years constructions should be object of preservation actions (...)*". It is also important to refer that building's maintenance activities in Portugal only represent 4% of the global construction activity, while in the European Union the mean value for this percentage is of 35% [[19]].

Simultaneously, the Portuguese law for the Educational System only states that " (…) construction and maintenance of school buildings and its equipment must stand on an effective regional policy, with a clear definition of competencies for every intervenient, who, in this matter, should have the necessary resources(…)" [[2]].

In fact, the importance of building's maintenance is not yet being considered as a key element of Portuguese school board's mission statements. Several studies concerning the educational sector have been carried out in Portugal, dedicated to Primary, Preparatory and Secondary schools, but all in areas such as pedagogics, politics and administration.

Among the numerous publications of the Portuguese Board of Education, a few consider the operational area of educational organizations and only two were found that focused on the importance of maintenance in educational buildings [[6], [20], [21]]. Those publications were presented as informative documents, suggesting that "*(...) each school board should develop its own operation, maintenance and security manual (...)*" considering each building constructive characteristics as well as the installed equipment and collecting data such as [[20], [21]]:

- Buildings layout;
- Data base with all school assets, including operation and maintenance instructions;
- School facilities operation and maintenance instructions;
- Procedures for school facilities housekeeping;
- Procedures for school facilities and equipment periodic maintenance;
- Specification of technical responsibility for electrical and gas systems;
- Outsourcing contracts for maintenance.

5 PORTUGUESE SECONDARY SCHOOLS

The Portuguese Educational System is a complex structure and so, any suggestions to improve maintenance management, regarding management decision making, human resources, information systems and strategies employed in maintenance management, among others, must be based on the objective identification of those areas needing improvements, as the first step of an overall maintenance improvement process.

In Portuguese Educational System the specificity of the several levels of education refers not only to pedagogical practices but also to spaces, installations and equipments policies management, human and material resources management, as well as financial and administrative management. Therefore, the methodology for studying the Portuguese situation should reflect this reality.

In this context, it was decided to evaluate separately the situation for each level of education, not only in terms of maintenance management, but also regarding building characteristics, building systems, safety improvements and technology. Since it was not available any survey of the Portuguese Educational System, referring to those areas in particular, several questionnaires have been developed, to be answered by each school board, with the aim of collecting information for later analysis.

One of the developed questionnaires, designated by CARMA^{EE} questionnaire, was designed in the framework of the Portuguese Secondary School level of Education, and it was posted to all the 869 Portuguese Schools with Secondary Education, whose administrations where asked to provide information regarding their maintenance management policies, building characteristics and security, both inside and in surrounding areas of the school.

The CARMA^{EE} questionnaire was focused on the data categories presented in Table 1:

Table 1

Main structure of the CARMA^{EE} questionnaire

Data categories	Subjects
School Characterization	School identification and building characterization
	Geographical location
	Functional characteristics and socio-cultural structures
	Transportations and parking facilities
	Human resources
	General information
Security	People safety and assets security
	Fire protection
	Gas infrastructures and equipments
	Safety, health and hygiene
	Electrical infrastructures
Maintenance Management	Human resources
	Documentation
	Annual budgeting and operations and maintenance costs
	Building infrastructures and equipments conditions
	Maintenance strategies
	Large retrofitting interventions

The information about the Portuguese Secondary Schools maintenance management was collected in 2004, with the help of the above mentioned questionnaire, answered by 279 Portuguese Secondary Schools administrations. The analysis of the gathered information allowed the identification of the areas of opportunity in terms of maintenance management enhancement. It is important to note that, for this kind of studies, it is considered to be acceptable a percentage of participation from 5% to 40% and that the number of received answers exceeds 32% of the 869 Portuguese Schools with Secondary Education.

The results presented here are based on the analysis of the answers to the set of questions associated to Maintenance Management and its related subjects, as asset condition appraisals and maintenance planning.

5.1 General overview and budgeting

Portugal is divided in Continental Portugal and two autonomous regions, with specific administrative and fiscal framework: Açores and Madeira. The designation Continental Portugal is used to differentiate the mainland territory of Portugal from the insular territory, which is composed by Açores and Madeira Portuguese archipelagos, located in the Atlantic Ocean. Continental Portugal is divides in 18 districts, considered not only for political and administrative subdivisions but also for public education or health care purposes.

Figure 1 represents mainland and insular Portugal territory, divided in its 18 districts and two autonomous regions.

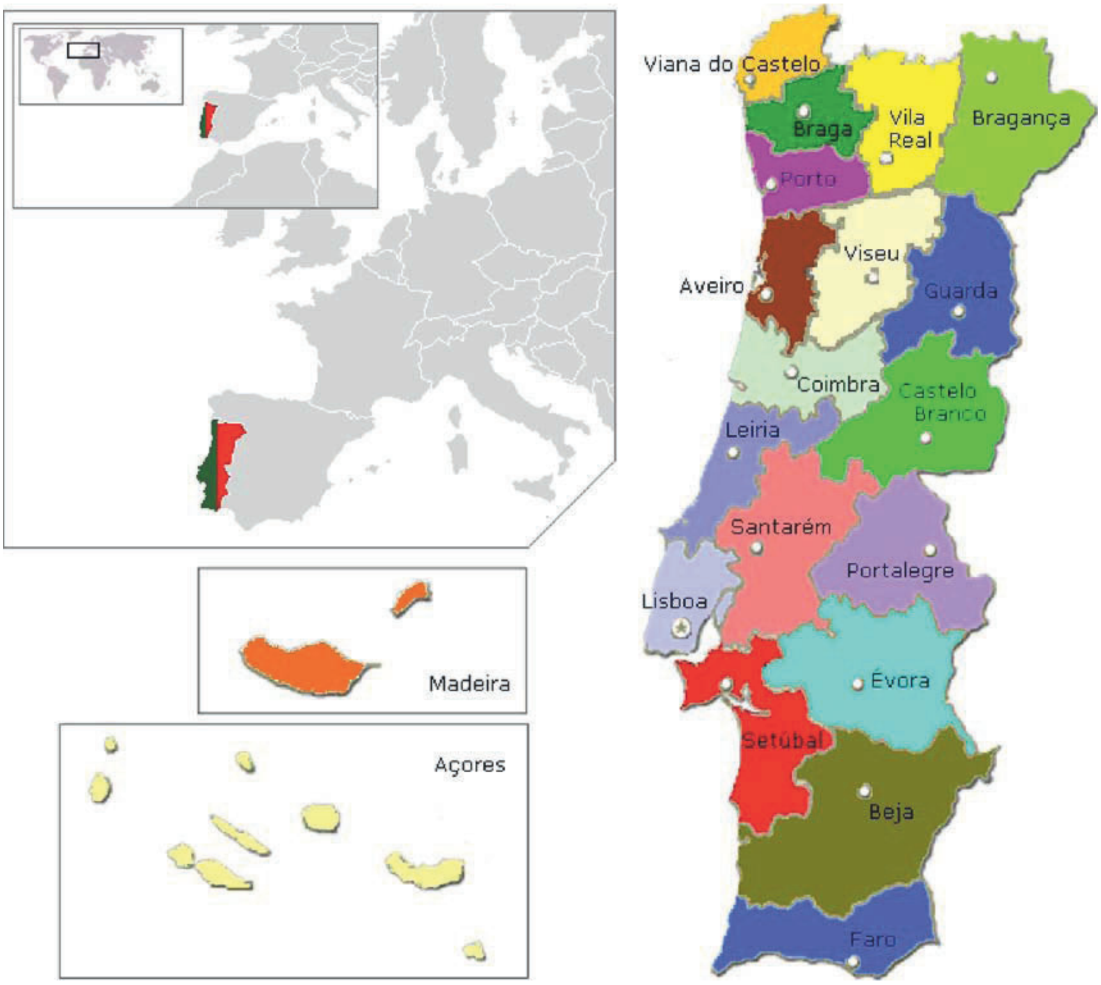

Figure 1 – Portugal in the world, mainland districts and autonomous regions of Açores and Madeira.

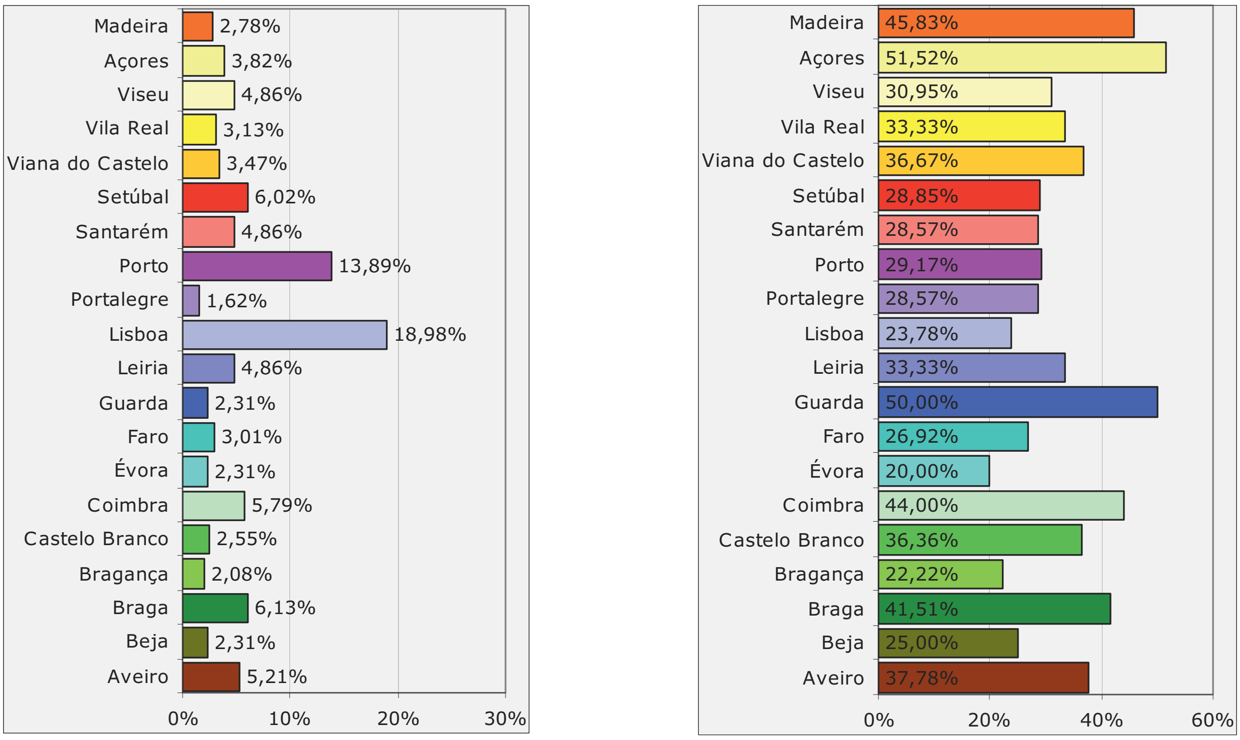
As illustrated in Figure 2, among the 20 Portuguese districts and autonomous regions (Açores and Madeira), the highest rate of participations occurred in Açores archipelago with 51,52% responses received. On the other hand the lowest rate of participation (20,00%) refers to Évora district.

Considering the 279 Portuguese secondary schools participants, 47,25% have less than 20 years old and only 12,92% of those schools buildings have more than 50 years old. As illustrated in Figure 3, all the Viana do Castelo district participant schools occupy buildings with less than 25 years old and, on the other hand, all the school buildings in Bragança have more than 20 years old.



(a) **(b)**

Figure 2 – Portuguese school institutions with secondary level of education: (a) distribution of the 869 schools by the 20 districts and autonomous regions under analysis; (b) percentage of participation from the 20 districts and autonomous regions under analysis, considering the 279 answers.

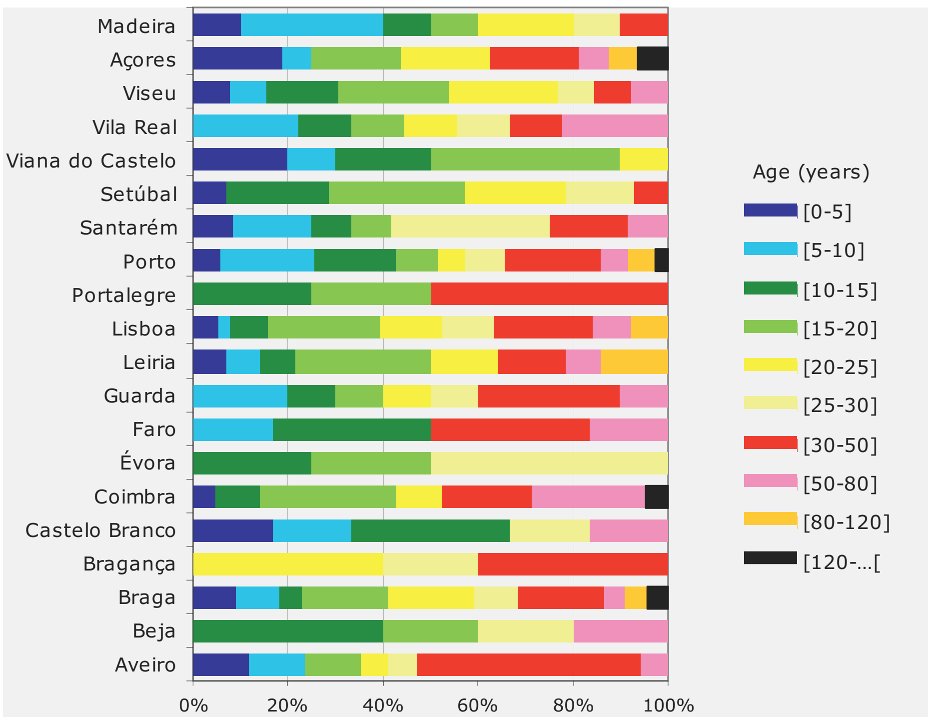


Figure 3 – School buildings distribution by age, considering the districts and autonomous regions of Portugal.

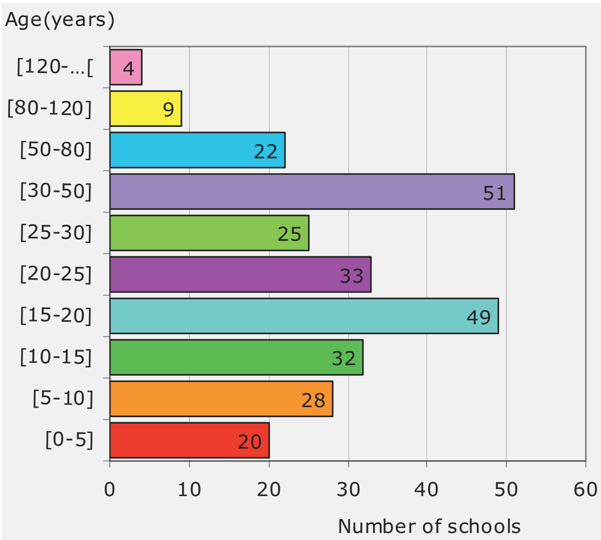
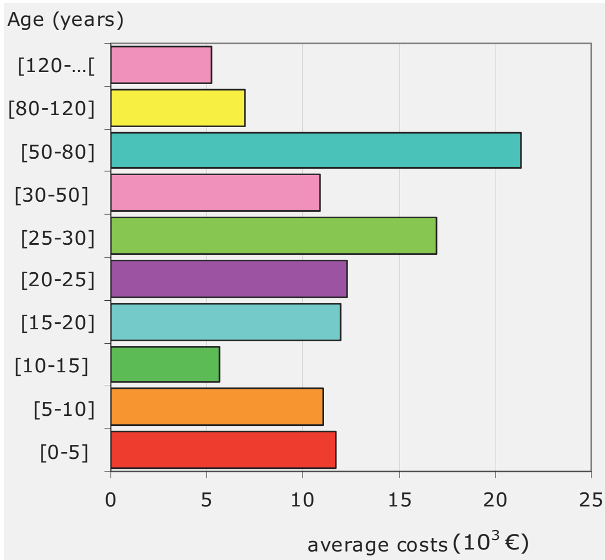
Figure 4(a) illustrates that 39,78% of the school buildings have more than 25 years old and 80 of the 279 participant institutions (28,67%) occupy buildings with less than 15 years old.

The maintenance and operation costs indicated by each school board reveal that those expenses are not only a function of the buildings age and size but also depend on the public or a private administration of the schools. Effectively, in Figure 4(b) the average values for each age interval tend to follow the building age, except for the extremes (below 10 years and above 80 years). The lowest values corresponding to school buildings with more than 80 years and less than 10 years old can be explained by the relation with the buildings areas, as illustrated in Figure 4(c).

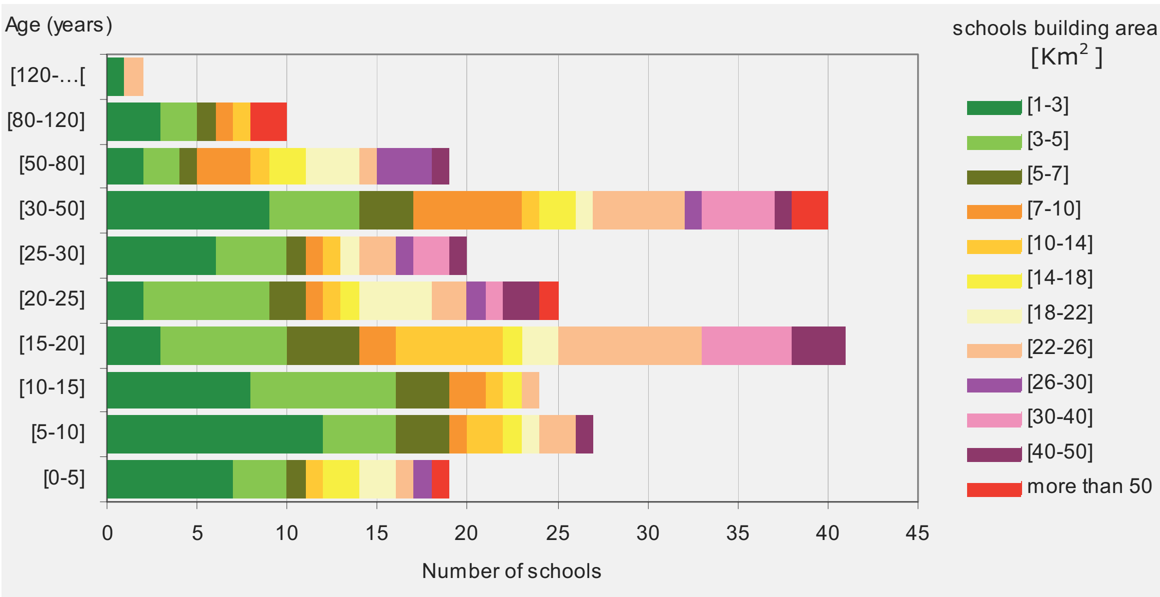
From the 279 participating schools, only 181 refer the amount of money expended in outsourcings, for example in maintenance of elevators and acclimatization systems. Simultaneously, no more than 81 of these schools assumed to have an annual budget for operation and maintenance.



(a)



(b)



(c)

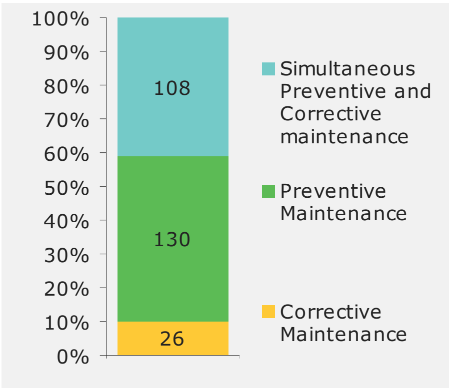
Figure 4 – School buildings distribution by age: (a) number of schools for each given age interval; (b) school's average maintenance and operation costs in each age interval; (c) schools building area in each given age interval.

5.2 Maintenance strategies

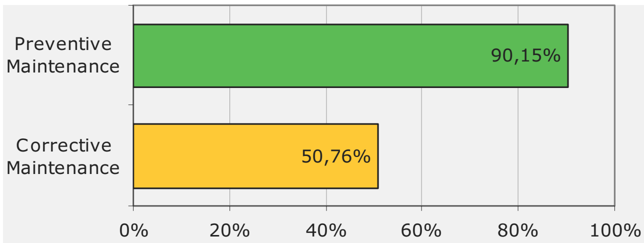
Figure 5(a) presents the number of schools referring to follow only one of the preventive or corrective maintenance strategies and those using both strategies simultaneously. As shown in Figure 5(b) a significant number of those 264 schools (90,15%) refer the application of preventive strategies. Nevertheless, 40 of this 238 schools (16,81%) where not able to identify any equipment or structure maintained in a preventive basis nor the periodicity of the preventive maintenance applied.

For some assets, it was also observed that school boards indicated a time period for preventive maintenance that is not in accordance with the standards. As an example, some schools mentioned a monthly based maintenance of the roofing while others indicated a time period of less than one year (69,56%), despite the 15 years time interval suggested in the literature for the same structure [[6]].

A similar situation was observed with respect to walls. Respectively, 73,33% and 61,9% of the schools indicated time periods of less than one year between preventive maintenance interventions in interior and exterior walls, when the literature usually indicates periods of 5 years between small interventions in interior walls and 10 years between interventions in exterior walls [[6], [12], [19]].



(a)



(b)

Figure 5 – Maintenance strategies: (a) total number of schools referring to follow a maintenance strategy; (b) percentage of the 264 schools using preventive and corrective maintenance strategies.

5.3 Documentation

According to the maintenance policy for Portuguese schools, expressed in section 4, each school should implement its own operation, maintenance and security manual. Several other documents referred in section 3 reinforce the idea that this manual must be developed in order to address the individual and different needs of each school and their systems.

Besides their own manual, documents like manufacturer's literature, legislation or test results may be used by school boards to support their activities. Table 2 shows that 74,55% of the participating schools use support documentation, mainly manufacturer's manuals and legislation (58,65% and 76,92%, respectively).

From the 208 school boards that have answered to this question, only two of them identified the "*Schools Operation, Maintenance and Safety Handbook*", publish by the Portuguese Board of Education, as one of their supporting documents.

The percentage of schools developing their own operation, maintenance and security manuals is very low (22,22%), as shown in Table 2 and every one of the participant schools from the districts of Beja, Bragança, Évora, Portalegre and Santarém and from the autonomous region of Madeira do not have a school own manual.

Effective preventive maintenance programs depend on the feedback from maintenance personnel and the reporting system used, namely with respect to costs associated with preventive maintenance efforts [[13]]. With respect to maintenance management documents, Table 3 shows that 46,59% of the participant schools developed annual documentation, such as budgets (29,03%) and reports for maintenance activities (25,8%). For those schools, 29 (10,39%) guarantee to develop simultaneously Maintenance Plan, Reports and Budget for maintenance, but 23,08% of them refer to follow a corrective maintenance strategy. At the same time, only 59 school boards assured to simultaneously developed documents for recording execution dates, description and costs for every maintenance activity.

Table 2

Support documentation for safety and maintenance activities

Use of supporting documentation	Frequency	Percentage of the 279 participating schools	Percentage of the 208 schools using documentation
Yes	208	74,55%	
School own manual	62	22,22%	29,81%
Manufacturer manual	122	43,73%	58,65%
Legislation	160	57,35%	76,92%
Others	11	3,94%	5,29%
No	51	18,28%	
Do not answered	20	7,17%	

Table 3

Documents for maintenance management developed by the school board

Annual documents	Frequency	Percentage of the 279 participating schools	Percentage of the 208 schools using documentation
Yes	130	46,59%	
Maintenance Plan	77	27,59%	59,23%
Reports	72	25,80%	55,38%
Budget for maintenance	81	29,03%	62,31%
No	138	49,46%	
Do not answered	11	3,94%	

5.4 Building infrastructures and equipments conditions

Figure 6 presents two examples of the analysis made for school building's assets general situation.

In the particular case of the interior lighting systems, Figure 6(a) shows that, in general, these assets are considered by school boards administration to be in god conditions. Only three schools have very bad problems with interior lighting but two of them have already asked for an intervention.

The results presented in Figure 6(b) show that almost 20% of those schools with ages between 25 and 30 years old have serious problems with their interior walls. It is important to note that one of these schools considers itself to be using preventive strategies.

6 CONCLUSIONS

In order to manage the available resources in an effective way, it is extremely important that educational organizations may have actualized, detailed and accurate information about the buildings, their systems and equipments, and the way they are managed. In this scenario, maintenance audits provide a framework for organizations to systematically review, analyse and recommend improvements in maintenance management performance.

This paper presents the results of a study regarding the Portuguese secondary schools buildings and it emphasises the necessity to develop periodic asset inspections, not only to verify their condition, but also as a support to establish retrofitting maintenance programs.

The study supported by CARMA^{EE} questionnaire lead to the main conclusion that it is very important to review management and administration models, since it is necessary to improve the global effectiveness of the Portuguese educational system, namely by using resources in a most effective way.

Not only school board administrations but also the authorities responsible for educational system management must be aware of the importance of school building's assets maintenance management and so training must be considered. Areas such as maintenance management and organization provides the indispensable technical support for their activities of planning and scheduling maintenance activities, as well as a support for inspection activities, reporting and analysis of the collected data. Additionally, team management, leadership and motivation are a valuable support for school managers to better deal with maintenance personnel.

Unquestionably, school buildings have management special needs but they also present unique development challenges in terms of new studies and applications. Simultaneously, school organizations may have a privileged influence both in individuals and institutions.

When effectively applied, maintenance management and organization allows school buildings to be preserved in good operation conditions and simultaneously guaranties occupant's health, well-being and safety. Therefore, maintenance management and organization will contribute to ensure Portuguese educational system effective operation, reason why it is important to develop not only manuals but also standardization for buildings maintenance in general and for school buildings maintenance in particular.

DEVELOPING STRATEGIC ASSET MANAGEMENT LEADERS THROUGH POSTGRADUATE EDUCATION

Dr David Thorpe

Faculty of Engineering and Surveying, University of Southern Queensland, Toowoomba, Queensland 4350 Australia.

Abstract: The modern engineering asset manager is required to develop, operate and maintain engineering assets economically and in a socially responsible and sustainable manner. Key issues confronting the asset manager of today include taking a strategic life cycle approach to asset management, meeting user requirements and minimising risks. To achieve this, it is necessary to understand asset life cycle issues including economic analysis and sustainability, be aware of social impacts, understand technological risks and work at the cutting edge of technology. While undergraduate engineering programs can meet this need to some extent, postgraduate education is often the best approach for learning the principles of strategic life cycle asset management. This paper discusses one such example of postgraduate engineering education, the Master of Technology Management, offered by the Faculty of Engineering and Surveying at the University of Southern Queensland. Topics discussed include the rationale for this type of study program, how it addresses the needs of life cycle asset management including risk and innovation management, its approach to learning, and its role in developing strategic technological leaders. The future role of programs of this type in developing leading asset management professionals is also discussed.

Key Words: Asset management, Technology Management, Postgraduate, Education

1 INTRODUCTION

The engineering asset manager of today faces many challenges. The types of assets managed may vary from infrastructure assets like major physical installations and distribution networks, to fixed and mobile plant and equipment such as manufacturing installations and transportation equipment, through to communication networks.

Asset management in such an environment is a complex task that requires application of a combination of engineering, strategic management and financial skills. In the modern world, it is also just as important to achieve social and environmental goals as it is to reach the more traditional technical and economic goals. The modern engineering asset manager is therefore required to develop, operate and maintain engineering assets economically and in a socially responsible and sustainable manner over the life cycle of the asset and throughout decommissioning and disposal.

While undergraduate engineering study programs include engineering management courses, their ability to develop the skills for effective asset management are limited, as undergraduate programs are principally aimed at meeting formal academic training to meet the requirements of professional organisations. Engineering management training in such programs is therefore of necessity at a fairly basic level. Postgraduate programs, aimed at providing sound engineering management training in asset management and related concepts like sustainable development, technological innovation and risk management, can achieve the goal of offering the additional academic development needs by today's integrated strategic asset managers.

It has been in this environment that programs such as the Master of Technology Management (MTM) program at the University of Southern Queensland (USQ) have been developed. As well as taking graduate engineering and technology management education beyond that at undergraduate level, programs of this type aim to develop the skills needed to compete and be successful in the complex world of technology, engineering and entrepreneurship in which the advanced engineering and technology manager will work.

This program was developed out of the recognition that a large number of engineers and other practicing professionals aspire to managerial positions in a technology or engineering environment. It was also recognised that qualified managers of technology play a crucial role in technologically advanced as well as developing societies. Thus it was reasonable to expect that many of these professionals would want to achieve postgraduate qualification in a coursework-based management-focused program [1].

This paper discusses the way in which the programs like the Master of Technology Management can assist to develop strategic asset managers through an integrated program that teaches not only asset management but also explores related topics like technological management and its impact, sustainable development, management of technological risk and other key technology management areas. Initially, the paper discusses the context and issues in strategic asset management. It then explores the options for strategic asset management education, discusses the MTM program and the approaches it uses for teaching, evaluates what it has achieved so far and explores the challenges of the future.

2 CONTEXT OF STRATEGIC ASSET MANAGEMENT

In developing a study package suitable for strategic asset management in an engineering environment, it has been firstly necessary to establish the context for the asset management process. This has consisted of developing an understanding of the types of assets being covered by the program and what the term "asset management" means in the engineering asset management environment; and from this developing the concept of the asset life cycle and the goals that need to be met by the asset manager. This was followed by an evaluation of the challenges faced by asset managers in the delivery of their responsibilities.

While an asset may be broadly defined in a financial sense to mean any item of economic value owned by an individual or corporation, it was decided that in an engineering sense an "asset" would normally mean installations, plant, equipment, knowledge, resources and related items that that support the community, commerce and industry.

Like "asset", the term "asset management" can be also defined in several ways. A common definition of asset management used in highway engineering is "A systematic process of maintaining, upgrading and operating assets, combining engineering principles with sound business practice and economic rationale, and providing tools to facilitate a more organised and flexible approach to making the decisions necessary to achieve the public's expectations" [2]. While not all engineering assets will have the public as asset owner or user, this definition can form the basis of a more general description of many engineering assets by substituting the words "expectations of asset owners and users" for the words "public's expectations."

The life cycle asset management process breaks into the four main streams of identification of the need for the asset; provision of the asset (including its ongoing maintenance and rehabilitation to suit continuing needs); operation of the asset; and disposal of the asset [3]. In performing these tasks, the asset manager is required to not only use sound engineering principles, but also sound business practice and an economic rationale. Modern asset managers also need to take account of social and environmental issues. The strategic asset management leader also needs to look to the future, and therefore as well as applying sound budgeting and engineering management practices is required to consider the long term as well as the short term.

Engineering assets typically serve a number of communities of interest (or stakeholders), and are usually closely liked with the environment of which they are part. For example, physical infrastructure assets are founded on the natural environment and support the economic environment and social environment; and serve the communities of interest of the owner and/or manager, user and the community external to the asset (see Figure 1). A road, for example, is constructed on a natural foundation and is part of the wider environment; supports the economic environment represented by the transportation industry; and serves the road owner, vehicle drivers and other users (such as cyclists and pedestrians), and the community external to the road (such as residents or owners of the properties passed by the road and the wider community whose products they transport). A similar discussion can be developed for other fixed (in location) assets like power stations, water supply and sewerage facilities, and distribution systems. This thinking can be extended to other assets, such as mobile plant and equipment.

The communities of interest to assets each have different requirements of the asset manager, who therefore has to meet a number of goals to meet these requirements. Thus, users expect the asset to have the ability to provide an adequate level of service at the required level of demand; and meet a required level functional serviceability (i.e., condition). Owners and managers require the asset to deliver the optimum service life consistent with the requirements of stakeholders; deliver maximum benefit over the life cycle consistent with other requirements; and operate at minimum life cycle cost, again consistent with other requirements.

Stakeholders external to the asset can be divided into the two sub-groups listed above – the local external community and the wider community. The local external community, which will have relatively close geographical proximity to the asset, will require that the asset satisfies external requirements of interest to that community (for example, environmental and political requirements) to a level acceptable to the community outside the users, owners and managers. Finally, the wider community, which often funds the asset (for example, taxpayers funding a community asset, financiers funding an industrial asset), will require the asset to deliver a whole of life performance (the integral of functional serviceability) acceptable to its stakeholders [4].

3 CHALLENGES IN STRATEGIC ASSET MANAGEMENT

While asset managers are required to meet (and optimise) the requirements of key stakeholders, they are also required to meet other requirements. One of these – sustainability - follows from the need to meet social and environmental requirements of the wider community. It is at the core of sound strategic asset management principles that ensure that assets not only meet the requirements of today's society but also the requirements of society into the future. This needs to be considered in practical terms. Johnson [5} sees sustainability is as an ideal state of long-term social, economic and ecological stability, a target towards which we strive, rather than one we expect to reach. In this scenario, sustainable development would consist of striving towards sustainability, while still pursuing production goals and overall economic growth

.

Sustainability has been identified as a desirable quality in engineering leadership competencies [6]. It has also been recognised as an important issue for research organisations, such as the Cooperative Research Centre for Construction Innovation, which has developed a report on sustainable subdivisions [7] and has placed considerable effort into the development of a life cycle assessment tools to evaluate eco-efficiency of buildings from CAD drawings [8]. The social and environmental responsibilities of engineers have also been adopted by Engineers Australia, which in its Code of Ethics has stated that its members 'shall, where relevant, take reasonable steps to inform themselves, their clients and employers, of the social, environmental, economic and other possible consequences which may arise from their actions.' [9]

A common outcome of the discussion on sustainability is that to achieve a sustainable future, any development and management project we undertake needs to carefully consider the needs of future generations, the ability of natural resources to continue to meet the needs of those generations, and what we can do to manage those natural resources to enure that this occurs. This argument can be extended to include all aspects of human endeavour. Thus, when we consider a sustainable future, we should be considering, in additional to environmental sustainability, concepts like social sustainability, economic sustainability, technological sustainability and sustainability in other fields of human endeavour and nature. Examples of this approach include a sustainable and cohesive society, the maintenance of historical artefacts, the ability to economically support the world's population and management of technological knowledge.

Clearly, the asset manager has a significant role in ensuring that assets are planned, designed, developed, operated, maintained, rehabilitated, retired and disposed of in a socially and environmentally responsible manner. Thus, there is a responsibility to investigate and resolve social issues and conduct environmental impact assessments over the whole asset life cycle. An example of this is in the use of some modern asset management materials. Fibre composites, for example, are now becoming used as a strong lightweight construction material, and are also used in applications like bridge asset management to replace timber, which is in quite short supply. While they clearly have benefits from this aspect of sustainability, there is also potential concern with their disposal when the structure of which they are part has come to the end of its useful life. Will such materials be disposed of easily? Should consideration be given to making them biodegradable at the end of their useful life? What other issues will arise? Such considerations require careful thought by the strategic asset manager.

A second key issue for asset managers is risk management. Risk is defined by the Australian/New Zealand Standard for Risk Management as a 'systematic process to understand the nature of and to deduce the level of risk' and risk management as 'the culture, processes and structures that are directed towards realizing potential opportunities whilst managing adverse effects' [10]. Risk so defined can lead to be both positive and negative outcomes.

The process of risk management as defined in the standard consists of seven main components: communicate and consult, establish the context, identify risks, analyse risks, evaluate risks, treat risks, and monitor and review [11]. It is important to recognise the importance of communication and consultation in this process.

An example of the role of risk management in asset management is the abolition by the High Court of Australia of the 'highway rule', which protected road authorities from action being brought against them due to failure to maintain a road, as part of the common law of Australia. This ruling is further explained in the cases of Brodie v Singleton Shire Council and Ghantous v Hawkesbury City Council [12]. It has led impetus to the management of risk in civil engineering asset management and of the development of good asset and maintenance management systems.

In some cases there have been specialised adaptations of risk management principles for a particular requirement. Thus, the risk management process described in the International Infrastructure Management Manual assesses critical failure in terms of a business risk exposure model that combines the costs of the consequences of failure of the asset (for example, repair cost, loss of income, loss of life, injury) and the probability of failure. The approach used in this manual has a strategic focus – 'should do' work that has to be completed within the next five years, 'could do' work that could possibly be deferred for another five years, and 'defer' work that could be deferred for a further five years. It also discusses strategies for risk management, such as risk reduction through capital or maintenance expenditure, emergency response plans, acceptance of some risk and carrying the consequential loss, and insurance against the consequential loss [13].

Other challenges for the strategic asset manager include the importance of seeking and adopting innovative practices in the asset management process, balancing short-term and long-term asset management requirements, quality management; systems management; project management; and management of resources. In particular, the asset manager is required to maximise life cycle economic return on the asset while optimising stakeholder goals, achieve social and environmental requirements, and to effectively plan and manage the asset management process to best achieve these results.

4 DEVELOPING STRATEGIC ASSET MANAGERS

The above discussion has outlined a number of the challenges faced by the strategic asset manager, including the need to optimise the achievement of a number of often conflicting goals, meet the requirements of various communities, address sustainability and other social and environmental issues, manage risk, be innovative, and plan and mange the asset management process for the benefits of key stakeholders.

While experience as an asset manager is relevant in developing these skills, it is important that the effective asset manager be given a solid theoretical grounding in them. From the point of view of the manager of engineering assets, this may be undertaken through specialised study. In particular, the strategic asset manager needs to focus on the larger picture as well as operational issues such as asset condition monitoring and maintenance.

Many engineering undergraduate courses now include courses (or subjects) that address engineering management and the responsibility of the engineer in society, and so partially meet the requirements of the education of the asset manager. This may commence with a compulsory first level course addressing communication issues, followed by courses later in the curriculum that deal with concepts like the engineer and society, and engineering management.

The University of Southern Queensland (USQ), for example, offers the course Principles of Professional Engineering and Surveying, typically taken during the first year of the engineering curriculum, which teaches engineering investigation and report writing. This lays the foundation for further studies in the responsibility of engineers in society and the principles and practice of engineering management.

This is followed by the course Technology and Society, typically taken in the second or third year of the engineer's studies, which builds on this foundation and deals with topics such as the history of technology, sustainability, environmental impact assessment, politics, economics, models of society, social impacts of engineering, a brief introduction to law and some key management issues such as management systems. As this course is offered in the second or third year of the engineering study program, all Bachelor of Engineering Technology (three year) and Bachelor of Engineering (four year) graduates (as well as a significant proportion of those exiting after two years with an Associate Degree) are exposed to key concepts like sustainability, globalisation, economics, and the need for the engineering graduate to relate to society and be innovative in addressing wider societal issues.

A third course, Engineering Management, builds on the principles of Technology and Society to teach management principles and practice for engineers and further develop the engineering student's appreciation of the social environment within which they will practice, and in particular those aspects of the law and ethics pertaining to the engineering profession. An optional fourth level course, Engineering Management Science, which provides the engineer a number of mathematical management tools, completes the undergraduate engineering management curriculum.

These courses, and similar courses at other educational institutions, provide the engineering undergraduate with a foundation in socially and environmentally responsible engineering principles and methods. This can however only be partially achieved in engineering undergraduate curriculum courses, as the large number of courses required to be studied by the undergraduate engineering student and the need to focus in undergraduate study on technical competence mean that there are limitations with developing the skills of effective and efficient asset management during the education of undergraduate engineers. For example, in the University of Southern Queensland engineering curriculum, the courses described above are only about 12.5 per cent of undergraduate study. Their impact is therefore lessened by the other 87.5 per cent of courses required to be studied by the engineering undergraduate.

Further dilution of the education of undergraduate engineers in the strategic management of assets occurs because the types of courses discussed above (with the exception of Engineering Management Science) are primarily verbally based rather than mathematically based, and therefore a number of students (particularly international students whose first language is not English) can find these courses difficult to understand, and hence may not achieve as well in some of them as they would in technically based courses. Students can also perceive that such courses are not really relevant to their future careers as engineering. For example, over the four offers to Semester 1 2005, the Technology and Society course had a drop-out rate of about 15 to 20 per cent, an overall pass rate of about 65 per cent, and only about 10 per cent of students achieving high grades (distinction or high distinction). These figures are worse for international students, to whom English is at best often only a second language.

The other main issue with undergraduate courses are that although they address issues such as social and environmental responsibility, economics, legal issues and management principles and practices, they of necessity cover these areas at very high level and do not really train engineers in the skills required to strategically manage assets. In addition, there tends to not be a very high emphasis on specific training in asset management and maintenance, and in key skill areas like risk management and innovation management.

Undergraduate education therefore achieves a basic understanding of the principles of sustainability and engineering management in graduate engineers, but falls short of providing the real focus on specific skills in particular specialisations such as asset management. Because of this limitation, the best opportunity of providing engineers with the skills of effective and efficient life cycle strategic asset management is through dedicated postgraduate engineering education.

It is therefore contended that postgraduate courses that focus on real tools for practising engineers provide the best approach for developing the required theoretical and practical concepts they require. Such courses must be directly applicable to practising professionals, and must been seen as a real asset to the corporations and institutions employing them. The University of Southern Queensland has consequently developed a number of postgraduate programs that meet these requirements. Several of these have courses suitable for asset managers, while one has a set of related courses that meet the requirements for asset managers outlined in the previous section.

5 POSTGRADUATE ENGINEERING PROGRAMS AT UNIVERSITY OF SOUTHERN QUEENSLAND

Postgraduate engineering education is offered within the University of Southern Queensland by the Faculty of Engineering and Surveying, sometimes in conjunction with other Faculties such as Business and Science. The programs offered include the Master of Engineering Technology, Master of Engineering Practice, Master of Technology Management (MTM), Master of Professional Engineering and Master of Engineering. There are also Engineering Doctorate and Doctor of Philosophy programs available.

In the Master of Engineering Technology, engineers and technologists develop increased technological skills through studying eight courses (equivalent to a year of full-time study) and undertaking a dissertation project equivalent in value to four courses (one semester of full-time study or equivalent), or alternatively studying an engineering management path of equal workload.

Students in the Master of Engineering Practice study a portfolio based program aimed at providing opportunity for experienced technologists to gain recognition equivalent to a four year professional engineering program.

The Master of Technology Management is a quite recent development. It is a coursework program that is aimed at combining technological and managerial skills for practising technologists and engineers. A related program is the related Master of Professional Engineering, which is a partial coursework and partial professional portfolio (and/or research) based program that utilises Master of Technology Management and other courses to develop a higher level of engineering specialisation.

A number of the courses offered in the Mater of Technology Management are also available in the Engineering Doctorate and in other University courses such as the Master of Project Management offered by the Faculty of Business. The management path of the Master of Engineering Technology program consists of a selected number of these courses.

6 OUTLINE OF THE POSTGRADUATE ASSET MANAGEMENT COURSES OFFERED AT USQ

The purpose of the Master of Technology Management is to produce graduates “that are equipped with essential management knowledge and an appreciation of the latest technologies much broader than the initial specialisation”, in order to equip them to manage complex technological or engineering businesses [14].

This program is completed by part-time external delivery mode, over a minimum of six semesters. It consists of twelve courses, four of which are core Master of Business Administration (MBA) courses and eight of which are specialised technology management courses, four of which are considered core to the program. The first specialised technology management courses were undertaken by students in 2004.

The engineering courses in this program are shown in Figure 2.

Core Courses (all to be completed)
Technological Impact and its Management
Towards Sustainable Development
Management of Technological Risk
Asset Management in an Engineering Environment

Other courses (4 to be completed)
Engineering & Surveying Research Methodology
Assessment of Future Specialist Technology
Management of Environmental Technology
Technology Management Practice
Whole of Life Facilities Management
Technological Innovation and Development

Figure 2: Engineering courses in the USQ Master of Technology Management

As previously stated, this program was developed out of the recognition that a large number of engineers and other qualified people aspire to managerial positions in a technology or engineering environment. It was also recognised that qualified managers of technology play a crucial role in technologically advanced as well as developing societies. This latter characteristic, which emphasises the crucial role of the technological manager in society, illustrates the importance of such a program in key technological functions like strategic asset management.

It is primarily aimed at attracting engineers and technologists who wish to develop management skills but want these to be in the field of technology management. They would come from both Australia and overseas, and would be likely to be ambitious and motivated, and see additional qualifications as a means of career enhancement.

In the next section, the key courses related to strategic asset management are described in more depth.

7 KEY ASSET MANAGEMENT RELATED COURSES IN THE MASTER OF TECHNOLOGY MANAGEMENT

The Master of Technology Management program contains a range of integrated courses that address the requirements of the strategic asset manager. Those currently offered are the specialised Asset Management in an Engineering Environment course, Technological Impact and its Management, Management of Technological Risk, Technology Management Practice, Technological Innovation and Development, Future of Specialist Technology and Engineering and Surveying Research Methodology. A course in sustainable development is expected to be developed in 2007.

To show how a program of this type can assist to meet the requirements of strategic management as discussed above, the courses of Asset Management in an Engineering Environment; Technological Impact and its Management; Management of Technological Risk; Technological Innovation and Development; and Technology Management Practice are discussed below in more depth. This is followed by an overall summary of how the program addresses the development of strategic asset management leaders.

7.1 Asset Management in an Engineering Environment

Asset Management in an Engineering Environment is aimed at developing the skills of asset managers in making strategic and operational decisions in the development and maintenance of engineering assets. It recognises that that in the modern world one of the highest expenditure for any government is the cost of developing and maintaining infrastructure.

This course is designed to enhance the ability of managers in making better economical and financial decisions for the construction and maintenance of engineering infrastructure assets. Such decisions, if properly made, will mean better use of resources in obtaining optimum performance and longevity of engineering assets. This course addresses this requirement by taking a strategic view of asset management; discussing the principles of the asset management process and asset management economics; and applying the principles to the asset management process.

Specifically, this course discusses the asset management context as discussed in section 2 of this paper and establishes the need for the asset manager to optimise the requirements of the main stakeholder groups – owner/manager, user (where the user is not the owner), local external community and wider community. Building on this foundation, it then discusses the strategic asset management framework including the asset life cycle and its issues, performance requirements and deterioration. Following a module on asset management economics, the course then applies the principles in asset operations, renewal and maintenance; integrated asset management including investment decisions for both individual assets and asset network; and asset management systems. It concludes with a discussion of future issues in asset management, such as developments in asset management systems, data collection, sustainability and globalisation and management practices.

The course aims to develop a multi-skilled strategic asset manager who is conscious of sustainability and globalisation issues and able to interact with a range of people from many facets of society [15}. A further course, Whole of Life Facilities Management, focusing on the tactical and operational process of asset operation and maintenance, is in the process of development.

7.2 Technological Impact and its Management

Technological Impact and its Management is based on the understanding that that the world of today is one in which there is dynamic change in the creation and development of technology. Therefore, it is necessary for managers of technology to understand the impact of technological development and the ways in which it can affect the society in which we live and the controls necessary to achieve a positive impact on mankind.

This course reviews current technological development, evaluates its impact on the world on we live in, examines the relationship between modern society and technological development, and discusses the role of technological development on wealth creation and business. It also assesses the overall social need to manage such development as well as technology creation, transfer and exploitation. While it does not specifically focus on asset management, it introduces the asset manager to the principles of strategically and innovatively managing technological development in a world that demands increasing social and environmental responsibility in the technological management process.

7.3 Management of Technological Risk

As previously discussed, risk management is a priority area for the strategic asset manager. It is particularly important for the asset management leader who needs to consider a range of risks when managing both single assets and asset networks. This course concentrates on the management of technological risk with respect to both taking advantage of opportunities and minimising the effect of negative impacts. There is a financial incentive, as well as community and corporate responsibility, to achieve the best results from an asset management point of view and to improve reliability. Increasingly, there are statutory requirements to address reliability and safety issues explicitly. In addition, there may be opportunities to manage risks to the benefit of the organisation. Consequently, strategic asset managers need to be aware of the tools and techniques used for the identification, assessment and treatment of technological risks.

In the first part of the Management of Technological Risk course, risk management is discussed in the context of the Australian/New Zealand Standard for Risk Management AS/NZS 4360:2004. In the second part of the course, learners apply risk management principles to technological and engineering projects and processes, and discuss the future of risk management, which is an important tool in evaluating the likely benefits and costs of alternative approaches in developing a sustainable future. Of particular interest to asset managers are sections on risk management in project management; health safety and environmental risks and their management; and a detailed discussion on risk management in asset management, which is based on the principles similar to those of the International Infrastructure Management Manual described in section 3 above.

7.4 Technological Innovation and Development

Technological Innovation and Development builds on Technological Impact and Its Management, and is designed to enable learners to understand the commercial research and development process; appraise the factors which impact on innovation and its development from a managerial point of view; understand and apply the organisational, social and environmental factors which impact on product and process innovation; appreciate and manage the relevant risks; and understand key issues such as intellectual property management and commercialisation. It begins with understanding the concept of innovation and the management of research and development processes, and discusses key issues such as technical risk, intellectual property management, commercial risk and social impact, and the technology transfer process.

From a strategic asset management point of view, this course develops the skills in the asset manager of not only being creative in the asset management process, but also to seek and adopt advances in technology to optimise the life cycle planning, development and ongoing operation and maintenance of the assets for which the manager is responsible.

7.5 Technology Management Practice

Technology Management Practice covers a range of engineering management topics. In particular, it covers the principles of management, project and works management; engineering economics, probability and statistics, law (as related to engineering), contracts and project delivery, accounting and personnel. It complements specialised business management courses taken as part of the Master of Technology Management through teaching specialised engineering aspects of the management process. For example, the project and works management section takes the learner through the basic principles of good project management; then introduces the principles of planning, estimating and scheduling; and discusses procurement, quality management, plant and equipment management, and office management. The contracts module deals with tendering and contract management, and will in future deal with modern forms of project delivery such as public private partnerships and relationship contracting.

This course provides the tools to enable all engineers, including asset managers, effectively manage the engineering function.

7.6 Summary

While this program does not specifically target one particular discipline of the management of technology, it has specific courses designed for the strategic asset manager and a number of complementary courses that use a similar theme of combining technological, economic, social and environmental issues in a strategic framework aimed at developing the technology leader. From the specific asset management viewpoint, it aims to provide courses assist that manager to better implement whole of life strategic asset management, manage in a sustainable manner, manage technological risks, be innovative and apply engineering management principles to the asset management function.

8 DEVELOPMENT OF THE PROGRAM

8.1 Considerations in Development

Programs like the Master of Technology Management are designed to meet the needs of both potential learners and industry. It is expected that most learners will already be practising professionals, located in both Australia and overseas, many of whom will be working in organisations that are dynamically changing and will have different levels of technological maturity. While most students will be engineers and technologists, some (including some asset managers) may have other basic professions. Hence the courses in this program have been written with a view to their understanding by a range of professionals.

Learners in such a study program are likely to have differing needs, and come from a range of organisations. These organisations, and the people in them, will have differing understandings of the concepts in this program, and will also have differing geographic and cultural backgrounds. As an example, engineering asset management is likely to be quite different for a person in a developed country whose main concern is to ensure that an expected standard of service from a particular asset (such as a four lane asphalt surfaced road) is met, and a person in a less developed country, whose main concern might be justifying the construction of a road to a reasonable standard for its expected traffic and community needs. Course material therefore needs to meet both sets of requirements.

Similarly, requirements and expectations may differ across geographical and political regions. Therefore, course development has needed to consider both Australian and overseas practice. For example, Management of Technological Risk is primarily based on the Australian/New Zealand Standard for Risk Management. However, the course developer has had to appreciate that there are also other equally valid risk management methodologies which need to be considered. For example, see Chapman and Ward [16].

Finally, learners are likely to have different levels of access to the courses. In Australia urban centres, for example, most learners will have access to fast Internet access, and therefore they are likely to both expect and be provided with interactive on-line teaching materials. People in remote areas of Australia may well have minimal Internet access, and those in remote parts of the world could have little or no access to the Internet. Assessment (such as assignments) from students in some more remote regions of the world may need to allow for good hand-written assignments as well as the normal typed assignment expected of a person who has ready access to computers, and may need to allow for slower postage from some locations. Therefore, delivery of the course delivery needs to cater for all of these needs and expectations. This is particularly important for asset managers, many of whom will be managing assets in a range of geographical locations, with differing levels of equipment, expertise and access to labour and equipment.

Therefore, when developing the courses in the program, it has been important to be aware of the differing academic and professional backgrounds of learners, their needs and expectations and those of their employers, and the best way in which they can receive course materials and interact with lecturers.

8.2 Challenges in Developing the Courses

Because of the range of student interests and backgrounds undertaking programs like the Master of Technology Management, it has been necessary to develop courses so that they provide sufficient material in the course material to give basic information, while maintaining a strong focus on a balanced management approach. This needs to be balanced by providing sufficient challenge for people who want to learn a topic in depth. There is also a need to meet the requirements of people with differing levels of mathematical background. For example, people who have a bachelor level degree in engineering technology are likely to have less training in formal mathematics than people with a four year engineering degree. Asset managers can come from both groups, and also from people with business and other backgrounds with a lower level of mathematical skill than fully qualified engineers. Therefore, the level of mathematics in the courses in this program been kept to a minimum, subject to ensuring that necessary standards are maintained.

This requirement has been met by guiding learners through the necessary basic process while giving them access to learn the necessary basic quantitative skills (such as the use of statistics). At the same time, the needs of advanced learners have to be considered. Therefore, the courses have been designed to cover the necessary background material at outline level only, and then move fairly quickly to applications. Those learners who need to know the theory in more detail have been directed to appropriate books and websites..

This type of approach has also been used in other aspects of this course, such as the writing of English expression.

Developing courses to meet the needs of diverse learners is best illustrated by the example of developing Asset Management in an Engineering Environment, which is relevant to the needs of the asset manager. Thus, it was necessary to decide the asset management context (as discussed in section 2 of this paper), assess what material should be included in the course, identify the likely profile of potential learners, and decide how course material should be delivered and assessed.

A particular challenge was to decide on the way in which the course should be organised and presented to meet course objectives and to challenge learners. Thus, while the thrust of the course is on the strategic aspects of managing engineering and technological assets, operational aspects of asset management have also been addressed, both to enure that they are fully considered and to lay the platform for a future facilities and maintenance management course that is expected to cover tactical and operational management and maintenance of assets in more detail. In addition, material relating to sustainable development, whole of life focus, risk management, innovation and technological management has been included, at least to an extent that it links to other courses in the program.

A modular design has been employed, both for ease of study and to allow selected modules to be offered as future short courses suitable for possible industry training purposes. Therefore, the first modules that students study deal with theoretical issues, while later modules in the course focus on application of these principles. Current and emerging issues like sustainability, risk management and optimising multiple asset management goals are addressed throughout the course. The course uses guided research – reflection, research into key issues (supplemented by a series of questions to prompt the research process), development of opinions and problem solving. Use is made of on-line research to supplement written material. As with most courses in this program, a textbook is used to supplement study resources prepared by university staff.

To assist learners with mastering the amount of material in the course, it has a number of activities that are classified into differing ranges of importance. The first level is essential tasks, which provide basic knowledge of the course material. Tasks classified as “important” are designed to provide further understanding. They include reading and understanding explanatory course or text material, or undertaking a reading or exercise that aids understanding of the principles being explained. Learners may also optionally further research course material (“background tasks”) or undertake in-depth research to understand it in more depth (“other tasks”). Material in essential and important tasks is examinable and is accordingly structured to enable learners with minimal mathematical background to succeed in the course

9 IMPLEMENTATION OF THE STUDY COURSES

The Master of Technology Management program is in its third year of offer. The first courses, offered in Semester 1 of 2004, were Asset Management in an Engineering Environment and Technological Impact and its Management. These were followed in the second semester of 2004 by Management of Technological Risk. A further three courses were added in 2005. Students enrolling for these courses are from diverse academic backgrounds that include engineering, engineering technology, business administration, technology management and project management.

All course material is provided in written paper form. While there can be some variation, this usually consists of an introductory book, a study book, and a book of readings. The introductory book contains information about the course, the study book contains the course material, and the book of readings a number of readings to aid understanding.

Written learning material has been enhanced with on-line discussion using the WebCT on-line teaching tool. This allows online discussion, notices, and posting of supplementary course material on the web for those with web access (the majority of students). As systems and communications continue to improve, online learning facilities are being enhanced with discussions, quizzes and other interaction with students.

There have been many studies in the literature that support on-line teaching and learning. For example, Macdonald [17] reported on the use of online interactivity in assignment development and feedback in Britain's Open University; Deeks [16] discussed the use of web-based assignments for structural analysis; and Ferris [19] used web-based teaching for management engineering management. However, it is also desirable to be able to meet the requirements of learners in remote locations, and therefore it is expected that there will be a paper based system of study materials for some time.

Because the courses have been offered for a short time only and many have limited enrolment at this early stage, it is too early for statistically valid student feedback. However, comments received have been positive, and the program appears to be meeting student requirements.

10 THE CHALLENGES AHEAD

Educating strategic asset manager leaders requires a combination of understanding technological and economic asset management, the management of sustainability, risk management and innovation management within an overall technological or engineering management framework. Programs like the Master of Technology Management have been developed in an attempt to meet this requirement by endeavouring to combine business and engineering skills into an integrated package aimed at the innovative management of today's and tomorrow's technology assets and organisations in a changing world with changing demands.

Because of its need to be a dynamic program delivered by distance education to motivated professionals, this program has needed a tight focus, suitability for learners with a range of backgrounds and experience, and development within a tight timeframe. As the requirements of stakeholders change, new materials and methods emerge, better systems are developed, and more is understood about asset management, it is important to develop innovative asset management leaders who are strategic thinkers. This requires continuous updating and upgrading of the courses in this program and the program itself.

A significant component of the course adaptation process will be in meeting the needs of world wide approaches and demands in asset management. This will require better understanding and appreciation of international requirements, and of the diverse expectations of many communities across the world, each with differing social, environmental and economic values and needs. Incorporation of this information into the course delivery process is expected to improve the relevance of course material to learners in local communities and at the same time improve understanding of global issues by all learners. Recent feedback from this process is being incorporated in modification to this program and incorporation of some of its courses in other postgraduate engineering programs offered by the University.

One of the key challenges ahead within the whole engineering profession will be the extent to which a traditional engineering undergraduate program, with its strong emphasis on technical training, will be able to produce the graduate who can effectively manage engineering and technological assets. Courses like the Master of Technology Management can help to fulfil this need by offering a diverse postgraduate technology management education that considers current and emerging issues in strategic asset management, with a view to developing leaders in this field who have a combination of business and technological expertise, as well as a solid grounding in current and emerging issues such as sustainable development and risk management..

A future challenge is likely to be the development of industry based programs as well as the individual programs that are primarily currently offered for course work master degrees. In this way, courses like Asset Management in an Engineering Environment are likely to develop to meet a range of specific industry and community based educational and training needs. This will mean that not only should individuals attain the skills necessary for strategic asset and other management, but also that these skills are expected to be transferred to industry and the wider community.

11 CONCLUSION

While there are limitations in the management education of strategic asset management leaders at the undergraduate level because of the need for students at this level to focus strongly on technical issues rather than the broader issues associated with strategic lifecycle asset management, postgraduate education provides the opportunity to develop the broader skills necessary. Through combining business and technological education, and targeting a range of modern asset management requirements such as sustainability, risk management and innovation, postgraduate engineering management programs like the Master of Technology Management have the potential to develop and empower strategic asset managers in the execution of their duties.

Such programs are considered important in the process of educating current and future strategic asset managers in the sustainable management of engineering assets in a diverse, ever changing and increasingly global environment.

While there are a number of challenges to be overcome, education programs of his type aim to provide the opportunity for such managers obtain a level of postgraduate technological management education that enables them to posses the skills required for them to be leaders both now and in the future.

Ring Road, University of Newcastle, Callaghan 2308.

Abstract: There is considerable diversity of practice in High Voltage (HV) plant asset management throughout Australia in terms of geography and industry. This paper reviews the factors that make for good management of high voltage assets with reference to sources such as CIGRE, IEEE, IEC and Australian Standards. Covered are the basics of high voltage plant asset management and the applicability of condition assessment methods. This paper aims to present a clear and rational framework for plant owners to enable them to rate and if necessary to augment their approach to the management of high voltage assets. The content draws on the results of surveys, Standards and the experience of expert practitioners at Connell Wagner's Advanced Technology Centre in Newcastle. The group has been operating for over 48 years in the area of High Voltage plant condition assessment and testing and has been at the forefront of many trends in this field.

Key Words: High Voltage Testing, Insulation Resistance, Polarisation Index, Dielectric Dissipation Factor, Partial Discharge, Dielectric Spectroscopy, Frequency Response Analysis

1 THE AUSTRALIAN CONTEXT

There is a wide diversity of practice in High Voltage Asset Management in terms of geography and industry and those who provide guidance in relation to its management are equally diverse. There are a number of factors at work in the Australian contexts that are having an impact on the way asset management is being carried out. These factors are the disaggregation of the Government owned utilities, the ageing of the plant, the inevitable trend towards higher voltage plants and skills shortages.

In the electricity utility sector with the disaggregation of Government owned centres of expertise the task of asset owners has become more difficult. These centres were an independent source of expertise that provided industry with a reliable and impartial source of information as well as providing well-trained experts able to provide hands on assistance.

The advent of the electricity market has opened up opportunities for investors to come into the market and new smaller and less capital intensive plants are playing a role in the market as never before. These newer plants have been designed with an eye on initial capital cost resulting in very little if any capacity in redundant systems, every item is critical and detailed knowledge of its condition is both vital and a strategic advantage.

As Australian industry seeks greater prosperity the need to increase output is an ever present concern. This pushes plants that were happily working at 415V into the realm where 3.3kV motors and above are now being used to provide more power for the work that has to be performed. The skill set of Asset Managers must be expanded to meet the demands of the plant working at these higher voltage levels and this paper will lay the groundwork for a working understanding.

Whilst many Asset Managers have had experience with switchyards and high voltage switchgear and are aware of their requirements, in general the speed with which experience is being lost is not matching that at which it is being obtained. Thus today more than ever there is a growing need to provide soundly based guidance on aspects of high voltage asset management.

This paper will set out the fundamentals to allow those charged with looking after high voltage plant to achieve the greatest availability of the plant and facilitate sound engineering based asset management throughout the life of the plant.

2 ASSET MANAGEMENT PLANS AND STRATEGIES

Asset Management means different things to different people. Generally speaking Asset Management is the process of ensuring an organisation's assets perform to support the organisation's mission and satisfy the expectations of the various stakeholders in the organisation. Without an effective Asset Management Plan the enterprise cannot take advantage of synergies that exist between different asset classes and cannot guarantee the timely, consistent and effective management of its assets.

There is no one best model for the effective management of the assets of an organisation as the requirements depend very much upon the organisation's culture and external environment. Connell Wagner has found a number of common traits in successful Asset Management systems around the world. These traits include:

- the asset management documentation is well structured and is derived from organisational objectives
- the system is integrated with management systems including quality, occupational health and safety and environmental management systems
- personnel at all levels in the operations and maintenance area of the organisation are involved in its development
- the methodologies are developed through structured techniques such as RCM, or through guidance from technical organisations such as CIGRE's technique for Service Aged Insulation [1] for high voltage equipment
- maintenance systems are reliability based with mature condition monitoring and life assessment technologies
- staff are appropriately trained
- systems include management review of asset management outcomes such as failure, condition and maintenance information
- performance measures are well developed to continually improve the system

The structure of Asset Management systems will vary according to corporate requirements but a commonly used structure includes the higher level organisational Asset Management Plan, a more detailed Strategy for the asset class and individual Work Flow Instructions or Standard Operating Practices for each type of plant.

3 HIGH VOLTAGE PLANT AGEING AND FAILURE

The ageing and failure mechanisms of high voltage assets are many. It is essential for the asset manager to ensure that all possible ageing and failure mechanisms are reviewed including mechanical, thermal, chemical and environmental as well as the usual electrical modes. Typical ageing mechanisms of high voltage assets include:

- Electrical
  - Overstressing of insulating system by external stresses or failure of voltage grading systems
  - Partial discharge due to insulating system overstressing or contamination
  - Partial discharge due to delamination of composite insulating systems
  - Thermal instability of the dielectric in the insulating system
  - Tracking across dielectric surfaces
  - Short circuits between windings and winding components
- Mechanical
  - Mechanical failure due to forces from short circuit currents and vibration
  - Mechanical failure of insulating systems due to ageing
  - Failure of mechanical components due to cycling, creep and fatigue
  - Failure due to vibration or resonance
  - Failure of rotating component bearings
  - Failure of lubricating systems
- Thermal
  - Overheating of contacts/ connections/ joints
  - Thermal ageing of components
  - Failure of cooling systems
  - Ineffective maintenance of cooling system efficiencies
  - Ineffective maintenance of cooling medium condition (eg insulating oil in transformers)
- Environmental / Chemical
  - Oxidation
  - Hydrolysis
  - Corrosion
  - Contamination by ageing products including acids and ozone

From these failure modes, the maintenance and testing methods can be developed using a structured approach such as that outline in CIGRE's document on Service Aged Insulation [1]. This process describes the method used to develop preventive strategies from an analysis of dominant failure modes, ageing processes, influencing factors and available diagnostic techniques. One should never forget that improper maintenance would be a multiplier on any natural process of degradation.

4 LIFE CYCLE

The management of assets is improved if the asset management system takes into account all of the stages and cycles that the plant will experience through its life. These well defined stages each with their own specific risk benefit from particular attention and represent a junction at which it is judicious to qualify the assets' condition. If this is not performed at these stages then a valuable and relatively inexpensive opportunity is lost and no further insight into the risk is obtained. If these stages coincide with contractual boundaries then there is a transfer of risk from one party to another.

These stages are listed below,

- Specification
- Design
- Construction
- Factory Testing
- Delivery
- Installation
- Commissioning
- Acceptance
- Operation
- Maintenance
- Refurbishment/Life Extension

At any one of these stages the decisions that are made or events that occur may in the end have a profound impact on the life expectancy of the plant. Plant that would otherwise readily last for 30 years or longer may be reduced to scrap in a matter of weeks or months due to seemingly small and inconsequential acts or omissions.

Apart from the first item, the next seven items can be covered off by appropriate contractual mechanisms and ensuring that the service provider is appropriately qualified and experienced to perform the work. A most important element in plant life management is the effective management of the vendor's warranty. It is vital that appropriate plant tests are included in the contract with reference to Australian and International Standards appropriate to the plant. Allowing the contractor to specify its own testing standard and pass/fail criteria is negligent.

There must be an enforceable mechanism that assures that the manufactured, delivered, installed and commissioned plant not only meets the immediate requirements but will last well beyond the warranty period and be free from defects that will cause premature failure. Contracts commonly require that products are supplied free from defects, yet do not then specify appropriate tests, Standards and pass/fail criteria that can demonstrate that this is the case. A test prior to warranty expiration is the last opportunity to ensure that the buyer is not burdened with the supplier's risk.

After being placed into service the asset needs to be monitored with a regime appropriate to the asset's class, production impact and safety issues. If not before, then certainly at major outages, tests should be arranged to determine the state of the plant, gauge the requirement for maintenance and determine the stage of degradation or ageing.

It can be stated that not withstanding random failure or overload, that the vast majority of plant that has,

- been properly acceptance tested, as well as tested before expiration of warranty,
- has had applied a monitoring and testing program appropriate to the asset and its environment, and
- is operated within its rating,

should not fail from electrical causes without sufficient warning to enable the safe and timely removal of the plant from service. In fact such a regime when applied to HV motors with epoxy mica insulation would often give many months or years of notice for the vast majority of failure modes.

One should always consider plant that is not immediately required for service and is placed into storage as is often the case with rewound motors in a production constrained plant. The asset may require some degree of monitoring whilst in storage but if it is placed into storage without acceptance testing the owner is taking on all of the risks associated with the plant and absolving the vendor of any practical form of liability. The cost of doing this can be considerable if the plant value or down time cost is high.

It is worth remembering that all products come with defects, whether the defect impacts on plant life is an open question. The only tools available to identify the risk of defects that will greatly reduce plant life are initially contractual and then through condition monitoring throughout the life of the plant.

5 HIGH VOLTAGE CONDITION ASSESSMENT TECHNIQUES

Test and assessment methods are varied in the nature of equipment, required user expertise, ease with which results can be interpreted and diagnostic value. Below is an overview of some of the more common tests associated with high voltage plant condition assessment and testing. It is important that any person who is to effectively maintain a high voltage asset gains some understanding of the nature and effects of partial discharge of which an overview is included below.

It is noteworthy that high voltage plant is often tested above its normal operating level in accordance with the relevant Standards and guidelines and that this is a normal condition even for routine tests. The purpose of HV testing methods is to expose signs of degradation before they become active under operating conditions where they can lead to catastrophic failure. The desire to test at voltages significantly less, whilst generally well intentioned is not motivated by the science, but rather concerns to do with the potential for failure of the plant under test, lack of appropriate test equipment or the economics in bringing to bear the equipment required to do the test. It can be stated that people experienced in HV testing go about their business in a cautious manner, looking for signs of impending failure to prevent plant damage.

5.1 Insulation Resistance (IR)/ Polarisation Index (PI)

Measure the DC resistance of insulation, typically to earth. Used to determine the basic state of insulation with the higher the value the better, very temperature and humidity dependant. Will show up contamination and moisture ingress and low resistance paths. Polarisation Index is the ratio of the 10 minute to the 1 minute IR. It is an additional measure of moisture and contamination, values above about 2.0 are generally acceptable. Depending on the nature of the plant low values can have different implications. The test is at DC thus electric stress is not distributed throughout the insulation with the profile it would have under AC conditions. Depending on the voltage levels to be used, this may impact on interpreting or determine how and to what level the test is performed.

5.2 DC Ramp Test

A DC voltage is applied to the insulation relative to earth and is raised very slowly whilst noting the apparent resistance, a change shows up flaws in the insulation. This test is generally used to determine ground wall insulation properties of windings in motors and generators. Tends not to be used if a fully rated AC testing capability is available.

5.3 Winding Resistance / Circuit Resistance

Basic measure of the continuity and bulk DC resistance of the winding. Requires temperature correction and 4 wire measurements. Provides phase balance check (<1%).

5.4 Winding Ratio

It is a requirement of the Standards that the measured ratios are within 0.5% of the values indicated on the nameplate. This is a requirement mainly for operational reasons and not related to condition assessment although a change in ratio from factory values would most likely signal a fault. The test will find errors in connections, particularly after On-Load Tap Changer maintenance, which is a high risk time.

5.5 Dielectric Dissipation Factor (DDF)

Measures the AC loss when voltage across the insulation is raised. The characteristic of the relation between DDF and voltage is a good indicator of the condition of the bulk insulation. It will detect voids and corona, which can point to problems in areas such as,

- Electric stress levels and clearances
- Contamination of windings and bushings
- Delamination of windings
- Burning of insulation or other such damage
- Thermal Runaway
- Ageing of the bulk insulation system

In general the higher the value of DDF for the same voltage level, material and temperature, the poorer the condition of the insulation. The measurement is temperature dependant and very susceptible to surface contamination and humidity. The test is also very good at indicating thermal ageing and thermal runaway in insulation. Thermal runaway is a condition where insulation locally develops a negative temperature coefficient and the increased heat that it develops then further reduces the resistance, which in turn increases current flow in the insulation and so on until the insulation is destroyed through overheating initially and then possibly a fault. This condition generally affects certain paper-oil insulated systems such as those found in transformer bushings and instrumentation transformers.

In good insulation the voltage level at which the slope of the curve of DDF vs voltage changes significantly upward (the “knee” voltage) should be at as high above normal operating voltages as possible. As the plant ages this knee voltage reduces until there is significant DDF even at operating voltages. At this time the asset is often considered to be at the end of its economic life.

5.6 Capacitance

The capacitance of an object is a fundamental quantity and variations in capacitance with voltage are small in good insulation. This is generally measured at the same time as the DDF. A departure from the known voltage coefficient or a change in the absolute value of the capacitance can be indicative of insulation damage or shorted elements.

5.7 Partial Discharge Testing (PD)

Partial discharge (PD) testing is by far the most insightful method of determining the condition of a degrading insulation system. The measurement works by detecting the small electric current pulses that occur as part of the insulation degradation process. A partial discharge is an electrical discharge that does not bridge the insulation system. When the PD occurs in air it is termed corona. These discharges are transient breakdowns that allow charge to migrate from one location to another in a manner that does not occur at lower voltage levels. All practical materials will undergo partial discharge at some voltage and then as the voltage is increased sufficiently the electric stress will be high enough to flashover the insulation and cause a solid fault.

PD measurements can reveal the,number of insulation degrading voids present

- size of individual voids in energy terms
- distribution of voids within the insulation
- voltage and conditions at which the voids become active
- whether the discharges are to earth, air, oil, floating objects or within the insulation material
- state of degradation of the insulation system
- bar bounce
- clearance issues

The absence of PD at test voltages is the strongest indication that the insulation system is in good condition and is not suffering degradation from the eroding action of partial discharges (at the time of measurement). These measurements are made on all types of insulation systems including insulating materials, power and instrumentation transformers, motors, motor coils and assemblies of coils. Healthy insulation generally exhibits no or low PD at or above its normal operating voltage in accordance with its insulation type. In a PD test the source voltage is raised to a point where PD activity starts (inception) and is then lowered until it ceases (extinction). Similarly to DDF, when the insulation is in good condition both inception and extinction levels are well above operating voltages. In such circumstances if a transient such as a switching or lightning surge initiates a PD it will quickly extinguish of its own accord and prevent further degradation. As the insulation ages and if a fault develops then inception and extinction voltages track downward until even under normal operating conditions PD's are actively degrading the insulation.

PD tests are the most stochastic of the condition monitoring tests, varying widely both in magnitude and temporally. The same test repeated under the same conditions but separated in time may produce very different results. PD's can require a great deal of experience to interpret even thought the basic principles are easy to understand.

To gain the most benefit from PD testing the test voltage needs to be in excess of the normal operating levels with reference to phase-phase and phase-ground voltages or there is little benefit from the test. If the test is done at operating levels or below it only indicates that the plant is discharging at normal operating voltages which generally means it is near or at the end of its economic life.

The presence of PD is sometimes determined by non-HV test methods such as, radio interference, ultrasonic detection, ozone or other gas measurements. The presence of PD in air will generally result in corrosive ozone and nitric acid, which will corrode structural and insulating elements of the plant, this can lead to either mechanical or electrical failure of those elements. Borescopes can be used to look into internal insulating structures of motors when PD has been identified by test and it is considered prudent to visually inspect the insulation.

5.8 Ultrasonic or Acoustic Emission Detection (UES or AES)

This method can be used to indicate the location of discharges in air or oil. When combined with location methods on transformer tanks, it is commonly used in conjunction with PD measurement equipment to localise the position of a source of strong discharges. On the basis of this location and information from internal drawings a decision about the severity and urgency of the problem may be able to be made. Not recommended for shell type transformers and is less successful for transformers with extensive flux shunts.

5.9 Applied and Induced Tests

These tests are the most basic HV proving test and demonstrate the insulation's ability to withstand the rigours of the service environment from a voltage standpoint. The test involves applying a voltage at a level and for a time prescribed by the Standard, in the indicated configuration. The test is a go/no go test. It can be carried out with a PD test at the same time to add additional diagnostic capability. For transformers this is a routine test.

5.10 Ring Flux Test / Electric Core Imperfection Test (EL CID)

The Ring Flux test is used to test for damage to the laminations of stators. It requires about 80% of operating flux to be induced into the stator and a thermal imaging camera or some other temperature measurement device is used to highlight hot spots in the core laminations. Temperature is a major ageing and risk factor for the winding thus ensuring that there is no excessive temperature rise is important.

The EL CID test is a small signal variation of the Ring Flux test. A special instrument is used that measures the loss associated with a flux of approximately 3%-4% of the rated level. In this case there is no temperature rise of significance to measure. A loss component is measured using a small search coil in contact with the laminations. The measured values are related to predicted temperature rise for the fully fluxed condition.

5.11 Recovery Voltage Measurement (RVM) / Dielectric Spectroscopy (IDA) /Polarisation Depolarisation Analysis (PDA)

These methods which can nominally be regarded as equivalent, are generally used to determine the equivalent paper moisture of transformers and cables [2]. This is an important parameter as moisture in the insulation accelerates ageing. The three methods are different approaches to determining the same parameter. For most practical purposes they can be considered as equivalent although certain approaches have advantages under particular conditions.

5.12 Frequency Response Analysis (FRA)

Generally applied to transformers, FRA is a method of determining the impedance or transfer function between different elements of the windings. This captures the electric and therefore the geometric relationship between physical elements of the windings, core and earth. Any deviation from previous results, not attributable to magnetisation of the core, is indicative of a change in those relationships and possibly a shift in the winding. A loss of winding compression or alignment is generally a precursor to in-service failure of the transformer [3].

5.13 Dissolved Gas Analysis (DGA)

If you own an oil filled power transformer or instrument transformer then by far the best value for money is DGA and the science is mature although with the advent of vegetable based insulating oils new science needs to be developed. The oil in a transformer is a time capsule that not only holds information about the past but also enables prediction of the future. DGA is used to find evidence of all manner of maladies such as,

- arcing
- overheating
- **moisture**
- ageing
- paper or metal involvement in degradation
- need for oil reclamation

The virtue of DGA is its ease in sample gathering compared with the high tech requirements of the laboratory that needs to process the sample. It is easy for plant owners to facilitate their own sampling program and then simply send the sample to the lab by courier.

In looking at DGA one must mention oil moisture content. Moisture in the oil is implicated in many accelerated ageing and degradation mechanisms, it cannot be stressed enough that if you are not looking after oil moisture content you are throwing money away. There is no hard and fast rule but it is generally accepted that 20 ppm is starting to get high, 30ppm requires action.

5.14 Furan Analysis / Degree of Polymerisation (DP)

Furans are compounds released from paper into the transformer oil when the paper is degraded during operation. Given that most power transformers contain a substantial amount of paper in their HV elements then the condition of the paper is an important concern. The Furans are measured because they are a non-invasive way of estimating the Degree of Polymerisation (DP) of the paper. The DP is an average measure of cellulose chain length that makes up the paper. This average length is an important parameter in estimating the mechanical properties of the paper. Paper with a DP of less than about 200 has no mechanical strength and will crumble away. Thus as the paper ages the equivalent DP will track from values close to 1000 downward. The rate at which this occurs depends on the operating conditions and the success in keeping up preventative maintenance practices such as keeping oil moisture low. The relation between Furans and DP as well as the notion of bringing a complex variation in paper properties throughout the transformer down to one number is an approximation, the key to using the information is the trend in values over time [2].

5.15 Impulse Tests

Impulses to simulate lighting and switching surges are applied to the plant to determine if the insulation system can withstand such conditions. Due to the nature of the test equipment, impulse tests are generally carried out in a laboratory or at the OEM's test facility.

5.16 Thermography

This is not a test as such but a good component of any HV plant asset management strategy. Used primarily to discover hot spots, it highlights poor connections or plant that is thermally abnormal which can alert to control problems or accelerated ageing problems.

5.17 Visual Inspection

This low tech and hands on approach to asset management is an important part of any strategy. Many forms of degradation or problems that are sure to lead to degradation or failure can be identified through simple visual inspection. Locating of leaks, low oil levels, damaged components, water ingress, noisy or abnormally sounding components are just some of the potential finds.

The basics are summarised in relation to their plant applicability in the table below.

	IR	PI	WR /	DC	DDF	Cap	Ratio	PD	UES	Applied	Induced	Ring / Flux	RVM / IDA / PDA	FRA	DGA	Furan	RSO	Impedan
Motors												X						
Generators												X						
Power Transformers													X					
Instrument Transformers													X					
Cables													X

6 CONTINUOUS ON-LINE MONITORING SYSTEMS

Continuous On-Line Monitoring Systems (COLMS) have been around in one form or another since very early times, e.g. over-current circuit breakers and protection relays. In these forms they have proven to be very reliable and effective. COLMS as applied to monitoring failure mechanisms in the insulation of high voltage electrical systems are far less reliable and effective then their protection counterparts. This stems from the fact that the protection systems work on mathematically well understood and readily verifiable principles. The insulation monitoring systems are not amenable to the same robust detection methods and are also often very adversely affected by interference. In insulation monitoring applications often a breakout from a trend is as important as the absolute value.

COLMS are a great benefit in certain circumstances in particular when there is a need to use the full economic life of a plant when a known degradation or failure mode is active. They almost invariably suffer from a lower level of reliability than the plant that they are monitoring and thus can be an expensive alternative to time based monitoring systems in many cases in particular during the early stages of a plant's life. Monitors that are improperly applied or operated can at best result in considerable expense in unnecessary additional testing of the plant, at worst they can fail to perform their basic task of monitoring and lead to a false sense of security putting at risk the plant and personnel.

Given the expense of COLMS and the relatively poor reliability the choice of an on-line system for high-voltage plant should be made when plant is critical or has a known defect likely to lead to catastrophic failure. If appropriate steps were taken from contract to acceptance testing and then condition monitoring there should be ample indication of incipient faults to better support the decision of where to install on-line systems to nurse through a deteriorating plant. It may be cost effective to consider the installation of a provision for a COLMS through the installation of measurement transducers and connection points rather than a complete system.

It is important to understand that on-line systems are not a substitute for HV testing of plant. The failure modes of high voltage insulation systems are subject to considerable non-linear behaviour and early warning of many types of failure modes can only be obtained through high voltage testing at the appropriate test levels as specified in Standards and just to the convenience of the person performing the testing. Acceptance and warranty testing should only be performed though high voltage testing methods. On-line systems can only show the presence of a condition when it is already active at the operating condition of the plant and has limited early warning capability. In motors and generators with epoxy mica insulation systems, there is generally a considerable warning period of months or years of insulation degradation and on-line systems are best applied to the final stages of the process to ensure that the full economic life is obtained and capital is conserved.

Mechanical failures are in a different category and many types can lead to failure or significant loss of life in minutes or hours, eg, bearing or lubrication failure. The proven methods of vibration and temperature are invaluable in these instances. Of course there is always the need to have trained staff that can act rationally on sensor information to preserve the plant and ensure safety.

7 STANDARDS

The paper has discussed the need for reliance on Standards, the value of which cannot be understated. Standards come about through a process that seeks input from OEM's, industry practitioners and academic circles to reach a majority agreed position on those matters that the Standard seeks to address. As it is the result of a committee process the Standard generally represents an average opinion and depending on the way that the Standards Committee is formulated may result in a bias in the Standard to the views of the dominant group. OEM's have always found it in their interests to be well represented on Standard's Committee's to ensure that impractical requirements do not become part of the Standard. Thus a Standard can be considered to be the distilled wisdom of various interested and authoritative parties on what levels of performance and test results should be able to be met and represent good product.

With this view in mind, the Standard should be the minimum acceptable level. An offer of less than this is an offer to transfer risk from the seller to the buyer. Whilst many failures to meet Standards can be accommodated by extended warranties care should be taken to account for the total cost of plant failure, reduced life and increased monitoring costs. This can only occur if there is an understanding of the nature of high voltage insulation systems, their failure mechanisms and monitoring.

Failure to specify conformance to Standards for products at the contractual stage is a major risk management failure for a business. The only context in which this should occur is when there has been a rational assessment of the additional costs of compliance with Standards, taking into account availability of alternatives, expected cost associated with failure and failure frequency. Otherwise there is no accounting for risk. How many times has a venture of considerable economic magnitude been brought to a halt due to the failure of an element sourced at the lowest quote?

With reference to High Voltage plant items the following is a partial list of Standards that can be referenced,

Rotating Electrical Machines	AS1359, IEC60034, IEC34, IEEE 432, IEEE 56
HV Test Techniques	AS1931, IEC60060
Partial Discharge Measurement	AS60270, IEC60270
Power Transformers	AS2374
Switchgear	AS2560
Bushings	AS1265
Voltage Transformer	AS1243
Current Transformer	AS1675
Cables	AS1429
Shunt Capacitors	AS2897

These Standards often detail factory and acceptance tests that enable vendors to demonstrate the quality of their products as well as often indicating how to condition monitor many aspects of the plant. Plant that can meet the requirements set out in Standards will start service in a more robust condition than plant that does not do so and will generally have a greatly reduced risk of premature failure.

8 SUMMARY

High Voltage Plant assets have their own requirements for effective management that are above and apart from those of their low voltage counterparts. Any enterprise that follows the process of establishing an Asset Management Plan (AMP) which details and addresses these needs within the context of the enterprise will attain the best possible benefits in relation to their business. The AMP will be most effective if it addresses all the stages of the asset's life and makes use of synergies and opportunities to reduce costs and gain insight into plant condition.

The Asset Management Plan will be most effective if it is driven from senior management down and involves all the key maintenance stakeholders in its development. In operation it should be updated and reviewed at regular intervals to ensure that it is still relevant given changes in the business environment and plant.

There may be economic or practical constraints as to the scale and nature of the Asset Management Strategy. Nonetheless these compromises are best made in the context of a thorough understanding of the requirements of the particular plant. The availability of capable and experienced condition assessment practitioners will also have a significant bearing on what can be done, its frequency and cost.

The paper shows that there are a wide variety of methods available to gain insight into the condition of high voltage plant. What the tests do and their applicability for various plant types is covered. The value of Standards in relation to guaranteeing quality and the need to specify Standards and pass/fail criteria in contracts was emphasised. The benefits and difficulties associated with continuous on-line monitoring systems was covered and a view expressed that they are in general useful but that cost, ease of interpretation and their basic reliability were issues to be considered.

MODELLING AND SIMULATION - A PROFITABLE TOOL FOR ALL PHASES OF THE LIFECYCLE

Mark D Mackenzie [a] and Ryan Briggs [b]

[a] IRC, 26 Colin Street, West Perth, Western Australia 6005, Australia.

[b] IRC,26 Colin Street, West Perth, Western Australia 6005, Australia.

Abstract: At any time during the life of an asset, decisions are made that impact its performance and therefore economic return. These decisions are made using a variety of tools and techniques which take into account a whole range of factors concerning the asset. Modelling and simulation is one tool that uses these factors to predict the behaviour of the asset. The benefit of modelling and simulation is that its flexibility allows it to assist in the decision making process through all stages of asset life. This paper uses case studies to illustrate the benefits of using modelling and simulation throughout the life of an asset.

Key Words: Modelling, Simulation, RAM

1 INTRODUCTION

At all stages in the lifecycle of an asset there is a risk that an inappropriate decision will be made which will have a negative impact on the availability of the asset. Using sound engineering theory, lessons learnt and in some cases engineering judgement, the risk can be reduced and the availability of the asset maximised.

Predicting asset availability is probabilistic, based on failure and maintenance rates associated with the systems, subsystems and elements within the asset. An appropriately built simulation model, populated with accurate data, can be used at every stage of the lifecycle to assist in the profitable design, operation and maintenance of the asset.

This paper discusses how modelling and simulation has been used at all stages of the lifecycle. Each stage is supported by a case study to illustrate how substantial cost savings can be made if modelling and simulation is used as a tool to assist in the decision making process

2 MODELLING AND SIMULATION

Simulation refers to a broad collection of methods and applications to mimic the behaviour of real systems, usually on a computer with appropriate software [1]. A set of assumptions are made in order to study how the system works. These assumptions, which usually take the form of mathematical or logical relationships, constitute a model that is used to try and gain some understanding of how the corresponding system behaves [2].

The modelling and simulation referred to in this paper uses the discrete event simulation software Optimise©. This type of modelling is ideally suited for observing the time based behaviour of a system. Individual elements of the system are represented as blocks. The relationship between the blocks is determined by the functional relationships that exist between the elements within a facility. The behaviour of the blocks is represented by the input parameters of the element. Typical input parameters include, but are not limited to Mean Time Between Failure (MTBF), Mean Time to Repair (MTTR), and failure effects or loss of capacity for each element. The input data is obtained from industry data sources or maintenance management systems. When data is not readily available an approximation can be obtained using a workshop attended by Subject Matter Experts (SMEs) who are familiar with the product and its operation. A graphical representation of the simulation process is shown in Figure 2-1.

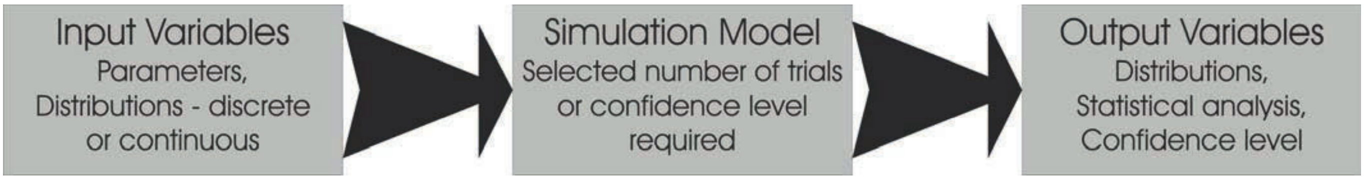

Figure 2-1 The Simulation Process [3]

The objective of modelling and simulation is to predict, with some degree of confidence, what the behaviour of the system (asset) will be under specific conditions. Each model is therefore built to answer a specific question. The answer being sought will determine how the model is built and what input parameters are required.

The reason modelling and simulation is so useful is that this "question" can be answered in a fraction of the time and cost of what it would take if the asset was allowed to operate for the actual time. Once the base model is built analysing different cases or "what if" scenarios is a relatively simple exercise.

Running the model consists of simulating a series of typical lifecycles. Each lifecycle is a realistic representation (based on the defined relationships) of the way the system may perform in operation. The model calculates the simulation results as averages over all the lifecycles. Simulation of multiple lifecycles also allows:

- Prediction of likely variation in performance (standard deviations); and
- Assessment of confidence levels in the predicted average performance.

Sufficient lifecycles are modelled in order that the results converge to statistically stable values.

3 ASSET LIFECYCLE

The life of an asset has been described as "Womb to Tomb" and "Cradle to Grave". What is really meant is that the lifecycle of the asset begins at its conception and finishes at its disposal. At all stages of the lifecycle someone is responsible for the asset and its cost effective management. There are many versions and theories on what constitutes the different phases of the asset lifecycle. The phases are not always easily defined and some phases may overlap. Examples of lifecycle phases include the Integrated Defense Acquisition, Technology, & Logistics Lifecycle Management Framework [4] model which has six lifecycle phases. The Systems Development Lifecycle (SDLC) [5] model has ten lifecycle phases. Blanchard [6] combines several phases to produce the following four lifecycle phases in which there are different opportunities to impact the design and cost effective operation;

The Design and Development phase includes the needs identification; options analysis; market research; maintenance concept; project initiation, and developmental testing. This phase is the most cost effective time to influence design as Figure 3-1 illustrates.

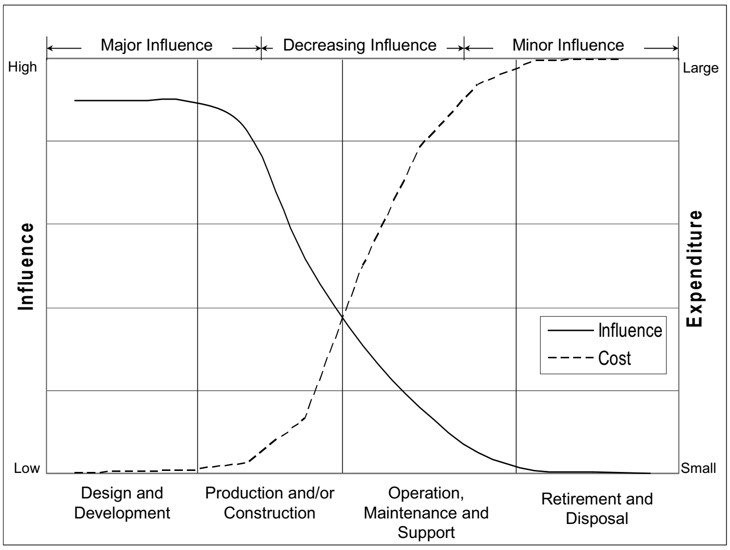

Figure 3-1 Cost and Impact during the Lifecycle Phases of a Asset [7]

The Production and/or Construction phase includes planning, contracting, system development, test and evaluation, technical reviews, maintenance planning, logistic support acquisition, and transition to the Operational Phase: Processes are presented for acquisition of each category of logistics support – support and test equipment, repair and overhaul services, software maintenance, facilities and renovations, drawings, manuals and software documentation, spare parts, personnel and technical training, engineering support.

The Operation, Maintenance & Support phase includes engineering support, operation and maintenance, problem identification and resolution, upgrades and modifications.

The Retirement & Disposal phase includes presenting scenarios and options, surveys and environmental audits, disposal planning and reporting.

Figure 3-1 illustrates the how the cost of influencing design increases and how the influence decreases as the asset life cycle proceeds.

4 COST EFFECTIVENESS OF MODELLING AND SIMULATION

The biggest cost involved in modelling and simulation is constructing the model to accurately represent the asset and populating it with appropriate data. The model may go through a number of iterations as it is refined to more appropriately represent the actual configuration, dependencies and relationships within the system. SMEs are an essential part of this process as their intimate knowledge of the system can be used to ensure the model is a true representation of the system being modelled. Obtaining the data to populate the model is often the single most difficult aspect of modelling the asset. However, once this has been completed the cost of making changes to design, production rates, maintenance philosophies, and life of the asset is easily determined.

A well constructed model that is developed during the design phase of the lifecycle can be developed and used throughout the entire lifecycle, up until and including the disposal phase. This is one reason why future use of the model is a cost effective tool as the majority of the cost is sunk. As updated operating and maintenance data becomes available the model can also be updated and simulations can be performed to determine if the asset is still likely to meet expectations. Making changes to the design, maintenance policy or trying to optimise availability can be done by simply modifying the model or updating the input parameters and running the required number of simulations.

5 DESIGN AND DEVELOPMENT PHASE

5.1 Overview

The design phase of the lifecycle is the time when the greatest cost savings can be made. As seen in Figure 3-1 if changes are required the most cost effective time to make them is early in the lifecycle.

When considering the design of any system or piece of equipment availability (capability) targets should be determined and specified during the design phase. As availability is a function of the asset's reliability and maintainability characteristics these characteristics must also be considered during the design phase. The availability targets will influence the design from the capacity and configuration selection to the maintenance and operating philosophy

If in a system, an item failure results in the total or partial loss of production then redundancy or increased capacity, respectively, may need to be built into the design. Consideration should also be given to the operational environment and the proposed maintenance program as they can have a significant impact on the overall availability, particularly when lengthy mobilisation periods occur prior to commencement of the maintenance activity.

Regardless of the type of equipment being analysed a preliminary design can be modelled and the results used to determine if the system availability is likely to meet the design and operational requirements. If the availability targets are not met after simulation then design changes can be implemented before construction begins. Updated models can be constructed and run in an iterative process until the desired targets are met. The following example illustrates a case study showing how simulation was used to influence the design to produce the most cost effective option.

5.2 Case Study [8]

5.2.1 Introduction

This case involved the creation of an integrated reliability based supply chain model to assist with selection of Liquefied Natural Gas (LNG) storage and fleet requirements. The supply chain model included all facilities and events that may impact on the performance of the LNG supply chain, including subsea production facilities, an offshore platform, an onshore LNG plant, LNG storage and port and shipping operations from the loading bay to various LNG receiving terminals.

A number of options with different combinations of LNG plant size, LNG tanker capacity and delivery locations were considered. The aim of this model was to determine, in terms of 'value' to the project, the 'optimal' LNG storage and fleet configuration for the option selected.

5.2.2 Method

As the project was in conceptual stage of design, project specific P&IDs and PFDs were not available for use. The model was constructed using design building blocks taken from the client's previous projects.

Modelling and simulation was used to investigate the following:

- the optimal shipping fleet configuration for given tanker sizes and delivery destinations;
- the optimal storage capacity at the LNG plant loading facility for each selected fleet configuration;
- the optimal LNG plant capacity; and
- the preferred LNG delivery split and delivery destinations.

Each option was assessed in terms of achieved LNG delivery and 'value' to the project. The 'value' parameter was determined by considering the revenue raised from additional LNG delivery and the costs associated with LNG tanker charter and additional LNG storage over the lifecycle of the project. The optimal solution was the best value result from the scenarios considered. The model is represented graphically in Figure 5-1.

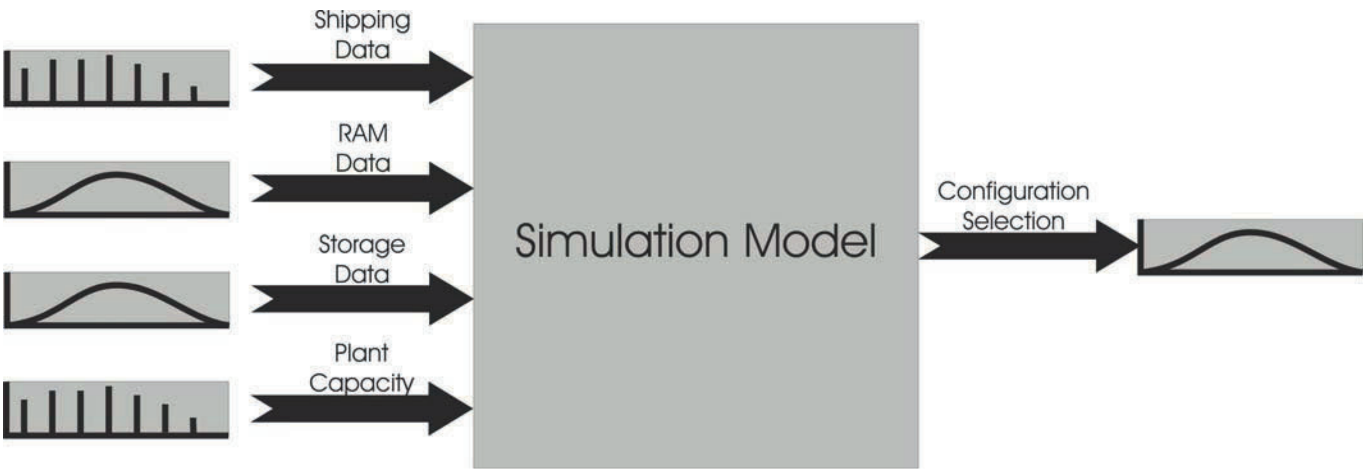

Figure 5-1 Plant and Shipping Model

5.2.3 Results

The study considered several configurations of LNG tanker size, delivery destination, RAM data, storage capacity, plant capacity and delivery split. For each arrangement, the optimal fleet configuration and LNG storage volume was determined. The results of a typical simulation run to determine the optimal LNG storage volume at the LNG plant loading facility for a given LNG plant capacity and a selected fleet configuration and LNG delivery split is shown in Figure 5-2.

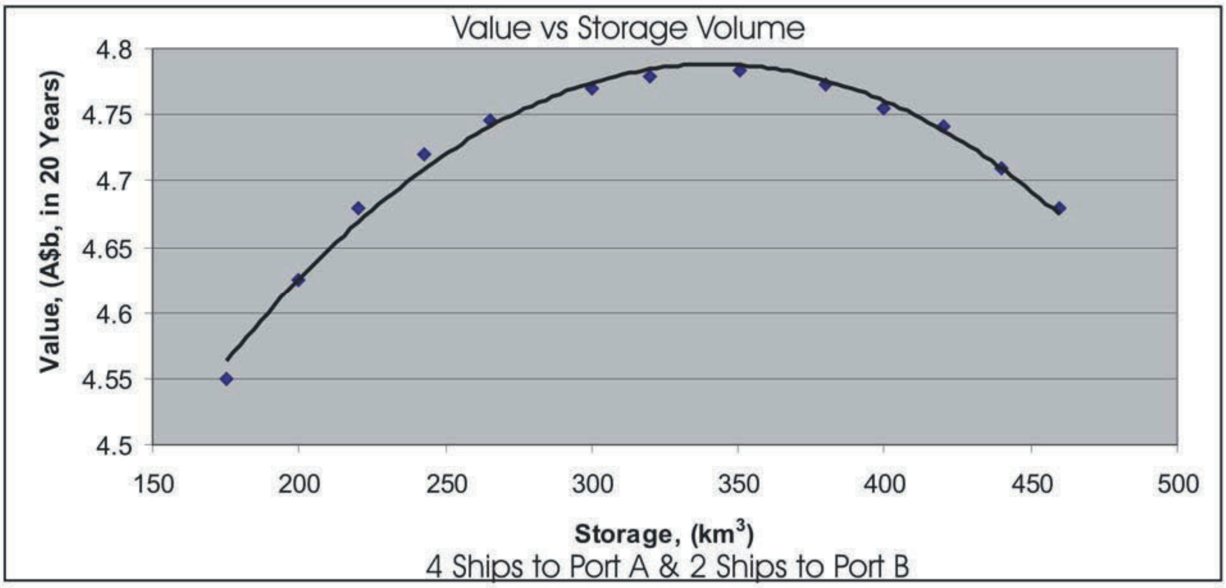

Figure 5-2 Value vs Storage Volume

In this case it can be seen that for the given fleet and plant configuration the "optimal" LNG storage volume is between 300,000 to 320,000m^3. This volume was determined to add the most value to the project I.e: the sale value of the additional LNG delivered with the extra storage volume offset the cost of additional storage. For storage volumes greater than 320,000m^3 the cost of extra storage is not compensated for by the sale of additional LNG.

5.2.4 Value of Modelling and Simulation

Modelling and simulation was used to support the decision making process during the Pre-FEED phase. Use of a reliability based integrated supply chain model enabled the selection of the fleet configuration and the LNG storage volume that provided the greatest value to the project.

Use of modelling tools in this stage of the design facilitated concept selection for the LNG plant, LNG storage and port and shipping operations. The final input parameters for the model can be used to form the basis for equipment reliability and performance specifications. It was essential to make these decisions as early as possible to allow the establishment of gas contracts with customers and for ship building to be undertaken within the lead times required by the vendors.

6 PRODUCTION AND CONSTRUCTION

6.1 Overview

Before production can begin the plant needs to be constructed and commissioned. During this stage the final design issues are resolved. This is last chance to influence design without serious cost consequences.

6.2 Case Study [9]

6.2.1 Introduction

In this case study a Hydrogen Sulphide Plant was to be upgraded to increase production. To support the design process a Failure Modes Effects and Criticality Analysis (FMECA) was requested to determine the impact of any potential failures on operations. As the design of the plant had been substantially determined two aims were identified: firstly to determine whether the current design could provide the required availability and production goal, and secondly to determine the impact on production of holding spares on site. Modelling and simulation was combined with the FMECA to help quantify the failure effect and to determine whether the plant had the capacity to meet the required production goals.

6.2.2 Method

A reliability block diagram, constructed from the P&IDs and PFDs, was reviewed by the engineering team to confirm the functional relationships and modified where required. A workshop, attended by operations, design engineers and maintenance personnel, was then conducted to determine the failure modes and their effects. The effect of holding spares on site for different equipment was a particular focus for the operations team. This was a significant issue as the effect on production due to maintenance activity delays associated with the lack of on-site spares had not been quantified.

The model was run for 1000 lifecycles of 20 years of operation. The input data for the model was provided from the workshop personnel. Two scenarios were analysed, one considered carrying no on-site spares the other considered carrying one spare of items that had maintenance delays while awaiting spares to arrive on-site. The model is represented diagrammatically in Figure 6-1.

Figure 6-1 FMECA Model

6.2.3 Results

The result of the analysis concluded that the proposed upgraded plant was capable of meeting the annual required production rates. The impact of holding spares on-site was an increase in the annual availability from 95.9% to 98% or an additional eight days of production per year.

Analysis of the sub-systems and elements within the system, to determine which were contributing the most to down time, was also conducted. The analysis revealed that the system contributing most significantly to the loss of availability was the Reactor and Quench Tower System. The typical contribution to loss of availability of each system is shown in Figure 6-2.

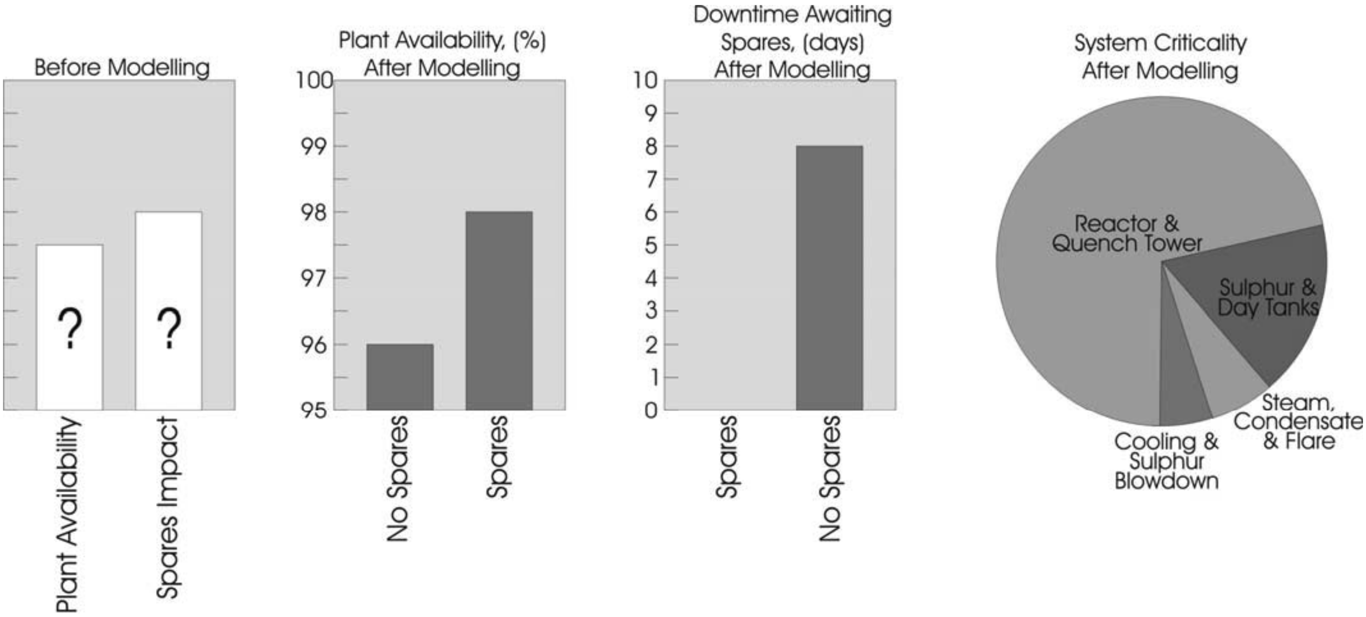

Figure 6-2 Simulation Results - FMECA

6.2.4 Value of Modelling and Simulation

Modelling and simulation was used to provide confidence that the proposed design would meet the required production requirements. The effects of holding spares on-site were quantified, allowing a cost benefit analysis to be performed to determine the value in holding spares on-site. The elements that contributed the most to the downtime were also identified to enable further engineering work to be done where required to further improve production.

In this case the modelling and simulation not only influenced the design but contributed to the operational and maintenance policy decisions. This was done with the cost of Lessons Learnt from the operation of the Plant.

7 OPERATIONAL PHASE

7.1 Overview

Operating and maintenance activities during the Operational Phase account for up to 75% of the lifecycle costs [10]. Modelling and simulation during this phase can be used to confirm design characteristics and assumptions. It is also used to de-bottleneck systems, subsystems and items that are having the greatest contribution to downtime.

A model built during the design phase can be updated during this phase to reflect the actual operating conditions. Any changes to the configuration, operations and maintenance activities to improve availability can be readily tested and refined using modelling and simulation before implementation of these strategies.

7.2 Case Study [11]

7.2.1 Introduction

During testing of the surface controlled subsurface safety valve (SCSSV) on a production well, the valve failed to fully seal. The well was shut-in awaiting assessment of the options available to enable production to recommence. SCSSVs are employed to shut down the well in case of a well blowout.

The client identified three options for the future of the well:

1. lock open the SCSSV and recommence production;
2. perform a well workover to replace the SCSSV and then recommence production; or
3. plug and abandon the well.

The aim of this model was to quantify the component risks for each option in monetary terms and estimate the total "opportunity cost" for each option by combining risk cost and actual cost.

7.2.2 Method

A fault tree was developed to represent the possible causes of a well blowout and the main risk assessment criteria was decided upon. Base data, including failure frequencies, Capital expense, operational expense and consequence costs for each risk that was not common to all options was then collated from a variety of industry sources. Using these data sources and risk assessment criterion, incident scenarios were developed and represented in an economic model to yield a monetary value. Capital expense, operational expense and risk costs were then combined to give an overall net present value (NPV) for each case, which allowed recommendations to be made.

7.2.3 Results

A risk based cost benefit analysis was developed to consider the three options available in terms of the lifecycle NPV costs. In each case an economic model was constructed to demonstrate the lifecycle costs and characteristics of each mode of operation over the remaining life of the well. Table 7.1 presents the summary of results for the three options.

Table 7.1 Summary of Results

Description	Option One	Option Two	Option Three
Environmental Risk	Negligible	Negligible	Negligible
Capital & Repair Costs	0	US$5,451,000	US$3,959,000
Production Costs	0	US$1,864,000	US$32,781,000
Risk Costs	US$2,600	US$9,100	0
NPV Cost	US$2,600	US$7,324,100	US$36,740,000
NPV Cost relative to Option One	0	US$7,321,500	US$36,737,400

7.2.4 Value of Modelling and Simulation

Modelling and simulation was used to support the decision to continue operations without a workover. The quantification of the risks in dollar terms helped demonstrate the value of option one. Other options or permutations of the existing options can readily be analysed using the base case that has been established.

Without modelling the three options a less financially rewarding option may have been selected. The expeditious use of modelling quantified the cost and risks (in dollar terms) of each option, allowing the production losses to be minimised.

8 LIFE EXTENSION OR DISPOSAL

8.1 Overview

There comes a time in the life of the asset when it is no longer profitable to continue operations with the existing plant. When profits are no longer high enough a choice to shut down operations completely or replace the entire plant may be needed. This phase of the lifecycle is the disposal phase where the residual value of the plant needs to be realised and all legal requirements met before divesting the asset management responsibilities.

Exactly when this time occurs for each asset is not easy to define. Life extensions, workovers, and economics changes could mean the asset is in operation for longer than originally predicted. Modelling and simulation can be used to determine the economics of continuing operations. It can also be used to determine if the entire asset or some small part needs to be upgraded to meet the production requirements.

8.2 Case Study [12]

8.2.1 Introduction

As part of an overall Iron Ore mining, processing and exporting expansion, the potential throughput of an existing crushing and screening plant needed to be determined. The crushing and screening plant consists of ten identical parallel screening units and four crushing units (one high capacity) in parallel with several material handling conveyors. A RAM analysis was conducted to assess the existing plant's availability at the proposed future production rate. This RAM analysis allowed the quantification of downtime and the identification of the major causes of downtime.

The aim of this model was to determine if the current equipment was suitable for the future throughput rate. If not, the quantification of RAM would determine whether the plant was suitable for upgrade or if a replacement was more appropriate. Popular opinion was that a replacement was required and $100 M was budgeted for the replacement.

8.2.2 Method

A workshop was held onsite to gather the required reliability parameters. The workshop participants included both site operators and project engineers. At the workshop, the equipment included within the crushing and screening plant was defined and divided into smaller systems for the purposes of gathering data, developing the RAM model and identifying areas of high losses and potential loss recovery.

The reliability parameters gathered in the workshop were used in conjunction with the project PFDs and operations and maintenance philosophies to develop the reliability block diagrams and a RAM model. The Optimise© RAM analysis software package was then used to simulate 1,000 lifecycles of the plant.

8.2.3 Results

Table 8.1 presents the summary of results of the RAM analysis for both the current and future throughputs. Increasing production increased the downtime and reduced the availability.

Table 8.1 Crushing and Screening Plant Performance Summary

	Performance Measure	
Case	Total Downtime, (hours per year)	Plant Availability, (%)
Current Throughput	1,200	86
Future Throughput	1,400	84

The modelling results showed a significant increase in downtime associated with production availability at the future throughput. The analysis of the subsystem criticality highlighted an increase in downtime associated with the plant screening and crusher systems. During current operations, the loss of a screening and crushing unit has minimal effect on achieving the desired throughput as there is some redundancy. However, at the future throughput, loss of either a screening unit or a crushing unit will have a significant impact on the downtime due to the lack of redundancy. Increasing the current throughput without upgrading the current screening or crushing units resulted in significant additional downtime annually. The results of the analysis are shown in Figure 8-1. If the screens and crushers are upgraded then the plant would be capable of meeting the production requirements. The cost to upgrade instead of replace was approximately $50M.

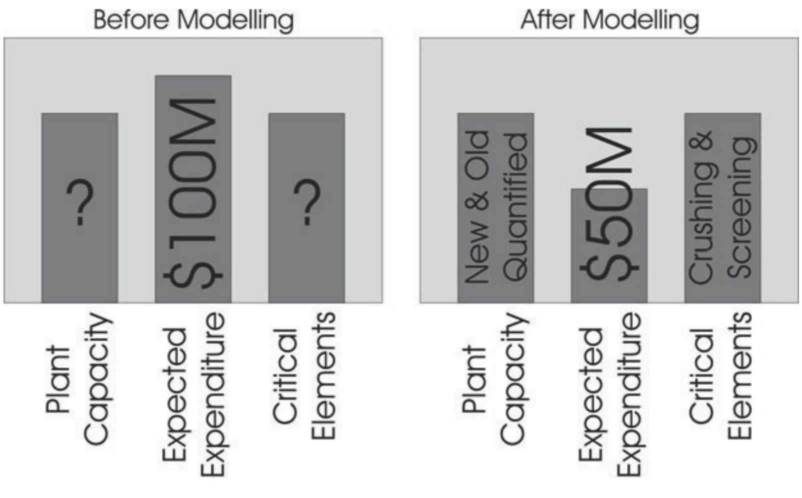

Figure 8-1 Simulation Results – Crushing Plant

8.2.4 Value of Modelling and Simulation

Modelling and simulation was used to support the decision to purchase new equipment or upgrade existing plant during the operational phase of the lifecycle. The quantification of the plant's potential future performance allowed the client to make an informed decision that the current equipment is suitable to be upgraded to meet future needs. The analysis identified the screens and crushing units to be the main systems which require upgrades.

Upgrading only the screening and crushing plant required less additional equipment than originally anticipated; the cost of the required upgrade would be approximately $50 million less than initially anticipated. Without modelling the plant an unnecessary upgrade may have resulted due to lack of understating of the plant. The model is now available if further upgrades are required and to validate their effectiveness.

9 DISCUSSION

The versatility of modelling an asset to gain some insight into how it will operate in the future and the benefit of knowing the effects of proposed changes make it an essential tool for any asset manager. As illustrated, using a few case studies, modelling and simulation can be used throughout the lifecycle.

Observations from industry indicate its use is more prevalent during the early lifecycle phases. Although the most benefit can be derived from its use at this stage it is rarely used in the later stages of the lifecycle.

Furthermore there appears to be little evidence that the models developed during the design phase are modified and used in the later phases of the asset's life. It appears there is a significant disconnect between the team responsible for designing the asset and the team responsible for operating and maintaining it. This is unfortunate as a significant leverage can be obtained by using a model that has already been paid for during the design phase. Using the model developed in the design phase to update RAM data and evaluate different maintenance and operational strategies is a simple exercise that can produce rapid results which can assist in the decision making process.

To assist in managing an asset throughout its entire lifecycle a greater awareness of the benefits of modelling and simulation needs to be highlighted. The communication between the design and operations teams needs to develop to allow the work undertaken in the design and development phase to be fully appreciated during the remainder of the life cycle.

10 CONCLUSION

The availability and performance of an asset is probabilistic with failures and maintenance activities following distributions specific to the each element. The dynamic interactions between the elements can be modelled using discrete event modelling and simulation. The results of the simulation can then be used to predict the performance of an asset before it has been built.

The model can then be used at all stages of the asset lifecycle to assist in decision making and provide the asset manager with a degree of confidence in the management strategy before it is implemented.

The most cost effective time to use modelling and simulation is during the design and development phase where it can assist in design and operational decisions. Full use should be made of the model by passing it to the operation team where it can be updated and maintained to reflect the latest configuration and conditions. Once the model has been updated it can be used to assist in decision making throughout the operation phase of the asset lifecycle. The model can also be used to assist in determining the most economical time for disposal.

STATE WATER CORPORATION TOTAL ASSET MANAGEMENT PLAN

Barrie R[a] and Gonzalez N[b]

[a] *State Water Corporation, Manager Strategic Asset Services, 2-10 Wentworth St, Parramatta NSW 2150, Australia.*

[b] *State Water Corporation, Senior Asset Planning Engineer, 2-10 Wentworth St, Parramatta NSW 2150, Australia*

Abstract: The State Water Total Asset Management Plan (TAMP) documents the background, principles, processes, information and outcomes of its total asset management strategy. The TAMP provides a strategic context for present and future decision-making on asset management, encompassing risk, financial, environmental, heritage, levels of service for water delivery and engineering issues. Because of its holistic and strategic context, the TAMP has become a vital source of information and reference for all staff, customers and a wide range of stakeholders across government and commercial sectors. The TAMP has particular application in the deliberations of NSW Treasury and IPART when establishing full costs, efficient costs, sharing of costs between customers and government, and bulk water pricing. The TAMP has been a key link in State Water's relationships with the Customer Services Committees representing the interests of water users. State Water continues to maintain a rigorous program of continuous improvement on its 'Knowledge of Assets' and total asset management processes in general.

Key Words: asset, management, risk, financial, environmental, heritage, service, water, delivery, users

1 ORGANISATIONAL BACKGROUND AND CONTEXT

State Water Corporation (SWC) was established as a State Owned Corporation (SOC) on 1 July 2004, under the provisions of the State Owned Corporations Act 1989, and the State Water Corporation Act 2004. Prior to this, State Water was part of various Government Departments. SWC incorporates NSW's bulk water delivery functions outside of the areas of operation of the Sydney Catchment Authority, Sydney Water Corporation, Hunter Water Corporation, and of other water supply authorities.

SWC's principal objectives are 'to capture, store and release water in an efficient, effective, safe and financially responsible manner'. Its core delivery business provides services to about 6,200 regulated river customers. These services include asset operation and maintenance to deliver water from storages, metering and commercial services. The operation of these assets enables the delivery of about an average of 5,000 GL/year of water in the 14 regulated river systems (valleys), along 7,000 kms of river.

State Water's head office is located in Dubbo, however, the day-to-day administration of the delivery of bulk water services is carried out from four regional geographical Areas each of which with its own administration centre. The four Areas are North, Central, Coastal and South covering fourteen valleys.

State Water's organisational context, including regulatory environment, is depicted in Figure 1.

The NSW Government grants an Operating Licence, which authorises State Water to capture, store and release water; and to construct, maintain and operate water management works. The term of the current licence is three years and it commenced on 24 June 2005. IPART is the price regulator as well as the auditor of the Operating Licence on behalf of the Government. IPART is in the process of determining prices for the 2006/07-2008/09 period; and is yet to audit compliance with the conditions of the Operating Licence.

DNR is the natural resource manager and it provides State Water with a licence to access and use water by means of a Works Approval. This arrangement minimises clashes between water resource management and operation activities.

Treasury is both a shareholder and a part-provider of funding resources. IPART determines the magnitude of Treasury's funding contributions for the period of each determination. State Water is required to provide Treasury with return on and of assets.

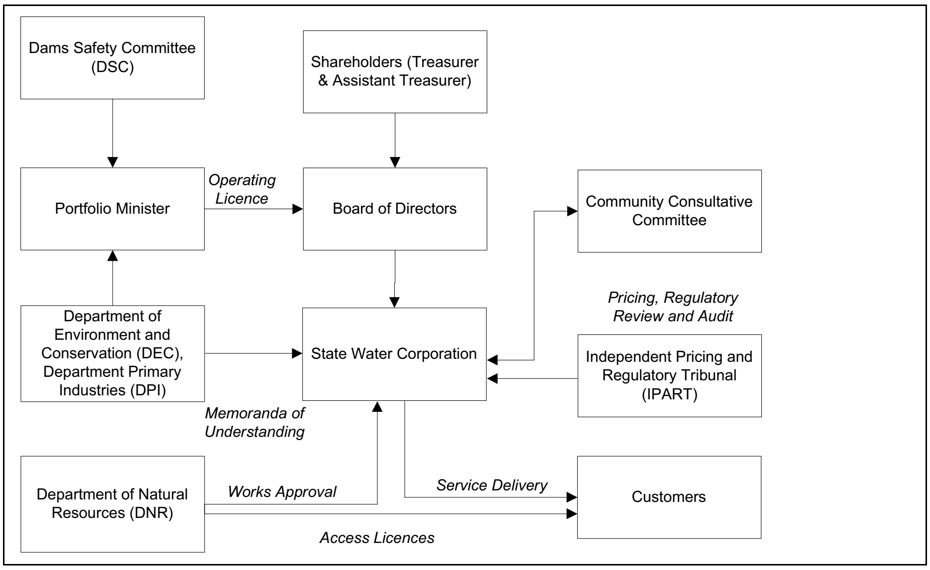

Figure 1 Organisational Context

2 ASSET BASE

As a bulk water service provider, State Water owns and operates an asset base worth $2.3b (Modern Engineering Equivalent Replacement Asset (2001 MEERA) value) or $300m (2004 regulatory asset base). This asset base comprises 20 large dams (all of them prescribed by the DSC), one small dam (prescribed by the DSC), approximately 300 weirs and regulators, 150 related river structures, 100 hydro graphic stations, approximately 500 buildings and numerous minor assets such as plant and equipment items. Additionally, it manages 11 small dams (three of them prescribed by the DSC) on behalf of NSW Department of Lands under a contractual arrangement.

The NSW Dams Safety Committee prescribes a dam if 'it has a potential for failure that could threaten downstream life, cause extensive property or environmental damage, or have a severe impact on the public welfare'.

3 ASSET MANAGEMENT DRIVERS

The key business drivers for the development and regular update of the TAMP include:

- Organisational Performance: Support corporate planning, implementation and allocation of resources, based on strategic asset management planning;

- Government policy: Premier's instruction on the principles of the NSW Government Strategic Management Framework, and the Treasury's Financial Management Framework including the government's Total Asset Management guidelines;

- Portfolio Risk Management: Provision of critical information for sound decision making. Information such as commercial and community risks, the development of risk management principles to define the duty of care and policy for the development of appropriate risk management strategies to remove, reduce or mitigate the risks; identify the linkages between assets, risks and insurance requirements;

- Compliance: Meet the statutory and regulatory requirements of NSW Dams Safety Committee, DEC, DPI and DNR;

- Corporate knowledge: Capturing long-term corporate knowledge will ensure informed decision making for planning, implementation and review. Avoid costs of repetition and of re-establishing lost information. Current information to support the preparation of budgets including CAPEX and OPEX;

- Public Good: Demonstrate to the Portfolio Minister who oversees public good, that community service obligations are delivered cost-effectively;

- Revenue: Meet the requirements of Treasury and IPART to develop plans of sufficient quality and detail as to enable the quantification of costs, and to meet cost setting guidelines;

- Cost Effectiveness: Demonstrate to customers, IPART, shareholders and community that asset management strategies are the most cost-effective, thus minimising costs for levels of service as defined in valley water sharing plans;

- Optimisation: The development of improved operations and maintenance strategies to optimise recurrent, renewal and capital expenditure;

- Benchmarking: Providing for rigorous measurement and benchmarking of all costs associated with the infrastructure, including operations and maintenance costs.

4 ASSET MANAGEMENT FRAMEWORK

As an infrastructure owner and bulk water service provider, State Water is chiefly an asset organisation. As such, asset management figures very predominantly within the corporate strategies. Figure 2 shows State Water's asset management framework.

Figure 3 further expands on the key asset management processes and asset management planning components of the framework and ties the detailed processes of the organisation into the overall framework. Both Figure 2 and

Figure 3 are colour-coded to facilitate visualisation of how the Asset Management Framework interrelates with Life Cycle Management Programs (LCMP).

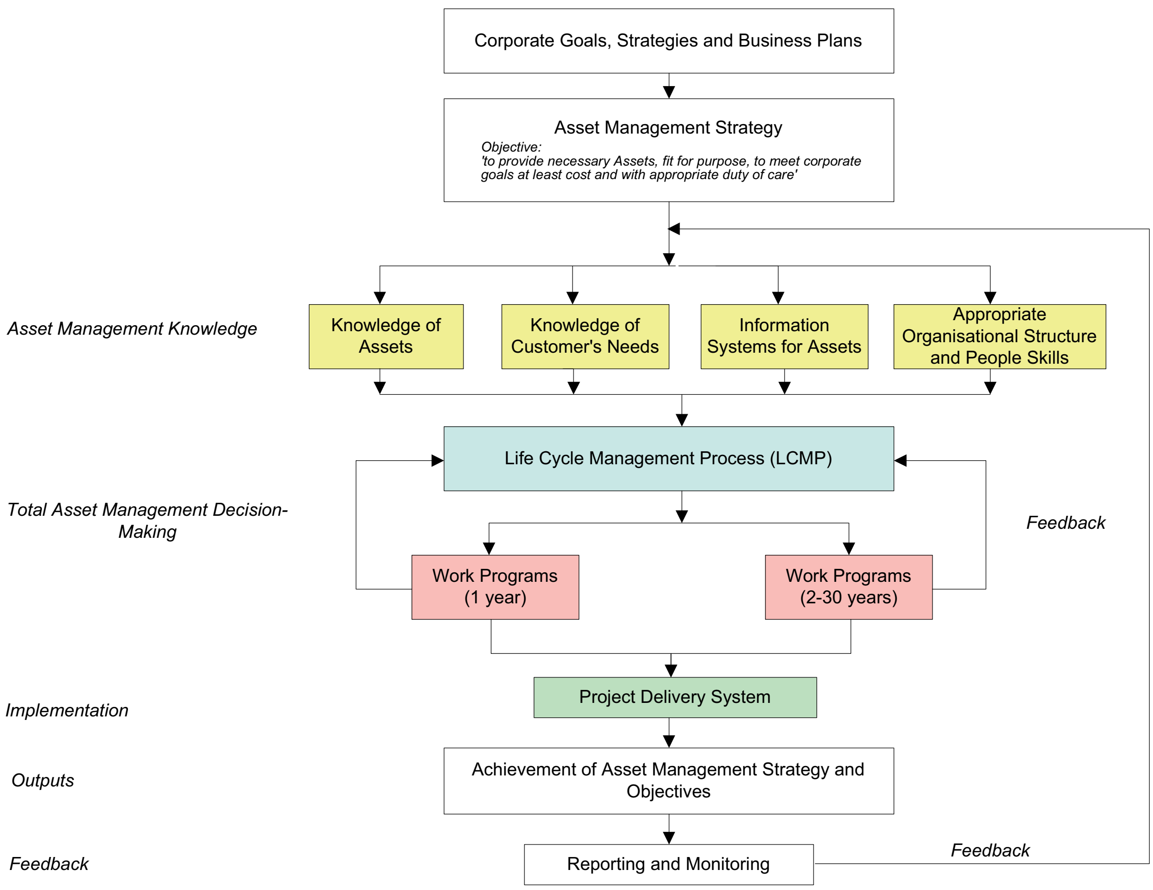

Figure 2 Asset Management Framework

The asset management framework is flexible and dynamic so as to minimise life cycle costs whilst delivering agreed levels of service to stakeholders. A very brief description of the components of the framework and how they integrate to deliver the Asset Management Strategy ensues.

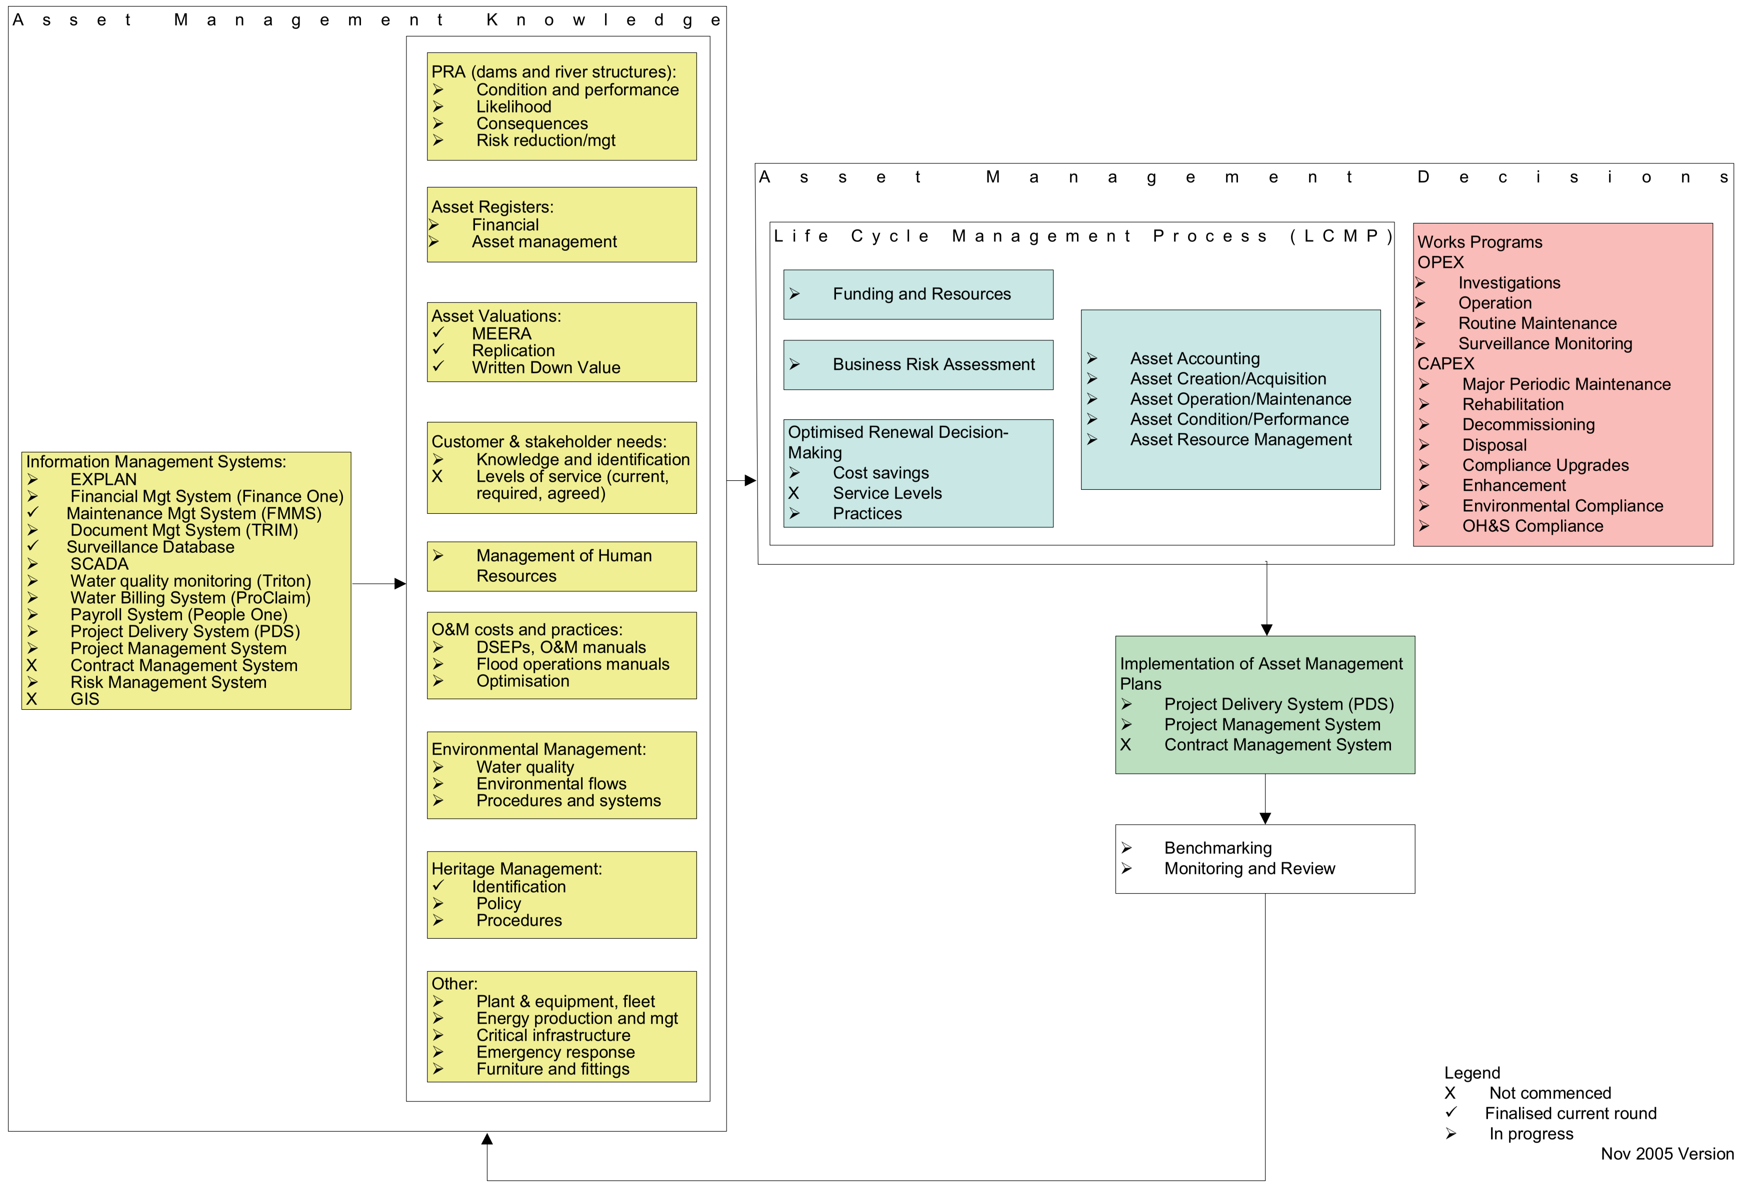

Figure 3 Life Cycle Management Programs

4.1 Knowledge of Assets

State Water is committed to continuously updating and improving the knowledge of its infrastructure because it realises its importance for asset management practices. Unless asset knowledge is regularly updated it will gradually deteriorate until it becomes unreliable and useless for asset management decision-making purposes.

Key components of various programs outlined in

Figure 3, which contribute to the improvement of asset knowledge, include:

- Condition assessments: State Water is in the process of developing a consistent quantitative rating system for asset condition for each of the various classes of assets. This program has two primary objectives, first to focus attention on components most likely to warrant immediate repair or further evaluation; second to monitor changes in the condition over time (and even at different locations). The latter is aimed at developing deterioration curves for predictive purposes;

- Maintenance and surveillance inspections: the frequency of these depends on the importance of individual structures. Some structures such as the large dams are subject to a strict program of surveillance inspection and maintenance audits according to requirements specified by the NSW Dams Safety Committee. Data collected from these inspections is recorded in registers and actions are tracked in subsequent inspections;

- Consequence assessments: Some assets, because of their importance, such as the large dams, warrant detailed consequence assessments involving population at risk (PAR), loss of life (LOL), direct and indirect damages, agricultural losses, intangible damages (environmental and cultural), etc. However, for the majority of the assets the consequence assessments are qualitative;

- Failure modes: the analysis of sequences or progression of events that may lead to failure is undertaken in detail for the large dams because of the complexity of the process and the expected consequences, should failure occur. State Water has developed a very good understanding of its portfolio of large dams, for which it carries out a thorough quantitative risk analysis, evaluation and control. A simplified process is being developed for the river structures as the risk drivers are more operational and the consequences are several orders of magnitude lower;

- Probabilities: Probabilities of failure, for different failure modes, are formally estimated in relation to the portfolio of large dams. For the remainder of the infrastructure base, probabilities are estimated on a qualitative base as part of risk analysis and assessment exercises;

- O&M practices and costs: operation and maintenance practices are recorded in O&M manuals that are regularly updated and which are available to users in hard copy at the different facilities or in electronic format through the document management system. Deviations from or additions to these procedures, particularly in relation to maintenance, are recorded in the Facilities Maintenance Management System (FMMS). The O&M manuals are updated regularly with these changes. Costs are captured both through the Financial Management System (Finance One) and through FMMS, at a more detailed level suitable for asset management purposes (e.g. by recording procedures followed, materials and plant used, etc.);

- Asset valuations: State Water conducts two sets of valuation. A Modern Engineering Equivalent Replacement Asset (MEERA) valuation and a replication valuation. The former it to satisfy regulatory requirements, the latter for asset management purposes, as the theoretical configuration of the asset may not reflect the existing asset layout. Valuations are used as proxy for value to stakeholders and are particularly useful for consistent benchmarking (internal and external) of performance (financial and asset management);

- Environment: State Water has developed, with input from relevant environmental agencies such as Department of Primary Industries (Fisheries), environmental protocols and checklists. These are designed to ensure compliance with environmental legislation and regulations;

- Heritage: State Water has completed a full assessment of heritage values for its entire portfolio of infrastructure and has set up a heritage register. It is now in the process of developing heritage management guidelines and conservation management plans for assets with identified heritage value.

4.2 Knowledge of Customers and Stakeholder Needs

State Water, as a State Owned Corporation, operates under the conditions of an Operating Licence, which formalises service delivery requirements to customers. IPART is charged with reviewing compliance with the conditions of the Operating Licence, which it is yet to do as the Operating Licence only came into effect on June 2004.

Some stakeholder requirements are clearly articulated through legislation including Occupational Health and Safety Act; State Water Corporation Act, Protection of the Environment Operations Act, Anti-Discrimination Act, State Owned Corporations Act, ICAC Act, Dam Safety Act and Protected Disclosures Act, amongst others. As such, they are not explicitly mentioned in the Operating Licence other than by reference.

A number of other less formal stakeholder requirements are negotiated in a collaborative manner through memoranda of understanding such as the one with the Department of Primary Industries for matters relating to fisheries.

There are eight valley-based Customer Services Committees (CSCs) that operate under agreed terms of reference. They are the primary means of consultation with customers on operational activities, pricing strategies, financial and business matters, and levels of service for water users within individual valleys. CSCs meet on a regular basis with senior management and the feedback they provide is duly incorporated in relevant processes. There is also a Customer Service Charter that guides the day-to-day interaction with over 6,200 regulated river customers.

State Water is committed to continuous improvement of service at the customer front. For this purpose it conducts customer satisfaction surveys and is in the process of developing an Issues Management Policy and accompanying computerised register, to manage customer/ public complaints. State Water also aims to be an employer of choice in the water industry and to that end it regularly conducts staff satisfaction surveys. The internal staff consultative committee has the responsibility to progress identified areas of improvement.

4.3 Information Management Systems

- State Water has been using a computerised Facilities Maintenance Management System (FMMS) for the last five years. This has assisted with planning and tracking progress to the extent that State Water is now quite confident that maintenance has reached a good standard;

- It has developed in-house a planning tool (EXPLAN) to assist with the IPART submission, forward capital investment planning and decision-making processes;

- It has recently acquired and is in the process of implementing a document management system (TRIM) and uploading information from previous systems into the new one;

- It has been using a procedural system to manage the delivery of projects (PDS) for the past three years. It is now investigating options to move into a computerised system for project management, audit and control with links to or integration with other corporate systems;

- It has a number of valley-based spreadsheet-type applications (CAIRO) for the day-to-day planning of water releases from storages and operation of river systems. It is now in the process of investigating the conversion of these into a central database application with live links with the water ordering system;

- The separation of State Water from its parent government department followed by its corporatisation in 2004 has forced it to acquire a number of computer systems that allow it to operate as a stand alone organisation. This process is still in progress and may continue for a few more years. The most important of these, is a package of three integrated applications for financial management (Finance One), water billing (Pro Claim) and human resource management (People One).

4.4 Human Resources

Prior to corporatisation, State Water had a staff base of around 240 employees including a small number of contractors. The corporatisation process brought with it a restructure exercise that had participation from relevant stakeholders. It reviewed organisational resources against the effects of statutory, operational and service delivery changes. The two most significant changes from the restructure were the creation of a new branch, risk management, and the establishment of a small group of engineering specialists. The former is aimed at addressing legislative requirements in a more rigorous manner from a business perspective. The latter seeks to improve the technical depth of the organisation, reduce reliance on consultants and account for the potential for expansion into external tendering. Overall staffing levels have increased across a number of organisational units, particularly in the areas of finance, information technology, human resource management and other corporate services. These changes are still in progress.

Another change derived from corporatisation has been the review and upgrade of a number of positions. This effort is aimed at attracting and retaining suitably skilled and experienced personnel. In addition, all segments of the organisation are locally formulating the skill requirements in detail to manage training needs accordingly, at local level.

A recent initiative is the set up of Technical Improvement Groups (TIGs). These are groups of skilled and dedicated staff across all areas of operations and abilities. They pursue excellence in work practices and technical knowledge in their specific areas of expertise and convey that expertise in the form of guidance on work practices and standards for the whole of the organisation.

Nine TIGs have been formally set up under terms of reference, they are:

- Lifting equipment and scaffolding;
- Corrosion control;
- Mechanical equipment;
- Electrical equipment;
- Major civil structures (dams, weirs and bridges);
- Emergency operation and stand-by equipment;
- Concrete and cement;
- Environmental engineering; and
- Contracts and contract management.

In 2005 State Water formed an internal storage management review committee to determine the most effective, efficient and economical framework to manage the risk of owning and operating large water storages and bulk water river assets. The objectives of the committee are to:

- Determine the most effective and efficient Area/ cluster/ site management structure for State Water Corporation storages that will enable it to meet regulatory and operational compliance requirements under both normal and exceptional circumstances;
- Recommend work practices that have higher value and will provide better short-term and long-term outcomes for the organisation, its staff and key stakeholders;
- Consider the impact on individual work sites, valleys, Areas and the whole of the State Water Corporation in making recommendations. (A variety of recommendations may result from differences in geographical separation, physical access conditions, site peculiarities or other factors.);
- Develop an understanding of the issues to be considered in an analysis of surveillance and operational work practices;
- Recommended changes to structures, systems, processes or work practices to allow increased operational efficiency with no reduction in customer service or compliance and no increase in risk to State Water Corporation;
- Increasing the quality of life for staff required to live on site for asset security; and
- Introduce higher value work practice through changed methods, systems, introducing technology or other means.

4.5 Asset Management Decisions and Life Cycle Management

The knowledge gathered through the seemly independent asset management processes, see

Figure 3 (e.g. asset valuations, risk, condition assessments, performance assessments, levels of service, O&M, etc.), is integrated together through the asset management framework, see Figure 2. All this information and recommendations from the individual processes comes together in the shape of works programs that take into account all these different drivers and which are prioritised according to alignment with the business objectives.

More specifically for large CAPEX works, State Water has formulated a 'capital investment and risk assessment framework' for decision-making. The framework is based on four principles formulated to ensure sound commercial outcomes for State Water, its shareholders and customers. These principles are:

- Complying with State Water's legislative and regulatory framework;
- Maximising State Water's net worth of investment by optimising social, environmental and economic outcomes;
- Managing risks within the business's risk tolerance levels whilst at the same time taking advantage of strengths and opportunities;
- Achieving consistency with ecologically sustainable principles in all investment decisions.

4.6 Implementation of the Total Asset Management Plan

Asset management plans are formulated on an ongoing basis and implemented annually through the budget process and in accordance with the rules of the project delivery system (PDS).

The PDS allows for the updating of information through the life of the project as it evolves. The template for project initiation and review includes business need, objectives, scope, constraints, stakeholder analysis, options comparison (including benefit cost analysis), risk management, communication plan, procurement options, etc. The PDS was introduced to:

- Minimise risk in the delivery of projects;
- Provide a system that is transparent and accountable;
- Ensure a uniform and consistent approach across the organisation;
- Improve communications and relationships through an understanding of the roles and responsibilities in delivering a project;
- Improve project risk management;
- Improve contract documentation and management;
- Ensure proper Environmental Impact Assessment of projects.

4.7 Benchmarking

State Water uses benchmarking as a means of reviewing its asset management practices, including decision-making, to continuously drive improvements. It does that by comparing resources and practices against those used in similar undertakings either within the organisation or outside. Some examples of benchmarking-type initiatives include:

- State Water conducted maintenance surveys over two consecutive years to assess its performance against industry standards. The results are very encouraging;
- It carried out internal benchmarking of maintenance costs and practices. The results highlighted a need for improvement in job costing practices;
- It participated in an international survey of dam spillway gate reliability the results of which were published to a selective audience in 2005;
- Initiated informal information sharing and benchmarking proposals with other organisations in the bulk water industry;
- Developed an internal technical exchange web page to promote information sharing;
- Identified a list of provisional key performance indicators and comparable organisations within Australia for benchmarking purposes.

4.8 Monitoring and Reporting of Performance

GHD has independently audited State Water's asset management practices and has conducted a number of gap analyses to compare its performance against best appropriate practice (BAP). Their reviews have shown that State Water has consistently improved its asset management activities and is able to bring a greater level of confidence to the planning and project tasks required for the delivery of bulk water.

This conclusion is based on comparisons with earlier audits in 1997 and 2000, with key improvements observed in asset knowledge, risk management, project implementation and the use of information management systems. See Figure 4.

5 BENEFITS DERIVING FROM TAMP

The TAMP provides a strategic planning framework which allows:

- Identification and linking of business drivers to asset management planning;
- Providing the mechanism for balancing competing drivers for the whole portfolio;
- Consideration of an appropriate range of options, both on strategic and tactical matters, so that decisions can be optimised and expenditures minimised in the delivery of services and other outcomes;
- Management of individual and collective risks, both in the short term and the long term;
- Demonstration of duty of care through appropriate planning, maintenance and operational actions.
- Monitoring of performance and a mechanism for identifying improvements required and adjusting plans, processes and systems;
- Contributions to strategic asset management planning by all staff, as well as, staff planning their own activities in the context of the TAMP;
- Communication with regulators in considering their requirements;
- Production of key outputs, such as lifecycle management programs, capital works, operational and maintenance plans;
- Communication of the strategy to all external stakeholders, and an opportunity for stakeholders to test the relevance of asset management plans;
- Basis to secure funding for asset management.

6 ASSET MANAGEMENT CHALLENGES FOR THE FUTURE

State Water's approach to asset management has been, and is expected to continue to be, subject to continuous change and adaptation given the state of the water industry and new developments in technology. Asset management is expected to undergo further changes to accommodate the operation of the organisation under commercial considerations. Decisions will be scrutinised more rigorously to demonstrate quadruple bottom line objectives and a level of water charges that enables the organisation to be self-sufficient.

Challenges for the future include:

- Modelling of asset condition deterioration based on history of condition rating assessments collected over time;
- Continuous refinement of useful and residual asset lives through condition and performance assessment programs. In particular the blend of these two concepts, physical condition and performance, needs to be clearly and consistently defined to assess how it affects the ability of an asset to meet its agreed level of service;
- Predictive modelling and optimisation (including sensitivity analyses) of asset replacement/ rehabilitation/ maintenance strategies and impacts on levels of service;
- Adaptation to international financial reporting requirements. This will not only force some changes in the way that the organisation accounts for costs but also have effects on who pays for what;
- Financial modelling of capital works program (based on a number of forecast cost profiles) aimed at formulating financial strategies to fund renewals. Alternatively, financial constraints can be set in the model to develop asset renewal budgets.

STATE WATER PORTFOLIO RISK ANALYSIS

Brian Cooper[a] and Robecca Gilham[b]

[a] *Dams & Civil, Department of Commerce, Rawson Place, Sydney New South Wales 2000, Australia*

[b] *Strategic Asset Services, State Water Corporation, Wentworth Street, Parramatta New South Wales 2150, Australia*

Abstract: State Water Corporation (SWC) is a bulk water supply business which manages a portfolio of large dam structures prescribed under the Dams Safety Act (1978). The Act sets out deterministic criteria to ensure that dam owners apply adequate consideration to dam safety for structures under their control. With limited funding and what may seem to be endless upgrading programs to keep pace with revised hydrology, in recent years dam safety management has moved away from application of traditional deterministic criteria, toward a risk based approach. Risk assessment provides the means to trade off the varying needs of structures in a portfolio, enabling owners to prioritise limited funding resources to areas likely to have the greatest impact and benefit. The process engaged to analyse risk in SWC's portfolio, and further to develop its capital works upgrading program will be the focus of the following discussion.

Keywords: Bulk water, dam safety, hydrology, risk analysis.

1 ABOUT STATE WATER CORPORATION & ITS REGULATORY ENVIRONMENT

State Water Corporation is wholly owned by the Government of New South Wales. The Corporation's principal objectives are *'to capture, store and release water in an efficient, effective, safe and financially responsible manner'* – for use by customers and the community – and for preservation of riverine ecosystem health. Water allocation to meet competing demands is governed by a Statutory Water Sharing Plan. State Water operates within the plan and its revenue is effectively capped by the plan limit.

As an owner/manager of large dams SWC is regulated by the Dams Safety Committee (DSC), a NSW government statutory authority created under the Dams Safety Act. Its role (among other things) is to *"formulate measures to ensure the safety of dams"* and to *"maintain a surveillance of prescribed dams"* (Dams Safety Act 1978). A "prescribed dam" is one listed in Schedule 1 of the Act.

In addition to the DSC, SWC is guided by the Australian National Committee on Large Dams (ANCOLD). ANCOLD's goal is to encourage improvement in the planning, design, construction and operation of large dams in Australia, and to ensure that dam owners have access to world best practice through the skills of Australian professionals.

ANCOLD has published the Guidelines on Risk Assessment (October, 2003), which has shown a significant move away from the deterministic approach to dam safety management. This Guideline has seen ANCOLD embrace the concept of risk, and has been a major source of guidance for SWC Portfolio Risk Analysis.

2 INTRODUCTION

The portfolio of dams owned by SWC presents it with a certain exposure to risk. The risk presented by some dams will be greater than by others. Some dams will satisfy deterministic standards for dam design while others will not, and will require remedial works to bring them up to standard. Of this latter group of dams, some will cause greater loss of life (LOL) and economic damage if they were to fail than others. It is apparent then, that there needs to be some means to rank the dams regarding their likelihood of failure and the associated consequences of failure. The Portfolio Risk Analysis (PRA) provides these means. The PRA is currently in the third stage of an extended risk management exercise that is briefly outlined below.

The first stage of risk assessment in its current form was the Screening Level Risk Analysis (SLRA). The SLRA was completed in 1999, and was a first pass at assessing the risk for 16 major dams (Hume Dam, Menindee Lakes and Fish River structures were not included) and 14 minor (ex-CaLM) dams that were under the control of SWC at this time. The SLRA developed probabilities of failure using event trees, however only made a rough estimate of LOL.

Following on from the SLRA, was the PRA (2002). This study developed the probabilities of failure (via event trees) from those estimated in the SLRA, and assessed the consequences of dam failure including LOL, economic damages, and environmental/cultural damages. A separate consequence assessment report was prepared, by consultants Sinclair Knight Merz, for each major and minor dam in the portfolio.

The current revision of the PRA is focussed on updating information that has become out of date, extending the study to include all prescribed dams managed by SWC, as well as developing the usefulness of PRA (2002) as a tool to guide SWC's program of capital works. The structures included in this revision of the PRA are listed in Table 2-1 below.

Table 2-1 Prescribed Dams in the Current PRA Revision

Dam Name
Blowering Dam
Brogo Dam
Burrinjuck Dam
Burrendong Dam
Chaffey Dam
Carcoar Dam
Copeton Dam
Glenbawn Dam
Glennies Creek Dam
Hume Dam
Keepit Dam
Lostock Dam
Menindee Lakes Storage's
Oberon Dam
Pindari Dam
Rydal Dam
Split Rock Dam
Toonumbar Dam
Windamere Dam
Wyangala Dam

3 ASSET MANAGEMENT FRAMEWORK FOR DAM SAFETY

The Role of the DSC

The DSC has statutory functions under the Dams Safety Act 1978 and the Mining Act 1992. Its main objective is to ensure that all prescribed dams in NSW are in such a condition as to not pose an unacceptable danger to downstream residents and property, or to adversely affect the public welfare and environment. This is achieved by requiring all dam owners to arrange for:

- Regular monitoring and surveillance of their dams;
- Ongoing assessment of their behaviour on the basis of monitoring and surveillance information;
- Regular review of the compliance of their dams with current standards;
- Review of all such information and assessments by experienced personnel;

The DSC has an ongoing watchdog role to oversight the safety of the State's prescribed dams and to prevent significant inadvertent or uncontrolled loss of their stored waters. In this context safety means that the dam complies with the Committee's current requirements and conforms to current accepted national and international practices.

The Committee requires owners of prescribed dams with known, or assessed potential, deficiencies to formulate appropriate remedial action programs and to implement appropriate surveillance and emergency plans. These actions are to be undertaken with a degree of urgency that is dependent on the extent of the deficiency and the scale of the consequences in the event of dam failure.

3.1 The Role of ANCOLD

ANCOLD is the Australian national committee of the International Commission on Large Dams (ICOLD), a non-government organisation established in 1928. As part of ICOLD, ANCOLD guidelines are generally representative of current accepted national and international practices. ANCOLD is an incorporated voluntary association of organisations and individual professionals with an interest in dams in Australia. Members include local, state and federal agencies, dam owners and operators, contractors, consultants and academics. Many disciplines are represented including planners, environmental scientists, engineers, hydrologists, geologists, social scientists, economists and legal practitioners.

ANCOLD's goal is to encourage improvement in the planning, design, construction and operation of large dams in Australia, and to ensure that dam owners have access to world best practice through the skills of Australian professionals. ANCOLD pursues this goal through a number of activities, however the publication of Guidelines setting national standards in many aspects of dams and their environs, are summaries of asset management activities which together constitute best practice asset management of dam structures. ANCOLD guidelines cover topics including, but not limited to the following:

- Risk Assessment
- Dam Safety Management
- The Environmental Management of Dams
- Assessment of the Consequences of Dam Failure
- Selection of Acceptable Flood Capacity for Dams
- Design of Dams for Earthquake
- Strengthening and Raising Concrete Gravity Dams
- Design Criteria for Concrete Gravity Dams
- Concrete Faced Rockfill Dams

3.2 Asset Management within the Regulatory Environment

In terms of dam safety, SWC has a statutory obligation to comply with the requirements of the DSC, and a professional responsibility to comply with ANCOLD guidelines and hence demonstrate best practice and due diligence.

Traditionally asset management in dam safety is composed of a number of areas, including design, operations and maintenance, surveillance and risk management and these are discussed in the topics of the ANCOLD guidelines listed above. Risk assessment is the most recent addition to the asset management tools, and it is important to remember that this provides one input into an asset management process.

ANCOLD is currently leading change in Australia, away from deterministic standards. The DSC is undertaking a review of the regulatory policy framework for dam safety. This revised policy, if implemented, will represent a large shift away from purely deterministic statutory dam safety standards, and move to focus on an integrated dam risk management process which includes risk analysis, risk evaluation, risk communication and risk control.

4 WHAT IS RISK?

4.1 Risk Analysis, Evaluation, Assessment and Management

There is often confusion between the terms Risk Analysis, Risk Evaluation and Risk Assessment. To clarify this difference, ANCOLD definitions for each follow:

4.1.1 Risk Analysis:

The use of available information to estimate the risk to individuals or populations, property or the environment from hazards. Risk analyses generally contain the following steps: scope definition, hazard identification, and risk estimation.

4.1.2 Risk Evaluation:

The process of examining and judging the significance of risk. The risk evaluation stage is the point at which values (societal, regulatory, legal and owner’s) and judgements enter the decision process, explicitly or implicitly, by including consideration of the importance of the estimated risks and the associated social, environmental, economic, and other consequences, in order to evaluate a range of alternatives for managing the risks.

4.1.3 Risk Assessment:

The process of reaching a decision recommendation on whether existing risks are tolerable and present risk control measures are adequate, and if not, whether alternative risk control measures are justified or will be implemented. Risk assessment incorporates, as inputs, the outputs from the risk analysis and risk evaluation phases.

Together risk analysis and risk evaluation, represent risk assessment. Risks are first analysed and then compared to tolerability criteria, and hence the risk is evaluated. The ANCOLD (2003) guidelines are directed to the practical application of risk assessment, with a primary focus on risk to life. The guidelines therefore provide guidance on tolerability criteria within the dam safety framework.

The SWC PRA is generally only concerned with risk analysis in terms of dam safety, with risk evaluation and assessment only really being introduced with respect to risk to life. ANCOLD provides guidance in the tolerability of societal risk, through the ANCOLD Societal Risk Curve and individual risk limits. However economic, environmental and cultural risks remain a matter for a business to decide upon a tolerable level. SWC has not considered the tolerability of economic, environmental and cultural risk at the present time. The outputs from the present process to revise and develop the PRA (2002) will remain a risk analysis with risk evaluation in terms of life safety risks.

Risk management is the end objective – risk assessment is a means to that end. In SWC, we have developed a risk analysis process, and assessed risk to life with respect to the ANCOLD guidelines. This process is the subject of this paper. The tolerability of risk in terms of economic, environmental and cultural risk remains yet to be addressed.

4.2 General

To quantify risk, the basic equation of Risk = Probability x Consequences was applied. The total risk is then the sum of all risks for the number of events considered, as is represented as:

$$\sum_{i=1}^{n} \{P(fail)_i * (csq(fail)_i\}$$

Where:

P(fail)i	is the probability of failure path i on the event trees
csq(fail)i	is the consequence of failure for failure path i (loss of life)
n	is the number of failure paths considered

4.3 Probabilities of Failure

4.3.1 General

Risk has been treated on a dam by dam basis, therefore to determine the probability of failure for a single dam, the structure is first broken down into its components (these may include the main embankment, spillway, reservoir and any subsidiary dams). Failure of these individual components is then considered separately.

The process of assessing the probability of failure of each dam component under various hazards follows a similar path. Hazards that have been included in the PRA assessment include earthquake, flooding, and sunny day (normal) events. In PRA (2002) piping was considered as a separate failure mode, however current practice is to assess piping following from one of the above hazards, using an event tree approach. The overall failure of the dam may result from a combination of the above hazards and the dam components not performing in a satisfactory manner.

4.3.2 Event Trees

Event trees have been developed to separate the dam components into events that are mutually exclusive, and therefore may be summed to calculate an overall probability of failure for the component, or the dam system. This overall probability of failure would therefore consist of earthquake, flooding, and sunny day events, relating to the various dam components. A sample even tree is shown in Figure 4-1 below.

Looking at Figure 4-1 we can see that the tree starts with a single node ‘F*R’, that is known as the initiating event. ‘F’ tells us that the type of initiating event is flood, and the characters following describe the particular flood partition. The probability of a particular flood partition occurring is the probability of the particular initiating event. Partitioning of annual exceedence curves within event types facilitates a more refined calculation, as it allows consequences relevant to the magnitude of each event being considered to be applied. Without partitioning, only one set of consequences would be applied to a probability of failure, which may, for example, overstate the risk. The initiating event is then followed by a number of branches (four in the example below), each with probabilities attached. The probabilities following the initiating event are known as conditional probabilities.

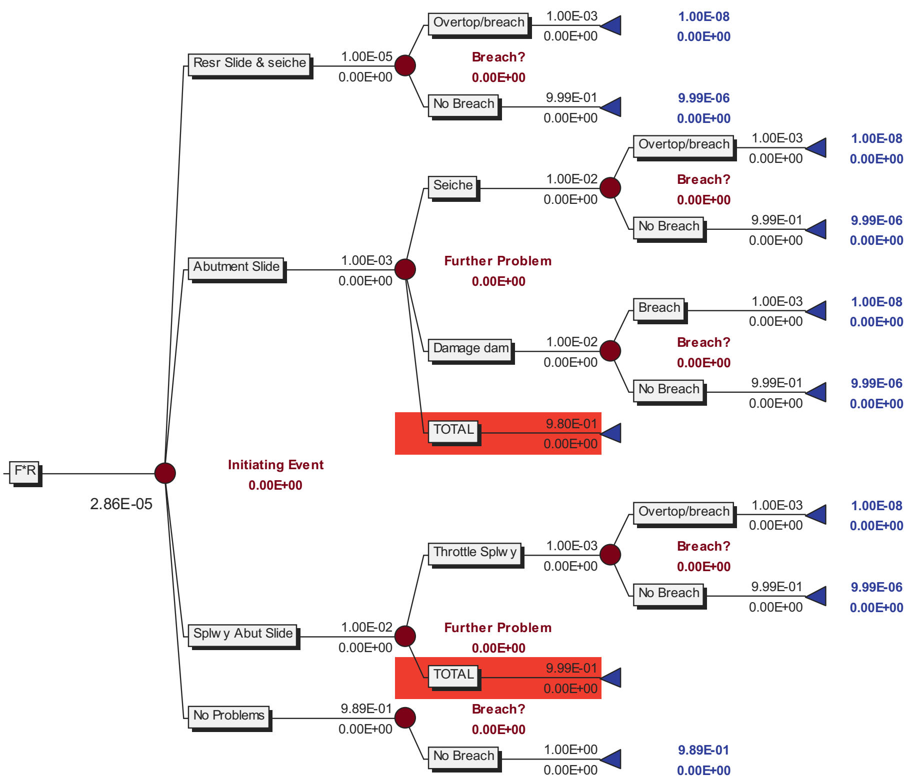

Figure 4-1 Sample Event Tree for Reservoir Failure

4.3.3 Conditional Probabilities

Conditional probability is the chance of an event occurring given that another event has already occurred. As with the SLRA, the conditional probabilities were estimated generally using expert judgement, on the basis of Table 4-1 below, supported by information contained in original design drawings, design reports, geotechnical investigations and design reviews, where information is available.

Table 4-1 Conditional Probabilities Mapping Scheme after Barneich et al (1996)

Description of Condition or Event	Order of Magnitude Annual Probability
Occurrence is virtually certain	1
Occurrances of the condition or event are observed in the database	10^{-1}
Occurrence of the condition or event is not observed, or is observed in one isolated instance, in the available database; several potential failure scenarios can be identified.	10^{-2}
The occurrence of the condition or event is not observed in the available database. It is difficult to think about any plausible failure scenario; however, a single scenario could be identified after considerable effort.	10^{-3}
The condition or event has not been observed, and no plausible scenario could be identified, even after considerable effort	10^{-4}

Reprinted from: ANCOLD Guidelines for Risk Assessment, 2003

The amount of data being analysed in the PRA can be appreciated if we consider the following:

- 20 prescribed structures make up the portfolio
- most structure have event trees for at least the main embankment, spillway and reservoir, and many have more than one subsidiary embankment

- all structures are analysed under the hazards of earthquake, flood and sunny day
- initiating events are often sub-divided further into partitions, which represent a level of consequences of failure. Each initiating event then required a set of consequences commensurate with the magnitude of the initiating event to be developed.

4.3.4 Joint Probability

Joint probability of failure is the chance of breach in any given year owing to a specified initiating event and set of conditions. Joint probabilities are determined by multiplying along each of the branches of an event tree. In the PRA (2002), the sum of the joint probabilities for all the initiating events on a particular event tree has been taken to be the probability of failure for that component of the system under the specified loading condition.

Care should be taken to determine the overall probability of failure as a result of all failure paths as when extreme events are estimated there may be a number of potential failure paths, all of significant conditional probabilities. In this case it is misleading to simply sum the probabilities of each branch, as the result may exceed unity, which is impossible. The uni-modal bounds theorem addresses this problem.

PRA (2002) has generally resolved this matter, through application of de Morgan's Rule between individual components within each initiating event. From de Morgan's rule, the estimated upper bound conditional probability (before application of the initiating event) is equal to one minus the product of the complements, or expressed as:

$$P_{UB} = 1 - (1 - P_1).(1 - P_2)\ldots\ldots(1 - P_n)$$

Where:

P_{UB}	= the estimated upper bound conditional probability of failure
P_1 to P_n	= the estimates of the several individual mode conditional probabilities of failure.

Technically, this rule should be applied between components of the dam system, as well as between failure mode types, before application of the probability of the initiating event. The influence of failure modes/components on one another, however, is generally minimal, since each conditional probability is a relatively small number, ie <0.01.

4.4 Consequences of Failure

4.4.1 Introduction

The consequences as a result of failure of each of the dams in the PRA (2002), were examined in a study carried out by Sinclair Knight Merz (SKM). The SKM study produced a report for each dam and in general analysed consequences of failure for failure (and no failure) modes including: Sunny Day Failure; Probable Maximum Precipitation Design Flood (PMPDF) with fail; Probable Maximum Precipitation Design Flood without fail; Dam Crest Flood (DCF) with fail; and Dam Crest Flood without fail.

The incremental consequences were estimated by subtracting the results of the no fail cases from those of the fail cases. The ANCOLD Guidelines on Risk Assessment (October 2003) now recognise the Graham (1999) method (used to derive LOL in dam failure cases) should not be applied to the without failure case. The consequences for the Sunny Day Failure represent incremental values directly because in this case the consequences of no failure are considered zero.

For dams where current dambreak studies and hence inundation plans were available, these were utilised to derive consequences. Otherwise, numerical hydraulic modelling was carried out to simulate the effects of flooding, and flood inundation maps were prepared. Three main groupings of consequences were derived including LOL, economic loss and environmental and cultural losses. These broad groups are described in greater detail below.

4.4.2 Loss of Life

The Graham (1999) method divides the fatality rate (loss of life as a proportion of a population at risk due to dam failure) into 15 different possible combinations; 3 flood severity categories, 3 warning time categories, and 2 flood severity understanding categories. Combinations of these categories assign a recommended fatality rate and a recommended range of fatality rates. It is therefore possible to not only predict a best estimate of the fatality rate from Graham's recommendation and site specific information, but also present the possible range. A range of LOL was presented in the PRA (2002).

4.4.3 Economic Consequences

The economic consequences from flood damage are both tangible and intangible. The tangible losses are those arising from destruction and losses which can be measured in terms of their market values. They comprise direct and indirect damages. Direct damage is that damage to property that is a direct consequence of flooding and includes:

- destruction and damage to homes, commercial/industrial structures, building contents, goods and equipment
- public building including schools, hospitals, libraries
- destruction and damage to infrastructure including roads, bridges, power lines, water supply pipelines, sewage treatment plants and other utilities
- vehicles
- mines and power stations
- farm assets
- agricultural, pastoral and stock losses
- agricultural losses due to loss of irrigation water.

- Indirect damages are those which flow on from the direct damages and include:
- cost of temporary accommodation
- cost of emergency services
- cost of traffic disruption
- loss of retail trade
- loss of industrial production
- temporary costs for provision of water and sewerage services
- lost agricultural and pastoral production in periods after flooding
- subsequent health costs that can be costed and attributed to the flooding.

Intangible damages are those damages that do not have a market value that can be easily measured. Factors such as anxiety and ill health cost the community but the costs are not readily measured. The consequences assessed in this study only quantify the tangible losses.

The damage costs presented are generally economic costs rather than financial costs. Economic costs are those costs measured in terms of consumption of resources from a community aspect. In this case, the community is the whole of Australia. Financial losses focus on the losses suffered by a single individual or group of individuals, businesses or government agency.

4.4.4 Environmental and Cultural Consequences

Dam failure is likely to cause significant environmental damage and cultural loss. A qualitative assessment involved classifying the ecological and cultural value of the following sensitive areas:

Environmental Consequences:

- Riverine Systems
- Wetlands
- Terrestrial Species
- Threatened Species
- Effect of Major Point Pollution

Cultural Consequences:

- European Heritage Sites
- Aboriginal and Heritage Sites
- Parks and Reserves

Impacts were ranked from 1 to 5 with negligible effect at th**e low end of the scale and total destruction at the high end of the scale. Intermediate impacts were minor, moderate and major.**

4.5 Calculating Risk

4.5.1 Risk to Life

Risk to life is comprised of both societal and individual risk. The ANCOLD definition of life safety risks is outlined below:

Individual risk:

The increment of risk imposed on a particular individual by the existence of a hazardous facility. This increment of risk is in addition to the background risk to life, which the person would live with on a daily basis if the facility did not exist.

Societal Risk:

Also referred to as societal concerns. The risk of widespread or large scale detriment from the realisation of a defined hazard, the implication being that the consequence would be on such a scale as to provoke a socio/political political response, and/or that the risk (that is, the chance combined with the consequences) provokes public discussion and is effectively regulated by society as a whole through its political processes and regulatory mechanisms. Such large risks are typically unevenly distributed, as there are attendant benefits. Thus the construction of a dam may represent a risk to those close by and a benefit to those further off, similarly a process may harm some future generation more than the present one.

To assess the tolerability of societal risk, SWC made reference to the ANCOLD Societal Risk Curve. On this curve, the cumulative frequency of the probability of failure of each initiating event is plotted against the estimated number of lives lost in order of decreasing LOL. Societal Risk Curves showing the limits of tolerability for existing dams, and new dams and major augmentations are shown in Figure 4-2 and Figure 4-3 below.

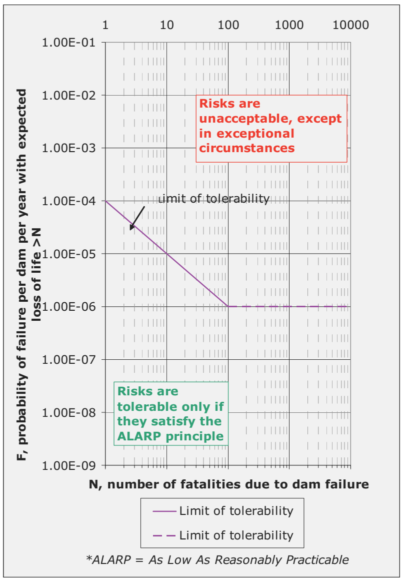

Figure 4-2 Revised ANCOLD Societal Risk Reference Guideline: New Dams and Major Augmentations

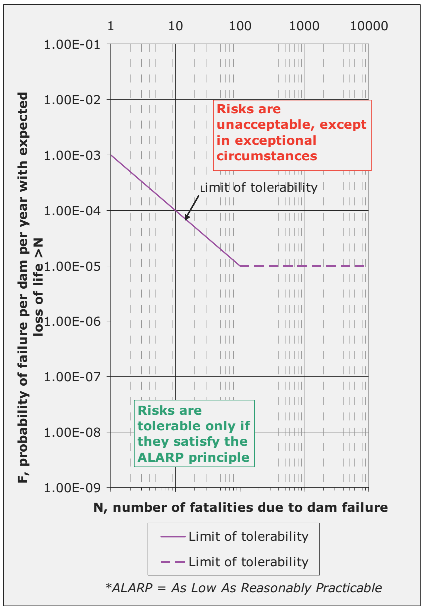

Figure 4-3 Revised ANCOLD Societal Risk Reference Guideline: Existing Dams

The tolerability of individual risk also varies depending on the nature of the structure being considered. For existing dams, an individual risk to the person or group, which is most at risk, that is higher than 10^{-4} per annum is unacceptable. For new dams or major augmentations of existing dams, an individual risk to the person or group, which is most at risk, that is higher than 10^{-5} per annum is unacceptable, except in exceptional circumstances.

Thus the risks contributed by all failure modes and scenarios need to be combined to obtain the overall risk to life in terms of both societal and individual risk. The chance of LOL per annum (individual risk) contributed by each earthquake, flood, and sunny day failure modes, is the product of:

- The annual probability of the event
- The conditional probability of dam failure, given the event
- The conditional probability of the individual's LOL, given dam failure (ANCOLD, 1998)

Using the ANCOLD Societal Risk Reference Guidelines, the 16 major and 14 minor dams included in PRA (2002) were ranked into risk categories for societal risk; being:

- Unacceptable risks which fall above the ANCOLD limit of tolerability and require high priority remedial works or investigations.
- Intermediate risks which fall under the ANCOLD limit of tolerability but above what was known as the ANCOLD Objective Line (in older revisions of the ANCOLD Societal Risk Reference Curve). These risks are subject to the principle of "As Low As Reasonably Practicable" (ALARP).
- Risks which are below both the ANCOLD limit of tolerability, and the ANCOLD objective line, and are tolerable only if they satisfy the ALARP principle.

The major dams, included in PRA (2002) were then separated into the above three categories and a group of SWC's 7 most critical dams, were formed. These dams are currently the subject of upgrading programs to satisfy the ANCOLD principle of ALARP. The dams included in the group of SWC's 7 most critical dams are Blowering, Burrendong, Chaffey, Copeton, Keepit, Split Rock, and Wyangala.

4.5.2 Economic Risk

In PRA (2002) economic risk was calculated as the sum of the products of the likelihood of dam failure in any one year, and the annualised economic damages for the full range of initiating events. In PRA (2002) the reporting of economic and financial risks followed the same principles as the reporting of risks to life, with "$" replacing "N", except that there is no parallel concept to that of the Maximum Individual Risk to Life. The tolerability of economic risks in SWC was not addressed in PRA (2002).

4.5.3 Environmental/Cultural Risk

In PRA (2002) environmental and cultural risk was represented by plotting the likelihood of failure in any one year, and the qualitative consequence ranking of pairs on environmental and cultural risk charts. Because the different categories of risks are incommensurable, risks cannot be aggregated across categories. However within a category, it may be appropriate to combine the raw "f" values, provided there is little variation in impact over the various failure scenarios. The tolerability of environmental or cultural risks in SWC was not addressed in PRA (2002).

4.5.4 Application of Consequences Assessments using Risk Database

As discussed above, consequence assessments including LOL, economic, environmental and cultural losses were assessed in PRA (2002) for the various cases of flood loading (Sunny Day, PMPDF with and without fail, DCF with and without fail) by consultants, SKM.

As estimates of the probabilities of failure for system components were derived for partitioned floods these ranges did not match those described in the consequences assessments. Interpolation of consequence assessments was required so that the results were appropriate for the level of flooding being considered, hence, results from the consequences assessments were not applied directly to the probability of failure numbers, but required considerable work to be interpolated.

Once each initiating event for every dam component had an associated appropriate set of consequences, this data was entered into a database, created internally within SWC, which could then be interrogated to derive risk data.

5 THE WAY FORWARD

5.1.1 General

As outlined above, PRA (2002) analysed 16 Major and 14 Minor dams within its portfolio and did not include Hume Dam or the Menindee Lakes Storage's. Since completion of this study, the minor dams have been transferred to the Department of Lands, and Fish River Water Supply has been merged with SWC hence Rydal and Oberon Dams need to be incorporated into the PRA. The PRA is now being progressed to include SWC's complete portfolio of dams prescribed under the Dam Safety Act which are listed in Table 2-1 above.

There have also been significant changes to the inflow hydrology of structures located in the area of the Generalised Tropical Storm Method Revised (GTSMR) application. Hydrology changes to inflow floods affect the areas of inundation determined by dambreak studies which in turn may alter the consequences, that may be associated with any failure event. Consequence assessments were previously undertaken in 2000 by consultants SKM. It is also possible that since this time developments have occurred within the inundated areas downstream of dams which may further impact 2000 consequences assessments. Overall, these changes may have a significant impact on the current risk level posed by dams in the region of the GTSMR. The changes required to review the current risk position of SWC are outlined below in terms of changes to both the probabilities and consequences of failure.

To move forward, SWC have also commenced a program of reviewing the revised risk position for each of the 7 most critical dams, post implementation of current proposed upgrading programs. This process will change the usefulness of the PRA for management and the Board in planning, particularly to prioritise proposed capital upgrading works. This phase of the PRA is outlined below and is known generally as developing the PRA.

5.2 Updating PRA (2002)

5.2.1 Revised Probabilities of Failure

Since completion of PRA (2002) the probabilities of failure have become outdated. To provide a current reflection of SWC current risk position, the following will be considered:

- Annual Exceedance Probabilities (AEP) of the inflow floods for dams in the GTSMR area, and the transition zone between the Generalised Southern Australia Method (GSAM) and the GTSMR areas have been revised, hence initiating events for dams in these areas should reflect these changes.
- Interim works have been completed at Keepit and Chaffey Dams. Changes to the structures relevant event trees and paths to failure should be revised accordingly.
- AEP's used to develop flood initiating events in PRA (2002) applied joint probability to the storage being at a level less than FSL, rather than the more conservative assumption accepted by the DSC that AEP's are derived from the storage initially at FSL. All dams to be included in the PRA should be reviewed to include initiating events commencing at FSL.
- In 2005 the probability of piping failure was revised using an event tree approach in lieu of the outdated UNSW Database method that was applied in 2002, this should be incorporated into the probabilities of failure for all dams in the prescribed portfolio.
- ANCOLD Guidelines on Risk Assessment, were revised in October 2003, hence these should be applied in revisions to the PRA.

5.2.2 Revised Consequences of Failure

Changes to hydrology in the GTSMR and the transition zone have a flow on effect to the consequences of failure associated with flooding events. Increased inflow floods increase the inundated areas downstream, hence possibly increase the population at risk and the LOL that may be expected.

PRA (2002) did not consider the effects of cascade failure at storage's with large dams upstream. Dambreak Studies and associated consequence assessments should consider these effects.

In PRA (2002), consequences for each of the partitioned initiating events were interpolated from the consequence assessments. This process was labour intensive, and included many assumptions. In moving forward with the PRA, a more practical approach is to run appropriate dambreak cases, and therefore evaluate consequences for individual flood partitions. This will provide a much greater level of accuracy, and be considerably more efficient.

Consequence assessments were undertaken for PRA (2002) by SKM and were largely completed in 2000. These are now upwards of 5 years old. Developments may have occurred downstream of dams, which may have an impact on the consequences associated with dam failure, even where there has been no substantial change to hydrology in the catchment area. Existing consequence assessments should be subjected to peer review particularly for currency.

The process to revise the consequences of failure has several stages, including the following:

- Update hydrology. Note that this task is discussed under probabilities above
- Revise the Dambreak Studies (including investigation of cascade effects where applicable)
- Review and compare existing consequence assessments. First, consideration should be given to ensure that previously developed consequences are still current (ie there have not been significant developments in the inundated area that were previously not identified). Secondly, a comparison should be made to determine if the existing consequence assessment data adequately covers the revised areas of inundation.

Changes in hydrology, as a result of changes to the GTSMR, therefore have a considerable impact on assessed consequences as a result of dam failure, and for this reason, SWC should reassess the consequences for dams in the GTSMR region as well as the transition zone. Dams in the GTSMR requiring consequence reassessment include Keepit, Chaffey, Pindari, Toonumbar Dam, Split Rock and Copeton Dams. Dams in the transition zone requiring consequence reassessment include Lostock, Glennies Creek and Glenbawn Dams.

The bulk of this work is required to comply with the statutory obligations of the DSC. To keep the PRA live and enable it to become a useful management tool, PRA (2002) should be revised and developed so that it is representative of SWC's current dam safety risk position, and hence useful as a management tool.

5.3 Developing the PRA (2002)

Together, the extended portfolio including revised probabilities and consequences will provide considerable data that SWC will be able to utilise to justify projects and programs to improve the dam safety risks associated with its large dam assets. This is one step to an improved risk understanding. Building upon this, SWC is currently developing PRA (2002) to analyse the risk position as a result of implementing upgrading works (staged where possible). This process will develop event trees for a staged program of work at each of SWC's 7 most critical dams. For dams where significant risk reduction may be achieved through undertaking upgrading works in stages, each stage of work, through to full deterministic compliance with DSC criteria, has been reviewed in terms of probabilities and consequences of failure.

The results of this analysis will provide the revised risk position (in terms of the ANCOLD Societal Risk curve) for the preferred option for each of the 7 most critical dams. This process is currently underway. It should be noted that each of these dams is currently at differing stages of progress toward upgrading, hence selection of a preferred option has been based on the available information at the time and may not reflect the final option selection. This process will allow SWC to compare the improvement to risk achieved at each dam with the implementation of staged/interim works, and ascertain the likely best value for money.

6 CONCLUSION

The goals of the current PRA exercise are two fold. SWC are currently reviewing the probabilities and consequences of failure, and in a parallel process, have also commenced a program to review the revised risk position as a result of implementation of upgrading works. Considerable resources will be required to deliver this extent of work, as well as work with management and the Board to ensure that the project is on track to deliver results that are useful, relevant and timely.

Many tasks to update the PRA, are justified to comply with the DSC, and hence require updating regardless of the existence of the PRA project. The challenge will be to ensure that studies required for statutory compliance, produce results with sufficient detail/information/data that may be used in the PRA.

SWC requires outputs of the PRA to enable it to understand and progress its business, and enable it to maintain and operate safe assets. As well as creating data that is useful to management, the PRA can be a useful tool to project managers of the 7 most critical dams to enable an understanding of issues of concern, and justify proposed works. It is important that adequate exposure and understanding is portrayed at all levels through SWC to enable further development of this tool in areas that will benefit the business as a whole.

HELICOPTER GEARBOX BEARING BLIND FAULT IDENTIFICATION USING A RANGE OF ANALYSIS TECHNIQUES

Sawalhi N* and Randall R.B*

* *School of Mechanical and Manufacturing Engineering, The University of New South Wales, Sydney 2052, Australia*

Abstract: Vibration acceleration signals were obtained from an overload test of a Bell 206 Helicopter Main Rotor Gearbox in order to complete a blind bearing fault analysis where no knowledge of the fault was made available prior to the analysis. A range of diagnostic techniques was applied. These included constant percentage bandwidth (CPB) spectrum analysis, spectral kurtosis (SK) analysis to determine the frequency bands with maximum impulsivity and to filter the signal to maximize that impulsiveness, and envelope analysis to determine the fault frequencies. Order tracking was used to compensate for speed fluctuations, while linear prediction using autoregressive models (AR) was used to remove the regular gear meshing contribution in the signals. As a result of applying these techniques, a fault in one of the planetary bearings was identified. A match with the cage frequency and the inner race ball pass frequency indicated deterioration associated with these components. Roller fault frequencies were not directly detected, but the fact that roller faults give a modulation at cage frequency shows that their effect was still detected. SK gave a good measure of the severity of the fault when compared to the amount of metal wear debris in the oil. Details of the test, as well as application of a statistical fault detection technique can be found in a companion paper submitted by the Defence Science and Technology Organization (DSTO) Australia.

Key Words: Order tracking, Autoregressive models, Spectral kurtosis, Complex Morlet wavelets, Constant percentage bandwidth.

1 INTRODUCTION

Many failures which occur in rotating components like gears and bearings often show their signature in the vibration signal, and can be detected in the early stages. Monitoring such vibrations in helicopter gearboxes often requires an extensive interpretation by a trained diagnostician. This is due mainly to the existence of a large number of rotating components, all of which contribute and mix in different ways [1], making it very hard to track changes in a certain component.

Helicopter transmission gearboxes have been investigated in detail to understand the types of baseline frequencies and failure indicators that can be detected by monitoring vibrations [2,3]. These efforts have resulted in a better understanding of the way in which different signals express themselves and mix with others, and have led to the development of a variety of diagnostic and prognostic techniques [4,5,6].

Different techniques have been utilized for bearing diagnostics in such environments, aiming at separating the gear signals from the bearing ones. These include the use of synchronous averaging [4], Self-Adaptive Noise Cancellation (SANC) [7], and Discrete Random Separation (DRS) [8]. Once the separation is achieved, envelope analysis [9] - which is a widely used technique for bearing analysis - is employed to extract bearing defect frequencies, thus indicating the source and the nature of the fault. However, as minor speed variation exists in practice, it is necessary to remove this variation and phase-lock the vibration signal to shaft speed. This is achieved through the use of order tracking, and is usually performed by re-sampling the vibration data at uniform rotational angles - using a tacho signal - rather than time based intervals [1]. In reference [10] Bonnardot et al showed that this re-sampling can be achieved using the signal itself, and combined that with the use of self adaptive noise cancellation, which resulted in a clear identification of a ball fault in a planetary bearing and proved to be much more efficient than using SANC on its own. However, the selection of the frequency band for demodulation purposes (envelope analysis) was performed on the basis of trial and error, and needed to test more than one band to be able to detect the fault.

In this paper, different techniques are combined to provide an effective and automated extraction of a fault from a planetary bearing, which was blindly analysed from accelerometer signals measured at the helicopter transmission test rig facility at DSTO. The proposed algorithm starts by compensating for speed variations by re-sampling the signal synchronously with rotational speed using a tachometer signal. The re-sampled signal is then analysed using a newly developed technique for rolling element bearings [11]. This technique combines the use of autoregressive models, complex Morlet wavelet banks and spectral kurtosis (SK) [12,13] to automate the selection of the best band for envelope analysis.

The algorithm is taken a step further, by investigating its suitability for trend analysis, and possibly the prognosis of the fault. This is made possible by comparing the outcome of the algorithm (Spectral kurtosis evolution and filtered signals) with the amount of metal debris obtained from the test rig lubricant, and also by comparing constant percentage bandwidth (CPB) spectra at different stages of the fault.

2 EXPERIMENTAL

Experimental data was obtained from a test performed in the Defence Science and Technology Organization (DSTO), Bell 206 test rig facility in Melbourne, and was blindly analyzed for a defect in one of the bearings in the transmission system. The conditions for generation of the data included an overload test, which was carried on over different time intervals allowing the monitoring of fault development at different stages.

2.1 Bell 206 Transmission Description

The Bell 206-transmission system as shown in Figure 1 is a two-stage reduction gearbox. The first stage consists of a spiral bevel pinion gear with ($N_{pinion} = 19$ teeth) driven by the input shaft from the engine side and rotating at a speed of ($f_{input} = 100$ Hz), which meshes with a bevel gear ($N_{bevel} = 71$ teeth). Triplex ball bearings and one roller bearing support the bevel pinion shaft. Duplex ball bearings and one roller bearing support the bevel gear shaft in an overhung configuration.

The second reduction stage is provided through a planetary mesh. The epicyclic gear system consists of a sun gear ($N_{sun} = 27$ teeth), splined to the bevel gear shaft, which in turn drives three planet gears ($N_{planet} = 35$ teeth). The planet gears mesh with a ring gear ($N_{ring} = 99$ teeth), which is attached to the top casing. Power is transmitted through the planet carrier, which is attached to the mast output shaft. The overall reduction ratio of the main transmission is (17.79:1) driving the output at ($f_{out} = 5.73$ Hz).

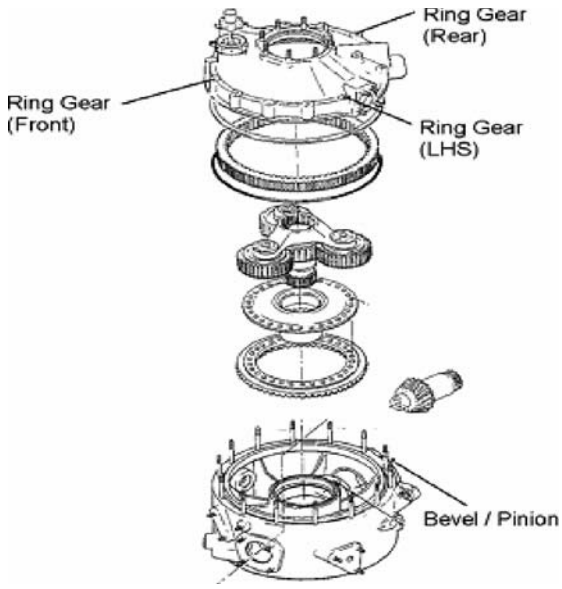

Figure 1 Bell 206 Transmission

Vibration data was collected from four accelerometers located on the transmission housing as shown in Figure 1. Three of them were attached to the ring gear, measuring vibration at the second stage (planetary gears). At a sampling frequency of 51.2 kHz, 30-second records were obtained at different stages of the fault. Each accelerometer is mounted so that its axis of measurement intersects the rotation axis of the shaft at 90 degrees. In addition to the accelerometers, two tachometers were placed at the input and output shafts. For this analysis, only one accelerometer was used as the one that gave the best indication of the fault. This was the front accelerometer.

Debris was collected from the gearbox oil using an inline MetalSCAN unit. This was done in parallel with vibration measurements, and the cumulative mass was recorded against the test hour. Oil temperature was also monitored all the way through the whole test.

2.2 Expected Frequencies

The vibration signal is expected to contain all frequencies due to meshing between the different sets of gears, their harmonics and sidebands. References [5,14] give a complete description of computing those frequencies. This is adopted here for the same purpose, taking into consideration the differences in rotational speeds and the numbers of teeth on the different gears. Figure 2 shows a schematic presentation of the planetary gear system. The motion of such a system can be easily understood by a superposition analysis, which can be done in two sequential steps and summed to obtain the relative movements between the different components [14].

In the first step, the carrier (arm) is “locked” in position and the ring gear is free to rotate. The planet gear and the sun gear rotations are estimated based on that.

In the second step all elements of the gear train are "locked" together and the entire assembly is rotated backwards until the ring gear is back to its original position.

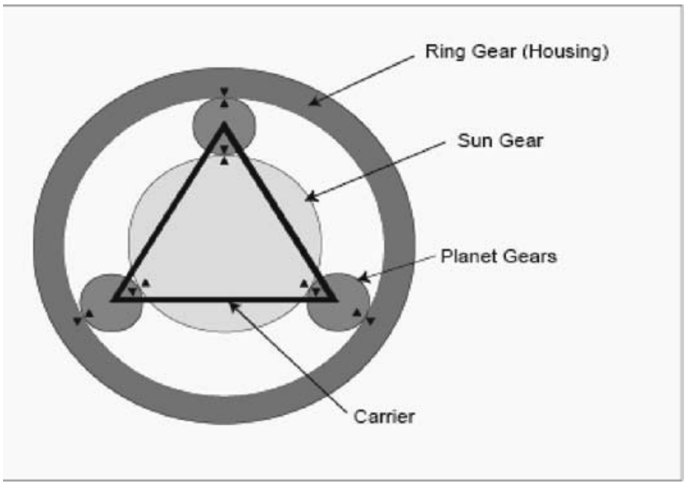

Figure 2 Elements of a simple planetary or epicyclic gear train [14]

Summing those two actions provides the total rotations of all components. The relevant values for the system under investigation are shown in table 1.

Table 1

Shaft speed estimation for different rotating parts

Rotational frequency* (Hz) of: -	Planet Gears f_{planet}	Sun gear f_{sun}	Gear carrier (Output shaft) f_{out}	Planet gear with respect to planet carrier (spin frequency) f_{spin}
	-10.48	26.76	5.73	-16.21

* Values estimated based on 100 Hz input shaft frequency.

Note that, as the planet gears and the carrier rotate in opposite directions, the net speed of a planet gear with respect to the carrier is the sum of the absolute speeds of the planet gear and the carrier. This is known as the spin frequency of the planetary gears, and can be alternatively calculated using equation (1).

$$f_{spin} = -\frac{N_{ring}}{N_{planet}} f_{out} \qquad (1)$$

where the negative sign in equation (1) indicates that the planets spin in the opposite direction to the sun gear and the carrier. Results showing shaft speeds and gear mesh frequencies in the Bell 206 transmission system are presented in table 2.

Table 2

Gear, mesh frequencies		
	Frequency of interest	Hz
Stage 1	Input shaft frequency	100.00
	Pinion Mesh frequency	1900.00
	Bevel Gear shaft speed	26.76
	Bevel Mesh frequency	1900.00
Stage 2	Sun mesh frequency	722.54
	Carrier frequency (output arm speed)	5.73
	Epicyclic mesh frequency	567.71
	Planet pass frequency	17.20

Rolling element bearing frequencies are generated when a bearing begins to fatigue. These will be too low to show up in the early stages of the fault due to the strong contribution from the meshing frequencies. For a fixed outer race (most common situation), the load direction is fixed with respect to the outer race, and equations (2 – 5), [15] are used to calculate the defect frequencies. Note that this is kinematically identical to the planet gears discussed above for a load angle $\alpha = 0$. The load angle is taken for the dominant load path, but actually varies for each rolling element, which is the reason for the random slip that always occurs. Thus, actual mean bearing frequencies typically differ from the theoretical ones by 1-2%, and the corresponding pulse period also varies randomly by about the same amount.

Inner Race Defect Frequency [BPFI]

$$f_{BPFI} = \frac{Nf_i\left(1 + \frac{d}{D}\cos(\alpha)\right)}{2} \tag{2}$$

Outer Race Defect Frequency [BPFO]

$$f_{BPFO} = \frac{Nf_i\left(1 - \frac{d}{D}\cos(\alpha)\right)}{2} \tag{3}$$

Cage Rotational Frequency relative to outer race (fundamental train frequency) [FTF]

$$f_{FTF} = \frac{f_i\left(1 - \frac{d}{D}\cos(\alpha)\right)}{2} \tag{4}$$

Ball/Roller rotational speed around its axis (ball/roller spin frequency) [BSF]

$$f_{BSF} = \frac{f_i}{2}\frac{D}{d}\left(1 - \left(\frac{d}{D}\cos(\alpha)\right)^2\right) \tag{5}$$

where N is the number of rolling elements, d and D are the rolling element diameter and the pitch diameter of the bearing respectively. f_i is the rotational speed of the inner race (shaft speed). α is the contact angle (from the radial).

Planetary bearings represent a special case, as the bearing is attached to the planet gear on its outer race, and to the carrier on its inner race, which means that both races will be rotating. Equations 6-10 are used to calculate the defect frequencies for the planetary bearings. Note that the load direction in the planetary bearings is fixed with respect to the inner race rather than the outer race (FTF is calculated as the cage speed relative to the inner race (carrier)), so that it is BPFO that is modulated by passage through the load zone, rather than BPFI as in the normal case.

Inner Race Defect Frequency [BPFI]	$$f_{BPFI} = \frac{N(f_{planet} - f_{out})\left(1 + \frac{d}{D}\cos(\alpha)\right)}{2}$$	(6)
Outer Race Defect Frequency [BPFO]	$$f_{BPFO} = \frac{N(f_{planet} - f_{out})\left(1 - \frac{d}{D}\cos(\alpha)\right)}{2}$$	(7)
Cage Rotational Frequency (absolute)	$$f_{cage} = \frac{f_{planet}\left(1 - \frac{d}{D}\cos(\alpha)\right)}{2} + \frac{f_{out}\left(1 + \frac{d}{D}\cos(\alpha)\right)}{2}$$	(8)
Cage Rotational Frequency relative to inner race (carrier) [FTF]	$$f_{FTF} = \frac{(f_{planet} - f_{out})\left(1 + \frac{d}{D}\cos(\alpha)\right)}{2}$$	(9)
Ball/Roller rotational speed relative to both races (ball/roller spin frequency) [BSF]	$$f_{BSF} = \frac{f_{planet} - f_{out}}{2}\frac{D}{d}\left(1 - \left(\frac{d}{D}\cos(\alpha)\right)^2\right)$$	(10)

where N is the number of rolling elements, d and D are the rolling element diameter and the pitch diameter of the bearing respectively. f_{planet} and f_{out} are the rotational speeds of the planetary gears and the output shaft (carrier) as in table 1. α is the contact angle (from the radial).

Table 3 presents the theoretically calculated defect frequencies for bearings in the Bell 206 transmission system.

Table 3

Bearing defect frequencies	Shaft speed (Hz)	(BPFI) (Hz)	(BPFO) (Hz)	(FTF) (Hz)	(BSF) (Hz)
Triplex bearing - Input pinion	100.00	822.72	577.28	41.23	276.43
Roller bearing - input pinion	100.00	616.58	383.42	38.34	202.79
Bearing lower mast	26.76	273.63	208.85	11.56	96.45
Duplex bearing, input gear shaft - lower support	26.76	369.22	299.80	11.99	127.55
Duplex bearing, input gear shaft - upper support	26.76	356.68	285.57	11.90	59.85
Planetary bearings		117.72	76.95	9.81	37.04

3 DATA PROCESSING AND FAULT DIAGNOSTICS

The data from the accelerometers was processed in a number of sequential steps as shown in the block diagram of Figure 3. The logic and ideas behind each processing step are as follows: -

1. Minimizing the speed fluctuations that may exist in the transmission system.

   As has been indicated in the Introduction, the system under consideration contains a large number of rotating components, which all contribute to the vibration signal. Although the system in general runs at a nominal constant speed, it will exhibit minor speed variation in practice. For this reason, sampling of the vibration data is performed at rotational rather than time-based intervals [1]. This angular resampling (also known as order tracking) will force the gear signal to be deterministic and is done here using the tacho signal.

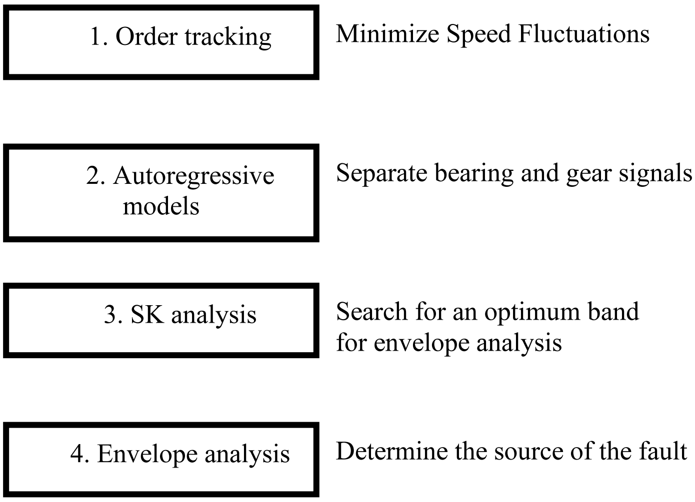

Figure 3 Block diagram presentation of signal processing steps

2. Separating bearing signals from gear signals and pre-whitening.

   This is done using autoregressive models (AR), with the aim of analyzing the residual signal of the model (the so-called pre-whitened signal). The use of this signal in further processing steps, is more favourable than the use of the original signal (order tracked), and proved to give better results for the spectral kurtosis analysis [16].

3. Searching for an optimum band for demodulation purposes.

   This is done using complex Morlet wavelets. These are used as a filter bank with constant proportional bandwidth (uniform resolution on a logarithmic frequency scale). Different banks are used to select the best filter for the envelope analysis as the one that maximizes the SK

4. Extracting bearing defect frequencies and determining the source of the fault.

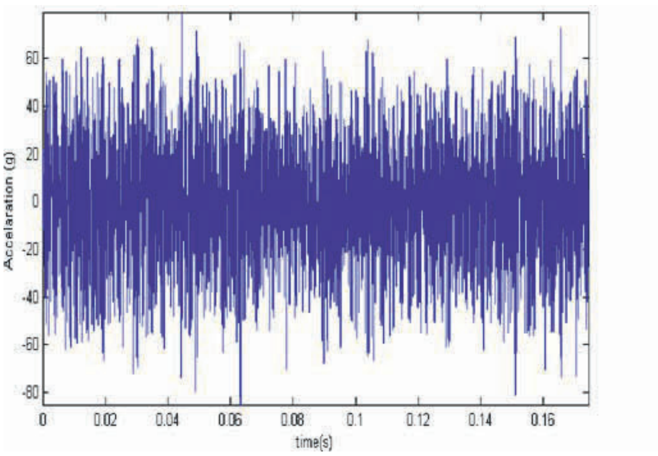

Figure 4 Accelerometer signal representing 1 rotation of the carrier

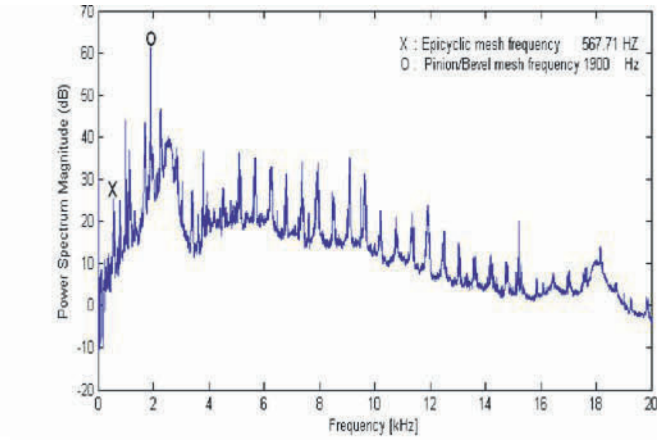

Figure 5 Power spectral density of the raw signal

For the sake of diagnostics, only the result from the last measurement is discussed here, while more discussion is given on the fault in its different stages in the prognostic section. A depiction of the first 8,930 samples (174.36 ms) representing the first rotation of the carrier (5.73 Hz) is given in Figure 4. With a kurtosis value of (-0.61) it is very difficult to recognize any impacts in the time domain signal. This is further investigated by examining the power spectral density (PSD) of the signal as shown in figure 5, which shows how the harmonics of the gear mesh frequencies (two families) dominate the spectrum, and can be seen over the whole useful range of the signal (to 20 kHz).

3.1 Order tracking

The main idea behind the order tracking is the removal of speed fluctuations that can exist in the transmission system leading to a non-deterministic gear signal. Order tracking is a way of ensuring the deterministic property of the gearmesh signal while facilitating its treatment and interpretation in further steps of the analysis. Order tracking in concept is based on re-sampling the signal in the angular domain rather than the time domain. This can be done either by using hardware (phase-locked frequency multiplier), or by digitally re-sampling the signal with the aid of a tachometer signal [1]. Recently this was done by using the signal itself, based on phase demodulation of the gearmesh frequencies [10].

In this study, all order tracking was performed using a digital re-sampling technique, where both the vibration signal and the tachometer signal were sampled simultaneously using a fixed time-based sampling frequency. Matlab® code was used for this purpose and included the use of a cubic spline interpolation of the vibration signal to calculate the values at the required sample points, based on the tachometer signal.

3.2 Linear Prediction filtering and pre-whitening based on Autoregressive modelling

Having obtained an order-tracked signal, with a deterministic gearmesh contribution, autoregressive models (AR) are used next with two main aims. The first is to remove gear contributions from the signal. This will result in the separation of the signal into two main parts, namely, a deterministic part (AR fitted signal – containing the gearmesh contribution) and a noise part (containing additive white noise and nonstationarities (impulses)). Because of the randomness referred to above, the bearing signals are contained in this part [7].

The second aim from using AR models is pre-whitening. The noise part of the AR model is close to that of a white noise (power spectral density changes with frequency are very small), as it is made up of impulses and additive white noise. This has the advantage of solving an anomaly in the SK, and gives better results when used prior to the application of the SK [16].

In the process of designing an AR filter for linear prediction, a value of the signal at time index k is normally based upon a linear combination of prior values, according to equation (11) [17]:

$$x_k = -\sum_{i=1}^{p} a_i x_{k-i} + \varepsilon_k \tag{11}$$

where the a_i are the autoregressive coefficients and ε_k is the residual error. The residual error ε_k (difference between the actual signal and the AR prediction) has an almost white spectrum, but can be made up of stationary noise and impulses.

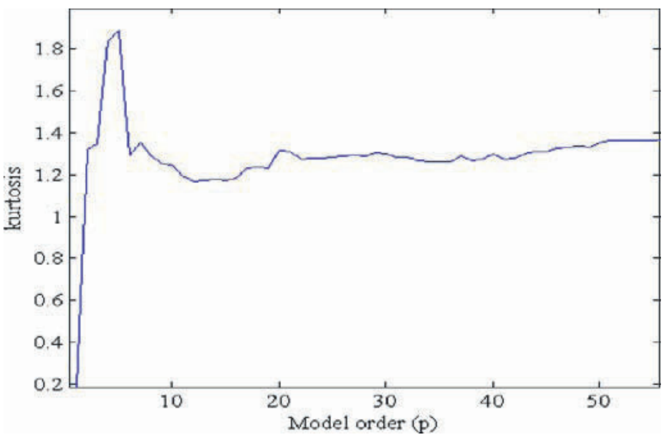

Figure 6 kurtosis of residual signals for different model orders

The AR filter as described by equation (6), well predicts the deterministic pattern of the signal but is not capable of adapting to the sudden impulses caused by a localized fault. As a consequence, the fault impulses will be left in the residual

ε_k of the AR filter. If SK is applied on the residual signal, high SK values and a clearer extraction of fault impulses are obtained.

Several criteria are in place to select the optimum model order, such as the Akaike Information Criterion (AIC) [18], however as the main objective of using the AR technique for rolling element bearings resides in separating the impulses from the original signal, it is intuitive to base the order selection criterion on maximizing the kurtosis of the residual signal, which as has been indicated earlier, contains both the impulses and the stationary noise. The optimum model order p should be less than the spacing between two consecutive impulses, as this guarantees that the model does not adapt to the impacts as being a part of the deterministic signal and that they will be contained in the residual signal.

The optimum order for the AR model was first examined based on maximizing the kurtosis of the residual signal. The result as depicted in figure 6 clearly shows that a filter length of five samples would be optimum and is preferred for a better extraction of impacts hidden in the system.

Figure 7 shows the effect of using a linear prediction filter and the benefits of analysing the residual signal rather than the raw signal. Impulses throughout the signal can be seen very clearly in the residual signal (b) when compared to signal (a) from the same figure. The passage of the planet gears can also be seen clearly (three bursts of increased amplitude in one rotation) when inspecting one rotation of the carrier as presented in figure 8. Other impulses do exist in the signal and will require further analysis to determine the source. A final point to mention in this regard is the increase of the kurtosis value from – 0.61 (in the order-tracked signal) to about 2.2 in the residual signal.

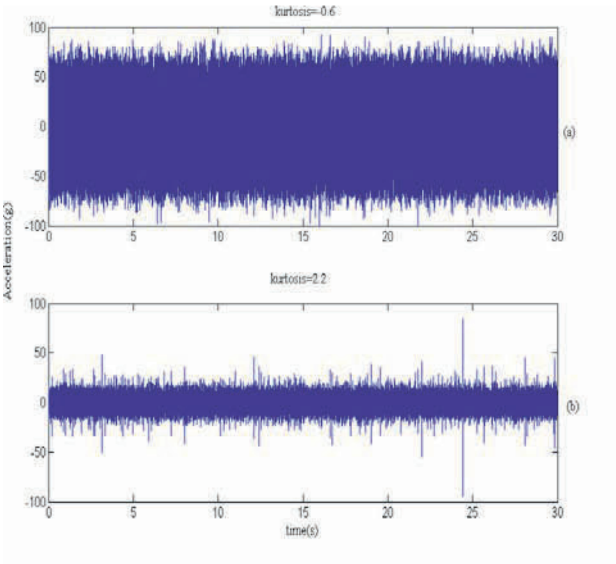

Figure 7 (a) Initially processed signal by order tracking (b) AR (5) residual signal

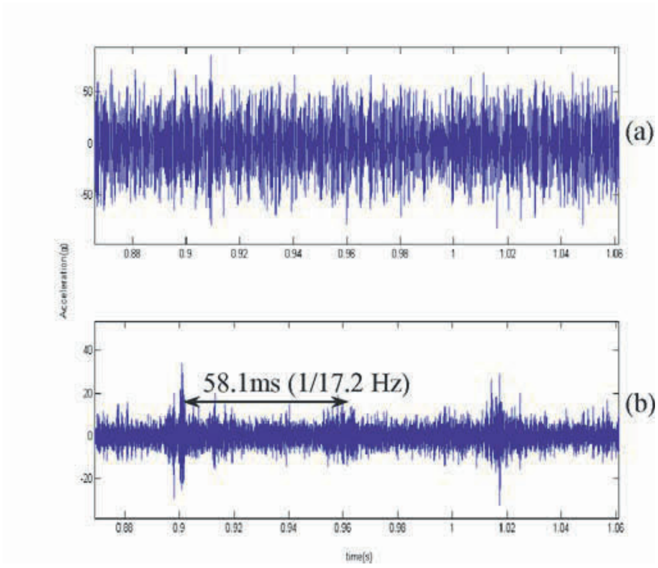

Figure 8 Zoom-in views (one rotation of the carrier) showing the effect of using an AR linear prediction filter for signal separation, (a) Order tracked signal, (b) Residual signal

3.3 Automated envelope analysis using Spectral Kurtosis and complex Morlet wavelet filter banks

The presentation of this section is based on what has been presented in [11], in which Sawalhi and Randall used different filter banks constructed using Complex Morlet wavelets to select the best filter for the envelope analysis - in terms of centre frequency and bandwidth - as the one that maximizes the SK. This approach proved to be well suited for the purpose of rolling element signal analysis due to:

- The use of wavelets being more favourable than the STFT (short time Fourier transform) as the duration of the wavelet varies inversely with frequency corresponding to constant relative damping.

- The choice of complex Morlet wavelets helps to design a filter, which acts as a ‘matched filter’ to condition transient signals in the data.
- The complex wavelets help detect transients in a uniform manner regardless of their phase.

The complex Morlet wavelet is defined in the time domain as a complex exponential wave multiplied by a Gaussian function, and has the shape of a Gaussian function in the frequency domain as follows:

$$\psi(t) = \frac{\sigma}{\sqrt{\pi}} e^{\sigma^2 t^2} e^{i2\pi f_o t} \tag{12}$$

$$\Psi(f) = \Psi^*(f) = e^{-(\pi^2/\sigma^2)(f-f_0)^2} \tag{13}$$

where Ψ(f) is the Fourier Transform of ψ(t). Since Ψ(f) is real, Ψ(f)= Ψ*(f), where * denotes the complex conjugate. f_0 is the centre frequency of the window and σ determines its width. Since the real and imaginary parts of ψ(t) are Hilbert transforms, it is analytic and its Fourier transform Ψ(f) is one-sided with positive frequencies only.

The advantage of the complex Morlet wavelets, compared with the real version using windowed cosines, is that the imaginary parts (sines) have their maximum when the cosines have zero crossings, so that the squared amplitude of the wavelet coefficients is not sensitive to the phasing of local features in the time signals.

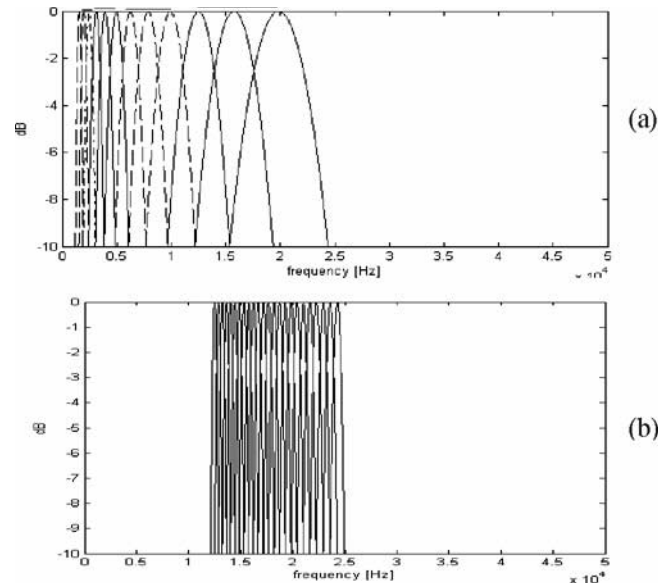

Figure 9 Morlet wavelet filter banks used in [12] (a) 1/3-octave over four octaves (b) 1/24 octave over an octave

To optimise the use of complex Morlet wavelets as a filter bank, and to gain a balanced representation of the signal in time and frequency domains, a few banks with different numbers of filters per octave e.g. (3,6,12,24) or (2,4,8,16) were suggested to decompose the signal. In order to gain efficiency, the number of octaves covered in each bank can be reduced as the number of filters per octave is increased, as the coarser analysis gives an indication of the frequency bands with the highest impulsiveness. Moreover, filters for lower octaves can be derived by progressively down-sampling the higher octave filters by factors of 2, which accelerates the analysis. Figure 9 shows two filter banks constructed using complex Morlet wavelets. A coarse one (3 filters/octave) spreading over 4 octaves and a fine one (24 filters/octave) over one octave.

Once the filters are constructed, the signal can then be decomposed correspondingly. This is easily performed by multiplying the FFT of the signal by each row of the filter bank matrix, then by performing the IFFT to obtain the wavelet coefficients (complex values) [11]. The multiplication of the wavelet coefficients by their complex conjugate in fact gives the squared envelope of the filtered signal. If y is the squared envelope, then the kurtosis corresponding to y can be calculated using equation (14), to give a single value for each filter.

$$kurtosis(y) = \frac{mean(y^2)}{(mean(y))^2} - 2 \tag{14}$$

The value 2 is subtracted here to obtain a value of zero for the squared envelope of Gaussian noise. The best filter is chosen as the one that gives the highest value of kurtosis, i.e. maximizing the SK from the squared envelope. This filter is retained and then re-used to obtain the squared envelope signal and the envelope spectrum.

After processing the residual signal (figure 6(b)) using the set of filter banks described, the result is plotted in figure 10 as an image, whose rows represent the filter banks (3,6,12,24 filters/octave), and columns represent the filters in each bank. The values assigned to each slot (filter) are the kurtosis of the squared envelope signal for that specific filter in the bank, and were calculated as shown in equation (9). The highest kurtosis indicates the optimum slot (filter) for the purpose of envelope analysis. The maximum SK was obtained using 12 filters/octave (centre frequency of 18800 Hz and bandwidth 1175 Hz).

To gain more insight into the excitation across the frequency range, the SK is plotted in figure 11 using a bank of 12

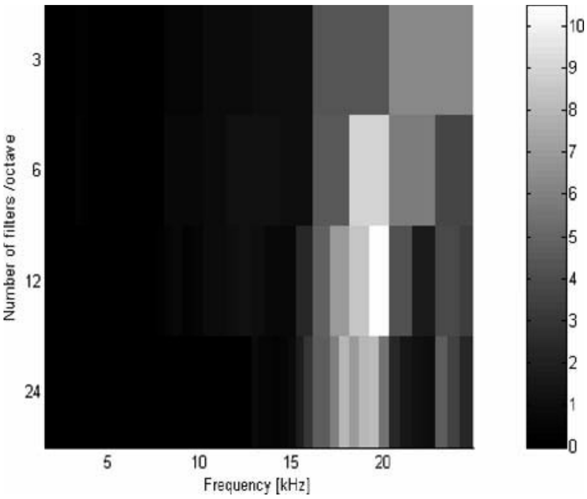

Figure 10 Image representation of SK variation for 4 filter banks; namely (3,6,12,24) filters/octave

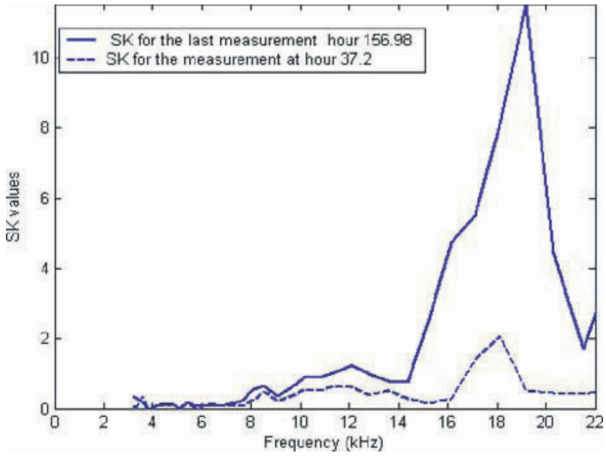

Figure 11. SK variations between first measurements at hour 37.2(dotted) and last measurement at hour 157

In figure 13, the harmonics of the carrier are highlighted. It is quite clear that the planet pass frequency (3 times carrier speed) and its harmonics show strongly in the spectrum. These are indicated by (x) in the same figure.

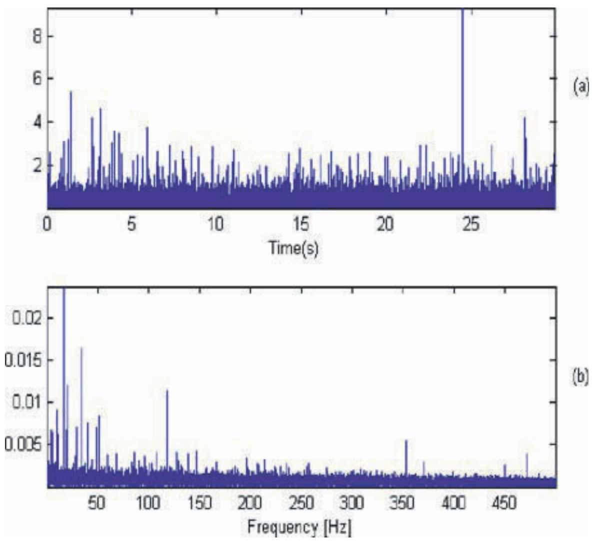

Figure12 (a) Squared envelope and (b) envelope spectrum of the filtered signal *(last measured signal)*

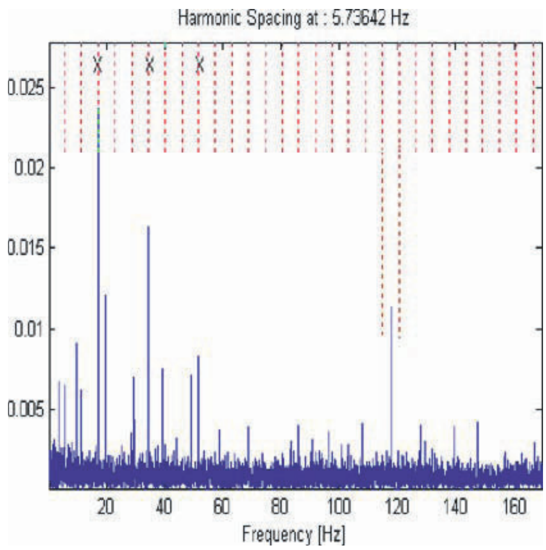

Figure13 Envelope spectrum showing the harmonics of the carrier - (dotted)- and the planet pass frequency as indicated by (x)

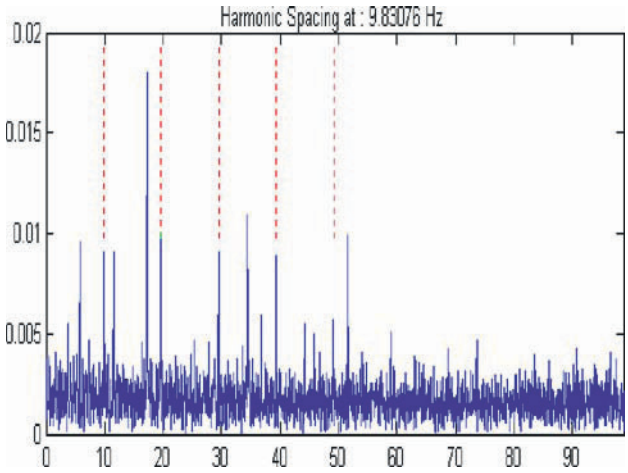

Figure14 Squared envelope spectrum showing the harmonics of 9.8 Hz

Figures 14 and 15 show the other dominant frequencies that exist in the envelope spectrum. A family of frequency spacing 9.83 Hz, shown in figure 14, and a family of spacing 117.69 Hz, shown in figure 15.

In Section 2.2 of this paper, interesting frequencies and bearing defect frequencies were calculated. These have been consulted at this stage to see if a match exists with the frequencies appearing in the envelope spectrum.

A search for 9.83 Hz and 117.69 Hz was conducted and a match was found with the frequencies of one of the bearings in table 3. This is the planetary bearing, which is a two-row bearing. The frequency at 9.83 Hz matches its cage frequency relative to the carrier (FTF), while the 117.69 matches that of the inner race (BPFI).

Figure 16 shows the sidebands around 117.69, which are related to the 9.83 Hz. This is because of the interaction between the inner race fault and the roller faults

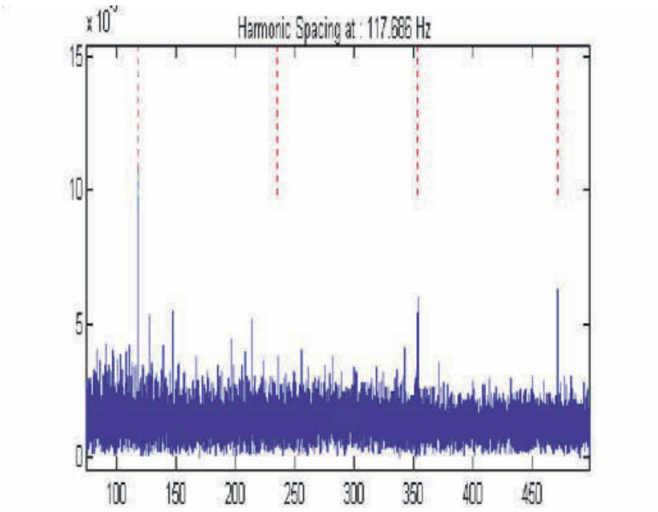

Figure15 Squared envelope spectrum showing the harmonics of 117.69 Hz

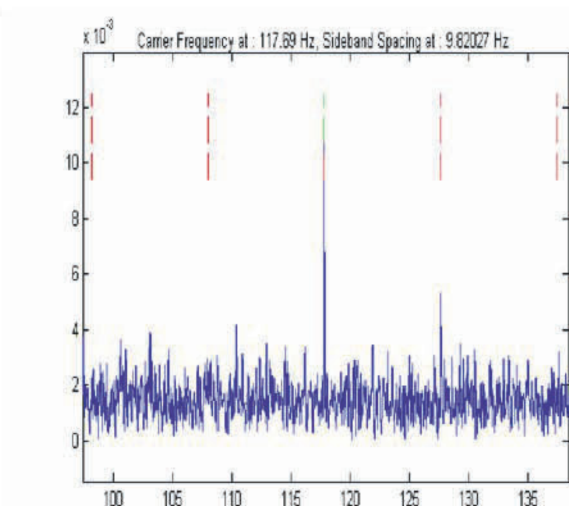

Figure 16 Sidebands around the 117.69 Hz

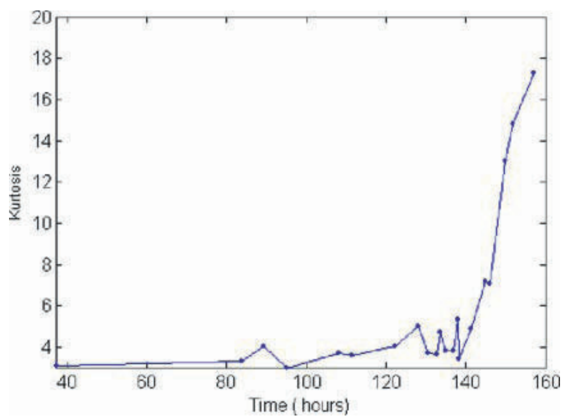

Figure 17 Kurtosis of filtered signal based on the optimum filter stated by the SK analysis

This is a clear indication of the source of the excitation sensed by the SK. *A defective planetary bearing* exists in the system. The existence of the (FTF) and its harmonics in the envelope spectrum, as seen in figure 14, and the BPFI with harmonics and sidebands – figures 15 and 16 - indicates a variation at cage frequency (usually due to differences between the rolling elements) and localised inner race faults.

4 PROGNOSTICS AND FAULT SEVERITY INDICATORS

One of the key issues in bearing prognostics is the ability to detect the defect in its incipient stages, which in turn gives enough time to track its development and avoid any catastrophic failure. SK armed with recent optimisations and enhancements gives a clear separation of the signal arising from a bearing defect, and thus is ideal for being implemented in prognostic models. It gave a good measure of the severity of the fault (figure 17) when compared to the amount of metal wear debris in the oil (figure 18).

Constant percentage bandwidth (CPB) comparisons were also performed to see how the fault severity is tracked using this technique. In the CPB analysis, as the name suggests, spectra used for comparisons are of constant percentage bandwidth (CPB), rather than of constant bandwidth and cover a wide frequency range of three decades.

Figure 19 shows a 3D plot of the CPB comparisons (linear frequency scale), showing where the most excited bands are, and how this evolves with time i.e. as the bearing condition gets worse. A clear increase of the dB difference is seen around 18 kHz frequency (which matches the results earlier presented through the analysis of SK). However, neither the values, nor the pattern indicates the severity sensed by the accumulated mass of wear detected in the oil, or the increase in the envelope spectrum as presented in the diagnostic section between the start of the test and the final measurement. A significant change is normally 6 dB or more. The CPB spectrum comparison gave a weak indication of the deterioration but could not be considered significant. There was also little change in the temperature of the oil (figure 20).

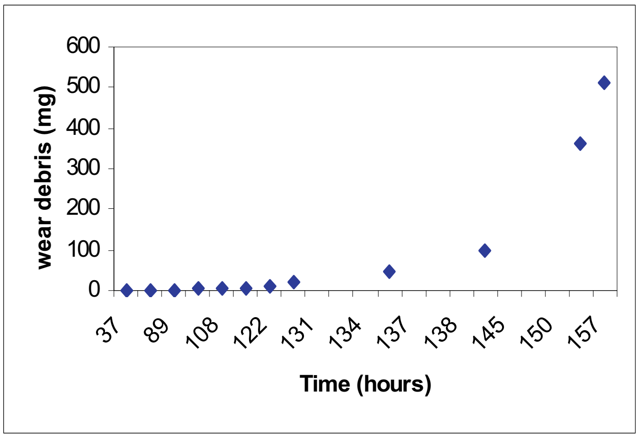

Figure 18 Accumulated wear debris as test proceeded

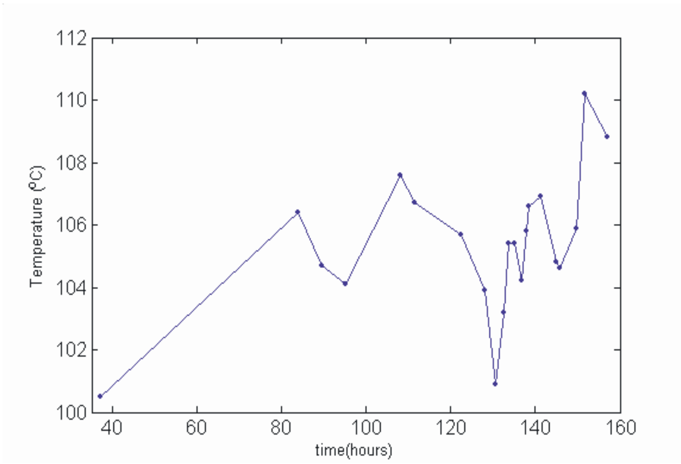

Figure 20 Oil Temperature variations as test proceeded

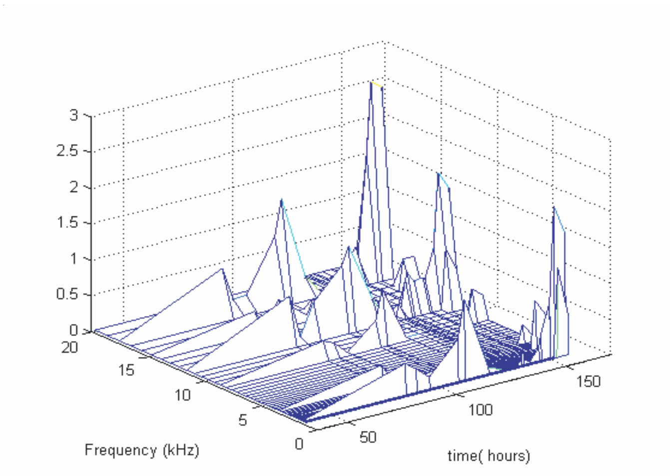

Figure 19 Constant Percentage Bandwidth (dB) - Reference measurements at hour 37.2

Figure 19 shows a 3D plot of the CPB comparisons (linear frequency scale), showing where the most excited bands are, and how this evolves with time i.e. as the bearing condition gets worse. A clear increase of the dB difference is seen around 18 kHz frequency (which matches the results earlier presented through the analysis of SK). However, neither the values, nor the pattern indicates the severity sensed by the accumulated mass of wear detected in the oil, or the increase in the envelope spectrum as presented in the diagnostic section between the start of the test and the final measurement. A significant change is normally 6 dB or more. The CPB spectrum comparison gave a weak indication of the deterioration but could not be considered significant. There was also little change in the temperature of the oil (figure 20).

5 FAULT INSPECTION AND VERIFYING THE FINDINGS

A good result was achieved for the analysis of the test data. The fault was in one of the planet gear support bearings as has been indicated in the analysis (figure 21.a). Furthermore there was damage to the inner race (figure 21.b) correctly identified, and to the rolling elements as well (figure 21.c). The fault, which developed in the inner race and the rolling elements, showed its signature clearly in the envelope spectrum through the harmonics of the inner race pass frequency, which were modulated by the load variation frequency in the last stages, indicating severe damage. SK gave an excellent measure of the severity of the fault and the bearing degradation process was clearly represented by its evolution. Other tested parameters for severity analysis such as CPB analysis and vibration statistics of the raw signal gave little indication of the fault. There was also little change in the temperature of the oil. The end result of the processing algorithm (envelope spectrum) contains all the necessary information and the whole algorithm can be automated for a complete identification of any bearing related faults. This is in contrast to the traditional diagnostic techniques, which require the analyst to select a suitable band for performing the envelope analysis (requires historical data or can be done by trial and error), and may need more than one position to measure at.

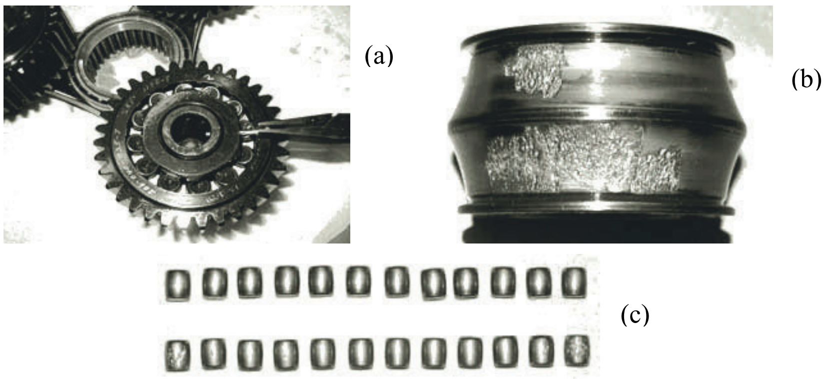

Figure 21 (a) Defective bearing, (b) Spalled inner race (c) Defective rollers

6 CONCLUSIONS

The presented processing algorithm needs minimal user interference to remove the strong gear signal and to determine the suitable band for the envelope analysis. No historical data is required and one sensor would be enough to detect faults in most cases. The presented processing algorithm for detecting faults in rolling element bearings is in fact an easy and effective tool that requires minimal interference and experience from the user. The algorithm is not only able to detect faults in noisy and awkward situations in a clear way but also is capable of tracking the fault severity.

DEVELOPMENT AND IMPLEMENTATION OF MAINTENANCE PERFORMANCE MEASUREMENT SYSTEM: ISSUES AND CHALLENGES

Uday Kumar

Division of Operation and Maintenance Engineering, Luleå University of TechnologyV971 87 Luleå, Sweden

Abstract: The cost of maintenance and its influence on the total system effectiveness is too great for asset managers to ignore. The modern days asset managers need to know the relationship between the outputs from the investments in the maintenance in terms of total contribution to the business goal and the inputs to maintenance processes. In addition, without any formal measures of performance, it is difficult to plan control and improve the maintenance process. The discussion in the paper is based on some of the R &D projects being pursued at the Division of Operation and Maintenance Engineering at Luleå University of Technology, Luleå in close cooperation with infrastructure owners and asset managers in Sweden. This paper will discuss the issues and challenges associated with development, implementation of maintenance performance system and maintenance performance indicators for effective management of infrastructure and industrial assets.

Key Words: Maintenance performance, Total maintenance effectiveness, Overall equipment effectiveness (OEE), Maintenance performance indicators, external effectiveness, internal effectiveness.

1 BACKGROUND AND INTRODUCTION

Many companies with capital intensive assets have accepted that an effective management of maintenance process is key to sustaining the long term profitability of their business organizations. With increasing awareness that maintenance creates additional value in the business process; more and more companies are treating maintenance as an integral part of the business process, and the measurement of maintenance performance has become an essential element of strategic thinking of many companies involved in service and manufacturing industry. Without any formal measures of performance, it is difficult to plan control and improve the maintenance process. Maintenance as an important support function in business with significant investment in physical assets plays an important role to achieve the organizational goals [1]. The following factors have made pressing demands towards an effective management of maintenance performance even more challenging:

1.1 Measuring value created by the maintenance

The most important reason for implementing maintenance performance system is to measure the value created by maintenance process. As a manager, one must know that what is being done is what is needed by the business process, and if the maintenance output is not contributing/creating any value for the business, it needs to be restructured. This brings the focus on doing right things keeping in view the business goal of the company [2].

1.2 Justifying investment

The second basic reason for measuring maintenance effectiveness is to justify the organization's investment made in maintenance organisation; not so much as to whether you are doing the right thing, but whether the investment they are making is producing a return on the resources that are being consumed.

1.3 Revising resource allocations

The third basic purpose for measures of effectiveness is to determine if additional investment is required and to justify the investment. Alternatively, such measurement of activities also permits you to determine whether you need to change what you are doing or how you can do it more effectively by using the resources allocated.

1.4 Health safety and environmental (HSE) issues

The fourth reason can be to understand the contribution of maintenance towards HSE issues. A bad maintenance performance can lead to accidents (safety issue) and pollutions (health hazards and environmental issues), besides encouraging an unhealthy work culture and environment.

1.5 Focus on knowledge management

Many companies especially those involved in delivery of maintenance and product support services are focused on effective management of knowledge in their companies. Furthermore**,** Technology is ever changing and is changing faster in the new millennium. This has brought in new sensors and embedded technology, information and communication technology (ICT) and condition based inspection technology like vibration, spectroscopy, thermography and others, which is replacing preventive maintenance with predictive maintenance. This necessitates a systematic approach for the knowledge growth in the field of specialization.

In the following sections, an attempt has been made on the basis of our experiences gained from R & D projects in the area of performance measurements from Norwegian Oil and Gas industry [3, 4], Swedish Mining Industry [5] and Swedish Railway sector [6, 7] and from literature survey to discuss these issues and challenges associated with development and implementation of maintenance performance indicators (MPIs).

The objective of this paper is to examine and discuss some of the important the issues and challenges associated with development and implementation of a maintenance performance system.

2 MAINTENANCE PERFORMANCE SYSTEM INDICATORS

Maintenance performance measurement is a complex task involving measurement of multiple inputs and multiple outputs. One way of measuring the performance is to develop performance indicators and implement them with a total involvement of entire organisation. It's more or less similar to implementing Total Productive Maintenance (TPM) [8]. Maintenance performance indicators (MPIs) are used for the measurement of maintenance performance, as performance indicators are an indication of performance [9]. Also, an indicator is a product of several metrics (measure), when used for measurement of maintenance is called a MPI. Maintenance Performance Indicators (MPIs) show the value of the contribution of maintenance process towards the ultimate objective of the company as a whole. The structure of the MPIs needs to be considered from different aspects, like the multi-criterion and hierarchical levels and from total maintenance effectiveness.

Measurement tells us the status of the job carried out and what action to be taken there after, and to indicate where those actions should be targeted. The selection of MPI depends on the way in which the maintenance performance measurement (MPM) system is designed and developed for application. For example, the MPIs could be used for financial reports, for control of performance of employees and other resources like the costing and appraisal system, for finding competitive position with in business organizations like the customer satisfaction and competitor ranking, for health, safety and environmental (HSE) rating for production industry, and finding internal effectiveness, like the overall equipment effectiveness (OEE) for the manufacturing and process industry. The selection of maintenance performance indicators to follow up the contribution of maintenance is an important but a complex issue. The structure of the performance indicator needs to be considered from different aspects.

SMART test developed by the Department of Energy (DOE) can be used effectively to test the attributes of the indicators [10]:

S: Specific; clear and focused to avoid misinterpretation. Should include measure assumptions and definitions and be easily interpreted. Maintenance cost/ton of ore

M: Measurable; can be quantified and compared to other data. It should allow for meaningful statistical analysis. Avoid "yes/no" measures except in limited cases, such as start-up or systems-in-place situations.

A: Attainable; achievable, reasonable, and credible under conditions expected.

R: Realistic; fits into the organization's constraints and is cost-effective.

T: Timely, the indicator should be reflecting the status in real time and on time.

3 TOTAL MAINTENANCE EFFECTIVENESS

A quick search of literature shows no dearth of performance measures being used by industry. Unfortunately most of them are focused on either measuring financial results or the health of the process in piece meal manner such as system availability, consumption of resources per unit of measures adopted etc. It was difficult to find any discussion on measuring total effectiveness of maintenance process. Some of the notable exceptions are from Sweden [14].

The total effectiveness is a product of the internal effectiveness characterised by issues related to effective and efficient use of resources to facilitate the delivery of the maintenance and related services to be delivered in the most effective way (engineering and business process related to planning and resource utilization) and external effectiveness characterised by customer satisfaction, growth in market share etc. [16]. See figure 1.

The performance measures for internal effectiveness are concerned with doing things in right way and can be measured in terms of cost effectiveness (maintenance costs per unit produced), productivity (number of work orders completed per unit time) etc. and deals with managing resources to produce services as per specifications.

The performance measures for external effectiveness deals with measures that have long term effect on companies profitability and are characterised by doing right things that is delivering services in a way (quality and timeliness) that as per customer requirement. Here the concept of delivering not only the services required by customers; but helping them in their other business process related to their own services. Such attitude often helps in market growth and capturing or creating new markets.

Whenever, we develop a balanced maintenance measurement system, we have to examine all the related criteria and parameters associated with the system. The concept of total effectiveness includes both the external and internal effectiveness. In any organization, first the maintenance process needs to be studied in detail and external effectiveness factors like the stakeholders requirements (front end processes) need to be understood. Then based on the internal resources and capabilities, supply chain management (back end processes), the maintenance objectives and strategies are formulated matching and integrating with that of the corporate ones. An important objective of the measurement system should be to bridge the gap and establish the relationship between the internal measures (causes) and the external measures (effects) [17].

Traditionally, the concept of OEE [8 used by the company is inadequate as it only measures the internal effectiveness. For example, the OEE level of an organization may be at 80%, but if the external effectiveness is as low as 60 %, the total maintenance effectiveness will certainly be low. The index for customer satisfaction; like the, quality (of repair/modification), timeliness of delivery, health, safety and environmental (HSE) index, and call back of product (promptness of response), are the decisive factors of total maintenance effectiveness as given at Figure 1.

For measuring the total maintenance effectiveness, a balanced, multi-criteria and hierarchical MPM system is considered to be effective, which considers both the external and internal effectiveness [18]. A need is also exists to workout an overall total maintenance effectiveness considering all the factors and criteria as discussed above.

In general measures for total maintenance effectiveness must be combined with process owners' capability to change processes and adopt to new technology and work practices without any major involvement of resources and at right time.

Front end processes

Total maintenance effectiveness	External Effectiveness	1. Customer satisfaction index - Quality - Timeliness of delivery
	Internal	Productivity Cost per unit

Back end processes

Total maintenance effectiveness = Internal effectiveness x External effectiveness

Figure 1. Total maintenance effectiveness

The MPIs are also considered from multi hierarchical levels of the organization. From hierarchical levels, the first layer could be at the corporate or strategic level, the second level deals with the tactical or managerial level and the third level deals with the functional/operational level. Depending on the organizational structure, the hierarchical levels could be more than three. Three level hierarchical levels are given in Figure 2.

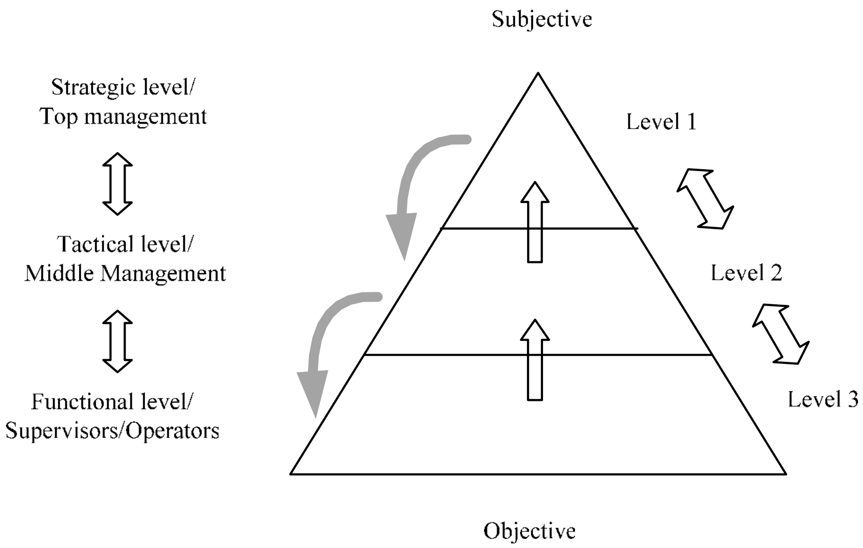

Figure 2. Subjectivity increases as we integrate the objective outcomes fromthe shopfloor to get key performance indicator at higher level

4 ISSUES AND CHALLENGES IN DEVELOPING MPIS

There are numerous issues and challenges associated with development of maintenance performance indicators which needs to be considered while developing and implementing MPIs in a company. Some of these are "what should be measured and how many measures are required, what feedback is necessary and who should receive the details of measures, what type of data is required and how to collect data, how the data is going to be used and analysed (which information software), what kind of information is needed for decision making, who should be responsible for measurement and reporting, and, who should sponsor/own the overall measurement process?. Many of these are taken care of by various maintenance indicators developed during the last 2-3 decades. Most of these are focused on measuring the internal effectiveness [1, 11, and 12]. Some of the researchers have focussed on external effectiveness with special focus on external stake holders requirements [13].

However the main issues of measuring the total maintenance effectiveness is still under study by many researchers involved in studying the maintenance business process and its work processes [14, 15].

The major issues challenges while developing MPI are namely:

- Measurement of Total maintenance effectiveness (TME): How to develop measures that reflect the total maintenance effectiveness?
- Involvement of strategic and operating managers in developing and implementing performance measures; How to involve every one in the process of maintenance performance measurement? Involvement of all employees in MPIs development and implementation process, so that everyone speaks the same language. As recommended in TPM philosophy, the measurement process begins at the highest levels within companies.
- Corporate goal and vision: How to integrate and link the outcome from maintenance at shop floor level into the corporate business goal and strategy at top management level? How to break down the corporate goals and strategy into more objectives targets/tasks for operating managers and engineers at shop floor level and integrating and linking the objective output at shop floor to the corporate goals and strategy? See for details [15].

Before commencement of the development process for indicators, a detailed understanding of the maintenance business process and its strategic positioning in the company is a must.

It is a challenge to inetgrate MPIs generated at shop floorlevel by operating managers to key performance indicators and linking back them to companies strategic visions and goals. The following questions needs to be answered to determine the effectiveness and quality of the MPI; those are identified to be used in the MPM system.

4.1 Does the MPI take care of stakeholders requirements?

The MPM system has to take care of the stakeholders' requirements from the organizational effectiveness, both from external and internal perspectives. In fact this should be the prime requirement of the MPM system.

4.2 Is the MPI measurable objectively?

The MPI should be measurable in comparison with the set target. It should be quantifiable and indicate an objective result of the maintenance performance. The indicator should be specific and must be identifiable with the objective it is meant for.

4.3 Does the MPI looks in to the efficiency and effectiveness of the organization?

The organizational effectiveness and efficiency are most important issue in to day's very dynamic competitive business. The importance of the effectiveness and efficiency of the operation and maintenance process of the organization needs no emphasis. The MPI formulation therefore, must look in to these aspects from the conceptual stage.

4.4 Does the MPI indicate a clear statement of the expected performance results?

The MPI need to be specific and clearly state the performance it is going to measure.

4.5 Are the MPIs challenging and yet attainable?

The MPIs should be achievable and at the same time they should be challenging. They should be able to create a interest for continuous improvement amongst the employees of the organization.

4.6 Are the MPIs linked to the benchmarks or milestones quantitatively /qualitatively?

The MPIs should be linked to the benchmark or standardization strategically, so that increasingly achievable milestones can be set. These milestones are set keeping the capability, resources and plant capacity in mind.

Some of the questions (5Ws and 1H) that need to be considered/answered, while developing the performance measurement system and indicators are:

- why measurement is needed,
- what should be measured to provide the right information and what type of data is required,
- who should own the process and measure it,
- where the details of measures are required to be undertaken
- when the data and information are required for decision making
- how to collect the data, and making it clear to all involved that, data is neither information nor knowledge, but provides a basis for making correct decision about the status/health of the system

Finding answers to these questions will lead to development of more relevant maintenance indicators and will also facilitate easy and effective implementation of the performance measuraement system in the company.

5 SUMMARIES OF THIS PAPER AND SCOPE FOR FUTURE WORK

In this paper some of the most important maintenance performance measurement issues and challenges are presented in brief. It is also proposed that a multicriterion hierarchical MPIs and MPM system be developed for a relevant, interpretable, reliable, cost and time effective, easy to implement, update and maintain the system for regular use by stake holders at various levels. The indicators at subsystem/ component level, plant level and corporate level are linked with that of the organizational objectives and strategy. Each measure that is selected must be linked back to the company's vision and goals. If this cannot be done, then the measure does not have the requisite attributes. The first step in developing MPIs is to involve the maintenance crew, who are responsible for the work and understanding the maintenance and business work process.

Abstract: In modern factories, production equipment maintenance represents a significant and important task to ensure that plant facilities continue to function properly. On the other hand, intelligent production dispatching generates maximal outputs for changing production demands. In this research, a system architecture, called Integrated Intelligent Equipment Maintenance and Production Dispatching (IEMPD) building on the JAVA Expert System Shell (JESS), is designed and developed to support collaborative maintenance, remote equipment diagnosis, job dispatching, and production simulation/verification. The IEMPD system is applied for dynamic shop floor equipment maintenance and production control. In the past, trouble shooting analyses were based on the experiences and skills of equipment engineers. The IEMPD platform allows knowledge engineers to construct, manage and maintain rules easily and flexibly to satisfy ever-changing collaborative maintenance and production requirements. Through the rule base, maintenance knowledge and experiences can be created, accumulated, shared and reused. Thus, IEMPD can rapidly help maintenance engineers identify the faults and suggest solutions. Further more, IEMPD can assist production engineers plan dispatched jobs based on the orders and the equipment status. This research uses a machining flexible manufacturing system (FMS) as the case study to demonstrate the IEMPD capability in supporting integrated intelligent maintenance and production.

Key Words: Rule Base, Knowledge System, Expert System, Intelligent Equipment Maintenance System, Production Dispatching, JESS

1 INTRODUCTION

Along with the global changes of market conditions as well as the impact of competition, speed and flexibility of production become key success factors for enterprises. One who can produce goods according to customer's demand, shorten delivery time and offer products with high quality and good customer services will survive the harsh challenges in the global market-place. Nowadays, factories are capital-intensive requiring highly sophisticated and automated production equipments. Therefore, the most challenging task during manufacturing processes is to diagnose and analyze the equipment problems and identify proper maintenance and repair methods effectively. Research has shown that a company can easily increase 20% of its operating cost if it does not maintain its production equipment properly [2]. Hence, it is important to develop intelligent diagnosis and maintenance systems to prevent equipment failures and unexpected breakdowns. An intelligent diagnosis and maintenance system should be Internet/web-enabled. It consists of intelligent machine monitoring, e-prognostic and e-diagnostics to keep manufacturing operation machines in good operating condition. Besides effective monitoring of the machine statuses and the good diagnosis and maintenance analysis to ensure that equipment continues to function properly, it is important to make the operation processes stable and smooth according to shop floor control logics. There is a growing interests in intelligent manufacturing shop floor control, specifically in the area of simulation analysis to predict the future impact of short-term decisions on the performance of a manufacturing system. With on-line simulation, the current status information can be used to predict system performance and to develop short-term scheduling and control alternatives. In order to perform the above-mentioned various tasks, an intelligent system must collect, extract, and manage adequate domain knowledge constantly [23]. Therefore, there are many research focusing on improving the rule-based expert systems. Lin, Tseng, and Tsai (2003) [15] proposed an object-oriented rule-based paradigms knowledge model based on the concept of learning and thinking behaviors of human. A rule-based paradigm provides us with general facilities for deductive retrieval and pattern matching, and the object-oriented programming provides us with an intuitive structure for programming in the form of class hierarchies.

In this research, an Integrated Intelligent Equipment Maintenance and Production Dispatching (IEMPD) platform using web-enabled JESS technology is designed and developed to demonstrate how the tasks can be realized and implemented effectively in the FMS maintenance domain. Further, this research uses the FMS dispatching control case to demonstrate the knowledge-based reasoning capability for intelligent production planning.

This paper is divided into five sections. In Section 2, the background research for rule-based expert system, JESS technology, and intelligent diagnosis and maintenance system are depicted. In Section 3, we describe the conceptual architecture of IEMPD system. Section 4 reveals a case study for the shop floor dispatching control of a machine shop FMS. Finally, the conclusions are drawn in Section 5.

2 BACKGROUND RESEARCH

In this section, the background research is divided into three parts detailing rule-based expert system, JESS technology, and intelligent maintenance and production planning issues.

2.1 Rule-based Expert System

The artificial intelligence (AI), since its inception in 1960's, has been widely developed in a variety of domains to solve problems and support decision making. Among well established AI methodologies, the most researched area is in Expert System (ES) [12] [21] [28]. Expert system uses heuristic knowledge captured in a software program to solve problems that ordinarily require human reasoning and accumulated expertise [24]. Figure 1 shows the typical architecture common to rule-based expert system (RBES), consisting of Knowledge Base (Rule Base), Fact Base (Working Memory), and Inference Mechanism (Rule Engine).

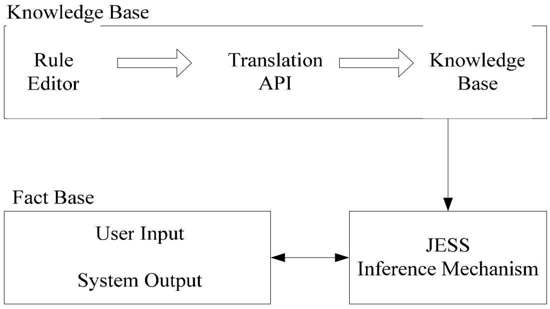

Figure 1. The architecture of a rule-based expert system [30]

- Knowledge Base (Rule Base): The development of an expert system involves the construction of the knowledge base by acquiring knowledge from experts or documented sources. The knowledge base contains domain knowledge useful for problem solving in rule formation [20]. Rule is a natural knowledge representation, in the form of the 'IF … Then…' structure.
- Fact Base (Working Memory): The facts database contains a set of facts, which can be entered by user or created automatically by the system. Facts must be presented in the working memory in order for a rule to become available for activation [17]. A set of facts and a set of rules that can be fired by patterns form the assertions. The basic operations of the assertions are to manipulate facts and rules in the knowledge domain, such as defining facts and rules, deleting rules, creating rule sets, as well as adding and removing facts from working memory.
- Inference Mechanism (Rule Engine): The inference mechanism, an interpreter of rule-based expert system, uses an iterative match-select-act cycling model. In act phase of the cycle, a fired rule may modify or generate some facts [15].

An rule-based expert system (RBES) has many advantages [19]. The first advantage is naturalness of expression since experts rely on rules rather than on textbook knowledge. The second advantage is modularity that permits systems easy to construct, to debug, and to maintain. Restricted syntax and ability of explanation are also the advantages of RBES. RBES has been widely applied in several domains. For instance, Wagner et al. (2002) [27] has proposed using a knowledge-based system (KBS) to financial problem domains. Yao, Lin, and Trappey [29] have used knowledge-based intelligent reasoning to support dynamic equipment diagnosis and maintenance. In the production verification aspect, Chiang, Trappey and Ku have developed a mechanical design intelligent system using JESS knowledge platform for collaborative designs [7].

2.2 JESS Technology

Built on top of the Java language platform, Java Expert System Shell (JESS) has become a popular ES development tool for intelligent system development. JESS is a simple and powerful tool to allow for the building of multiple ES applications in a single platform. JESS is essentially a reimplementation of a subset of the earlier CLIPS shell [8] in Java environment. CLIPS is the original expert system shell that formed the inspiration for Jess. Jess uses a customized Rete inference engine that is different than the one in CLIPS, but Jess can run most CLIPS files.

The JESS shell provides the basic elements of an expert system including fact-list, knowledge base that contains all the rules and inference engine which controls overall execution of rules as shown in Figure 2. Figure 2 shows the architecture of JESS and how all the parts fit together, including:

- Pattern Matcher: decides what rules to fire and when.
- Agenda: schedules the order in which activated rules will fire.
- Execution Engine: responsible for firing rules and executing other code.

When executing inference process, rules and facts are compared using pattern matcher. The matched rules are activated into a conflict set. Afterward, the conflict set resolves into agenda (called conflict resolution) and, then the execution engine fires on the agenda. The engine fires only once on any given set of facts in the working memory. The engine cycles recursively until all rules are satisfied.

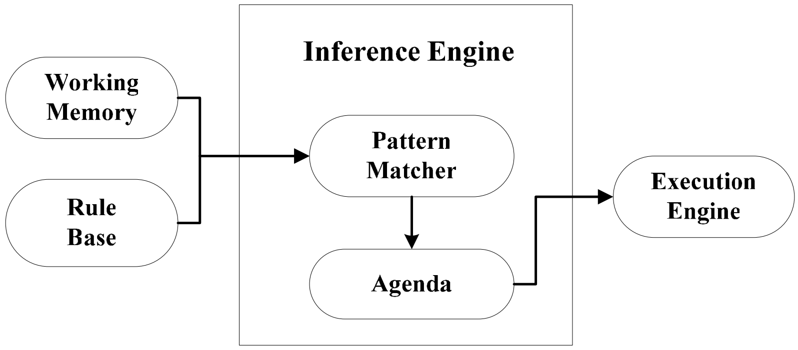

Figure 2. The architecture of JESS [10]

There are three types of facts defined in JESS [11]:

- Ordered Facts: Ordered facts are simple lists, where the first field (the head of the list) acts as a sort of category for the fact.
- Unordered Facts: Ordered facts are useful, but they are unstructured. Sometimes there is the need for organization. In the object-oriented languages, objects have named fields or slots in which data appears. Unordered facts offer this capability.
- Shadow Facts (Definstance Facts): Shadow facts are unordered facts whose slots correspond to the properties of a JavaBean. JESS lets user put Java objects into working memory as long as they follow the JavaBean specification. Shadow facts connect JESS' working memory to the application containing the JESS engine.

The expert knowledge and user inputs are stored as rules and facts in the JESS knowledge engine. The rules are "if then" statements that have a left-hand-side part (IF-portion) and a right-hand-side part (THEN-portion) with the "implies" operator in between. Rules are responsible for taking actions based on facts in the knowledge base. Whenever the patterns of the rule match with existing facts, the rule is activated and its right-hand-side actions executed. JESS uses the Rete algorithm to match the rules and facts. Then the rules will be executed to produce different results accordingly [4]. JESS's major advantage is its capability to easily integrate with other Java programs through its well-defined API [9].

2.3 Intelligent Maintenance and Production Planning

The development of on-line equipment diagnosis and maintenance systems, based on the latest information technology, has gained popularity among equipment providers and users [3] [25]. Some literatures [14] [6] proposed SPC and Run-by-Run methods to control the quality and eliminate the variations. Those methods not only show the quality of products but also reflect the running condition/status of the working equipments. Many papers have attempted to combine two or more methods, e.g., neural network, expert system and fuzzy system, to monitor or diagnose manufacturing systems. For example, Wang, Liu, and Griffin (2000) [26] developed a combination system of neural network and expert system for diagnosis with superior performance comparing to the old approaches. Shal and Morris (2000) [22] proposed a fuzzy expert system for the equipment fault detection using statistical process control of industrial processes.

Preventive maintenance affects the performance of equipments significantly. Efficient maintenance increases productivity and production quality, as well as reduces product defects. Some research have developed remote maintenance control through Internet. Lee (2001) [13] suggested a framework for web-enabled and Internet-based Intelligent Maintenance System (IMS) to seek near-zero-breakdown equipment conditions. Balakrishnan and Honavar (2003) [1] examined and compared several different approaches to the design of intelligent systems for diagnoses. Bengtsson (2003) [2] discusses the technical components of a complete condition-based maintenance system for industrial robot fault detection and diagnosis. About production plan and performance evaluation, Ngai and Cheng (2001) [16] proposed expert system application for performance measurement of advanced manufacturing technology projects. Performance evaluation or productivity analysis also fall in the area of auditing and internal control assessment [5]. Rao, Miller, and Lin (2005) [18] describes the framework for a comprehensive productivity analysis procedure and presents a prototype expert system that attempts to provide this analysis.

Although many systems and tools have been developed in the maintenance and production domains, effectively and dynamically designing, implementing and updating these systems, especially in e-manufacturing maintenance applications, is still a challenging task. The challenges are mainly in the ill-defined nature of the fault symptoms, real-time discovering of faults, complexity of knowledge representation and ever-updating diagnosis and maintaining rules. This paper addresses how the maintenance and production knowledge can be expressed dynamically and utilized in various sites using cyber-enabled JESS technology.

3 CONCEPTUAL ARCHITECTURE OF IEMPD

In this research, a web-based prototype IEMPD, which combines rule-based knowledge system and inference engine, is designed and implemented to support collaborative maintenance, remote equipment diagnosis, job dispatching, and related production decision via Internet. The system architecture and main functions of IEMPD, conceptual modeling of knowledge base and rule inference process are presented in the following sub-sections.

3.1 System Architecture and Main Functions of IEMPD

Figure 3 shows the conceptual architecture of the Integrated Intelligent Equipment Maintenance and Production Dispatching (IEMPD) platform. The system architecture is divided into three parts (i.e., IEMPD, User, and Data) to ensure the flexibility of system. All messages in the platform can be transmitted fast and efficiently through the Internet. IEMPD consists of three main system modules, i.e., (1) Knowledge Management Module, (2) Project Management Module, and (3) System Administration Module. The main functions of these modules are outlined as follows:

1. Knowledge Management Module has the following sub-functions.
   - Knowledge Type Management
   - Knowledge Component Management
   - Knowledge Component Attribute Management
   - Document Management
   - Mathematical Function Definition
   - Mathematical Function Attribute Management
   - Measurement Unit Management
   - Measurement Unit Conversion Management
   - Rule Management
   - Rule Sets Management
2. Project Management Module consists of sub-functions as follows.
   - Project (Case) Management
   - Project Role Management
   - Project Functions Management
3. System Administration Module includes sub-functions as follows.
   - System Administration
   - Authority Management
   - New Functions Suggestion Management
   - System Functions Management
   - User Management
   - Role Management

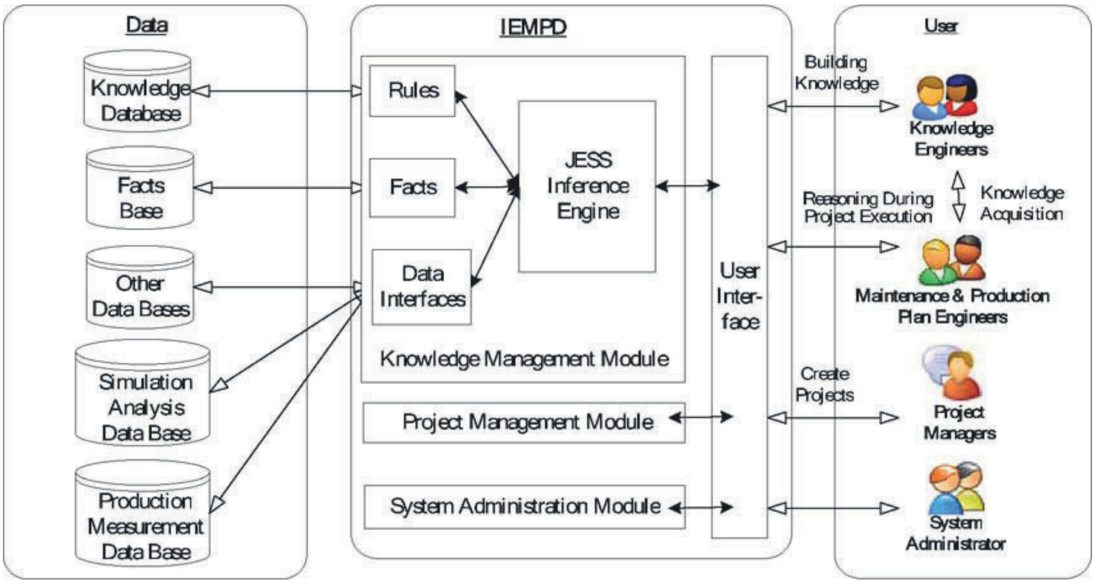

Figure 3. The conceptual architecture of IEMPD

IEMPD allows different members of teams participate through Internet for collaborative maintenance, remote equipment diagnosis, job dispatching, and production simulation/verification. IEMPD has four roles of users participating collaboratively in the system platform. They are knowledge engineers, project manager, maintenance and production plan engineers, and system administrators.

Knowledge engineers input knowledge rules into project database and fact database through the interface of knowledge rule management, which is responsible for managing and maintaining the entire knowledge base. A project manager (PM) can create, execute, save, and delete projects. He/She also has the authority to monitor and manage projects belonging to him/her. Still, a PM can define related variables and select the needed knowledge rule modules. Maintenance and production plan engineers have authority to execute tasks and modify their own profiles. They can input necessary parameters for the reasoning of optimal maintenance or production strategies when execute project tasks. Knowledge engineers usually acquire experiences and knowledge of the production/maintenance from senior equipment maintenance and/or production engineers. A system administrator has the highest authority to permit system functions to specific users. Figure 4 shows a use case diagram in Unified Modeling Language (UML) format for an overview of the IEMPD system modules.

In the data section, project database saves the data about maintenance or production projects (including the definition of projects, tasks, and process logics). The project database will produce rules into inference engine. Fact base saves the fact-format data. When facts in inference engine change, data in fact database will also be updated. IEMPD will connect other databases (e.g., simulation analysis database and production measurement database) to enhance the system capability.

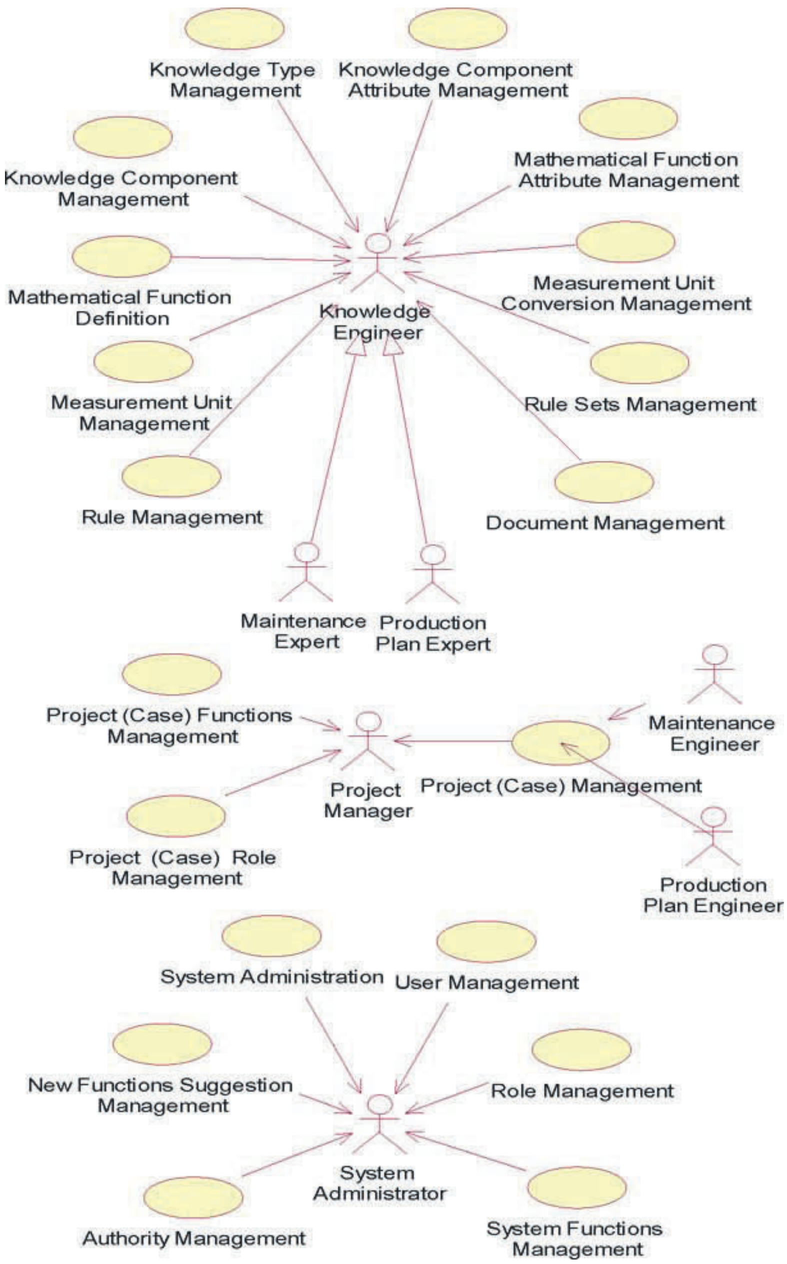

Figure 4. The UML use case diagram for an overview of system functions

3.2 Knowledge Management Module and Its Rule Inference Process

The detailed elements of the knowledge management module are shown in Figure 5. They include the definition and management of knowledge types, knowledge components, mathematical models, knowledge component attributes, mathematical model attributes, documents, measurement units, and rules.

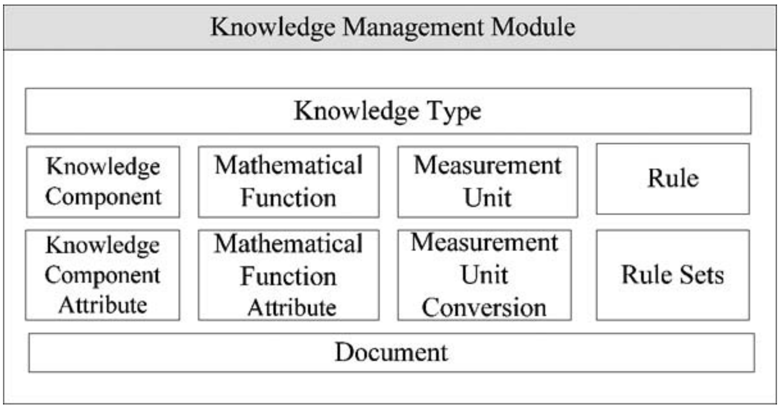

Figure 5. The detailed elements of the knowledge management module in IEMPD

When executing a project for maintenance or production decision, it is important to realize and analysis the relationship between the possible cause and breakdown indications for accurate diagnoses. To detect problems effectively, it is necessary to divide the machine or system into many modules and sub-modules that contain individual rules and facts for inference.

Based on a cognitive analysis of maintenance tasks, the rules are developed. Thus, maintenance and production plan engineers can make decision immediately by using IEMPD inference. In the rule inference process of the IEMPD, some basic data, such as knowledge types, knowledge components, mathematical models, and domain knowledge rules must be defined prior enabling and activation of all functions and rules. The flow diagram in Figure 6 shows the steps of utilizing IEMPD for every case/application of equipment maintenance and supporting production plan.

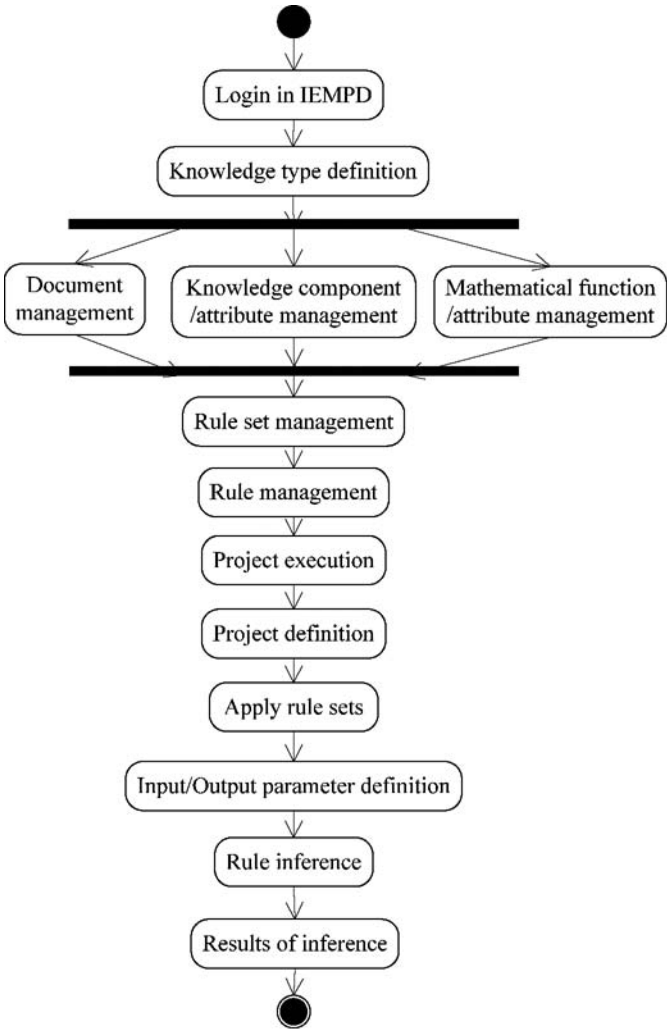

Figure 6. The rule inference process of the IEMPD

4 CASE STUDY

In this research, a prototype IEMPD is developed, which combines rule-based knowledge system and inference engine, to support job dispatching decision in the manufacturing environment. A machining shop FMS dispatching control project is used as a case study. FMS is a flexible and reliable automation system with huge productivity. The FMS consists of various types of capital equipments, e.g., Computer Numerical Controlled (CNC) machines and automated guided vehicles (AGVs). In FMS, the central control computer carries out the flow of works and some of its functions include scheduling jobs onto the machine tools, downloading CNC part-programs, and sending instructions to the AGV system for transportation. By using FMS, manufacturers can produce customized workpieces at a faster rate, making it easier to meet market demand. In the case study, an example FMS machine shop is used to describe the functions of the IEMPD (as shown in Figure 7). The system consists of three CNC milling machines, one CNC turning machine, two industrial robots, inspection station, an automated part storage retrieval system (AS/RS), an AGV for transportation, and an automated cart-based conveyor system. In addition to the automated equipments, a human operator is used to load part onto the AGV.

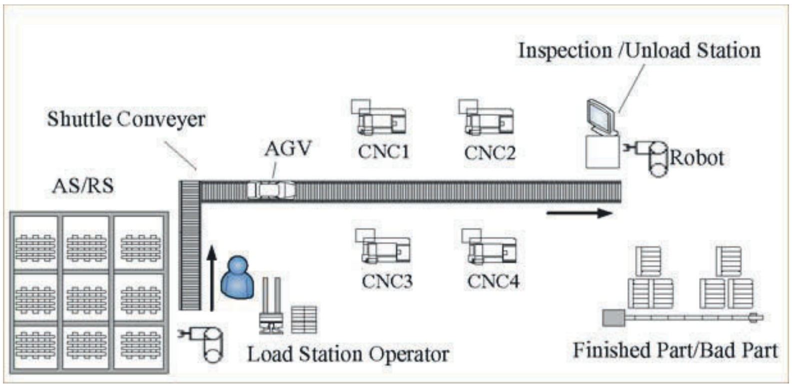

Figure 7. Layout of the machine shop FMS example (NTUT, 2005)

There are nine pallets which are deposited in the AS/RS. Products to be produced are manually loaded onto pallets at a loading station, and the computer system takes over, moving the parts to the various processing stations using AGV. If the next processing station is busy, the AGV will move the part and pallet to the AS/RS according to the Pallet-Number and wait for the next processing station to be idle. After having visited all necessary stations, the part is taken to the unloading station where it is inspected before removing from the pallet by robot. Each processing stations (i.e. CNC1-CNC4, load, unload) has a part buffer for the waiting-in-process (WIP) queues. This research uses the shop floor dispatching control of the example FMS to demonstrate the functions of IEMPD. This integrated IEMPD and FMS structure drives the JESS rule-engine as a “dispatcher” that handles the actual system shop floor control. The related information, e.g., equipment status and part status, can be collected and acquired via monitoring PLC or RFID reader of the FMS as shown in Table 1.

Table 1

Messages sent within the system

Concerning Equipment Information	Concerning Part Information
Operation Machine Status	Part Number and Status
AGV Status	Pallet Number Status
Success Signal of the Operation	Due Date
	Processing Times
	Moving or Waiting
	Processing Routing

Figure 8 shows the data flow through the integrated IEMPD and FMS structure. There is a timer application, which is programmed by the Java Servlet to scan the tables in the intermediary database. Therefore, the information can be trigger and passed to the JESS (Java Expert System Shell) for inferring. The dispatching rules include Shortest processing time (SPT), Earliest Due Date (EDD), and First-in-First-out (FIFO). They are formulated and stored in the fact base for applying to specific project. When IEMPD detects any dispatching indications, JESS automatically generates further message about the next AGV moving guide (from-to). Figure 9 shows the dispatching inference process of the integrated IEMPD and FMS structure using unified modelling language (UML). In this case, the situations of the manufacturing status for the FMS shop floor dispatching decision control are shown in Table 2, Table 3 and Table 4.

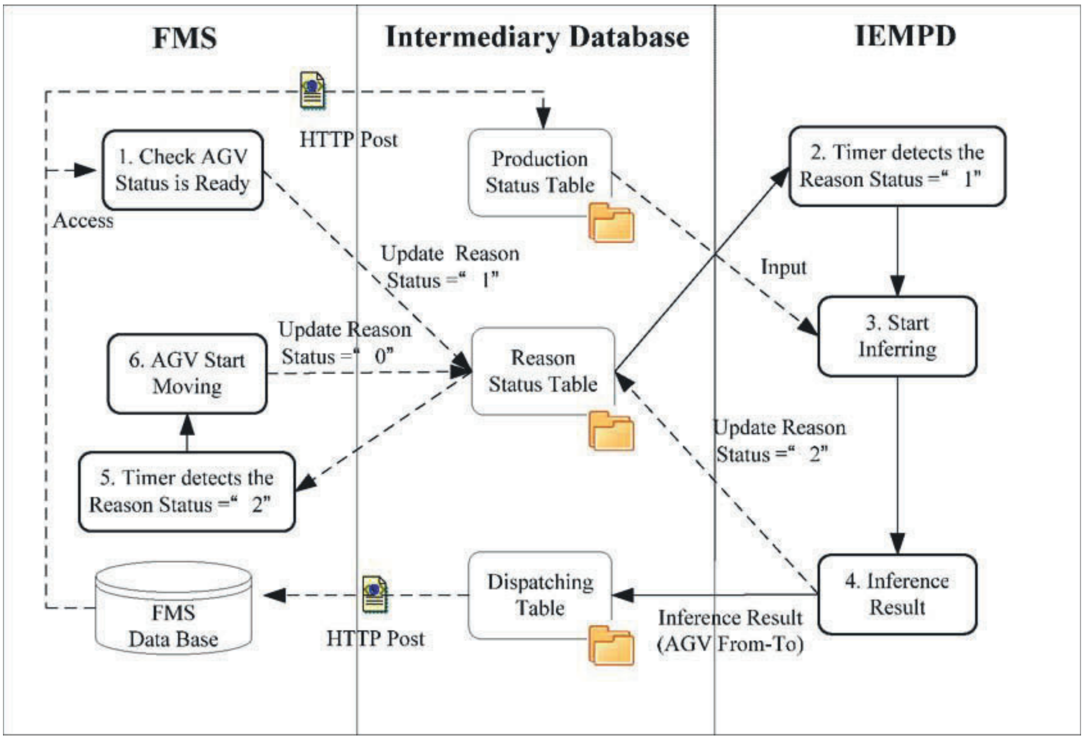

Figure 8. Data flow through the integrated IEMPD and FMS structure.

Table 2

Illustrated examples of the FMS dispatching decision analysis 1

Buffer with pallet (YnLs=HaPal)	Pallet is waiting for moving (YnMovCmd=Yes)	Result	Exposition
T	T	T	There is a pallet on the buffer and is waiting for moving.
T	F	F	There is a pallet on the buffer, but will not move.
F	T	F	No pallet is on the buffer, but is waiting for moving. (Not feasible)
F	F	F	No pallet is on the buffer nor is waiting for moving.

Table 3

Illustrated examples of the FMS dispatching decision analysis 2

Part has next process (CurOpSeq<TotalOp)	Buffer of next processing station is empty (Next Buffer=Idle)	Result	Exposition
T	T	T	Part has next process and buffer of next processing station is empty. (Pallet will move to the next buffer)
T	F	F	Part has next process and buffer of next processing station is occupied. (Refer to Table 4)
F	T	F	Part has finished all processes and buffer of next processing station is empty. (Return to AS/RS)
F	F	F	Part has finished all processes and buffer of next processing station is occupied. (Return to AS/RS)

Table 4

Illustrated examples of the FMS dispatching decision analysis 3

Buffer of next processing station is occupied (Next Buffer<> Idle)	Pallet-Number equals to Buffer-Number (PalNo=CurBufferNo)	Result	Exposition
T	T	T	Do not move
T	F	F	Return to AS/RS
F	T	F	Move to next buffer
F	F	F	Move to next buffer

The integrity and suitability of this integrated IEMPD and FMS structure provides a manufacturing decision-making environment. Further, simulation can be implemented by production engineers to validate the performance of the assignment dispatching rules. Knowledge rules of the manufacturing process can be reused by different projects. Various scenarios analysis of the projects based on the similar integrated IEMPD and FMS structure can be conducted to improve current manufacturing operations and to set the appropriate response plans confronted by the future development. Therefore, knowledge-based information (production manufacturing know-how and experiences) can be shared, accumulated, represented, and represented. The decision makers, i.e., production engineers, can efficiently conduct and evaluate the system status for optimal decision making.

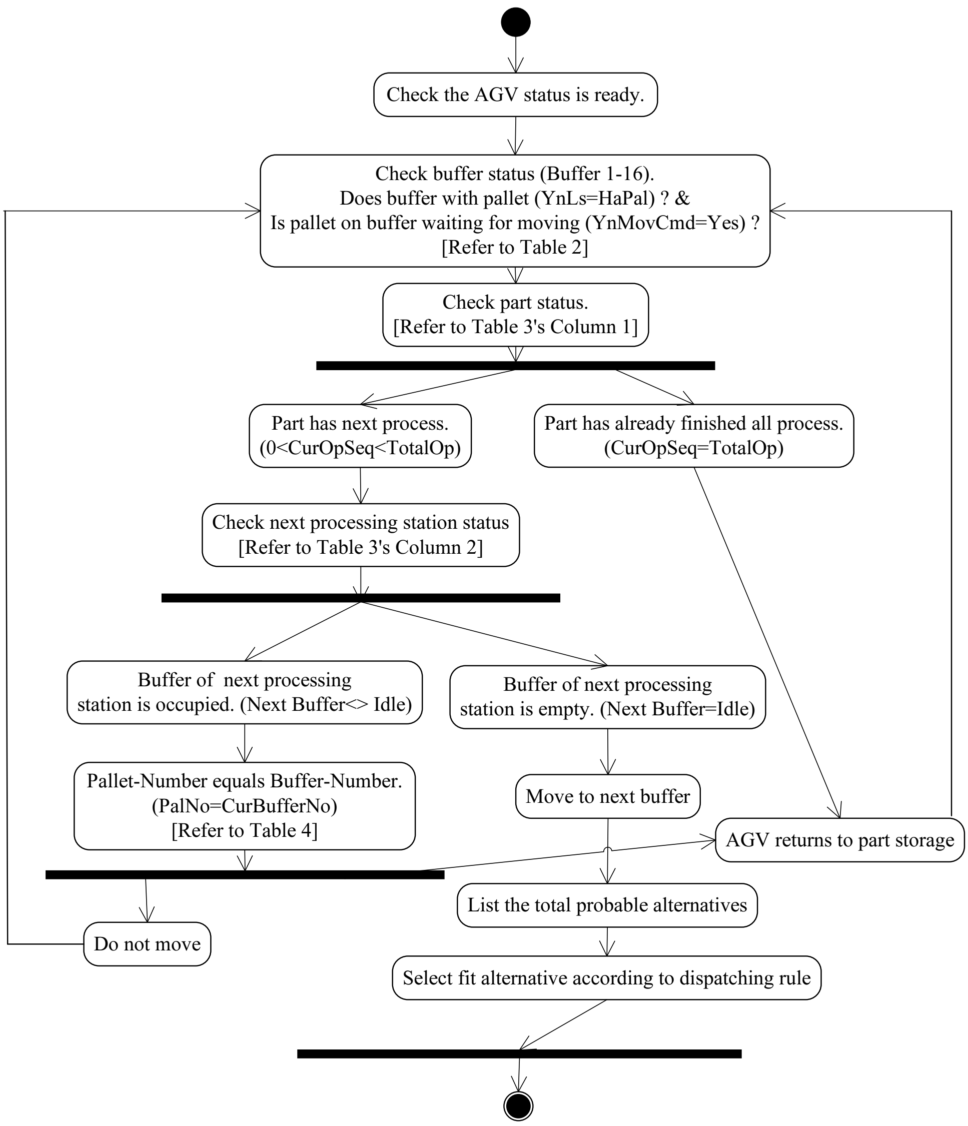

Figure 9. The dispatching inference process of the integrated IEMPD and FMS structure.

5 CONCLUSION

As flexible and agile manufacturing become prevalent, the ability to describe the short term future performance of a manufacturing system becomes critical. The prototype IEMPD system, which combines rule knowledge base and the inference engine, is developed and implemented. Knowledge engineers can construct, manage and maintain knowledge rules via the platform easily and flexibly to satisfy production or maintenance decision supports. Further, this research uses an example machine shop FMS to demonstrate the intelligent production supporting capability. And, the simulation methodology can be further implanted to compare the result of the dispatching performances. The prototype system enhances the agility of the manufacturing processes by supporting the decision making of equipment and production patching.

ASSET MANAGEMENT KPIS, VALIDATED, ANALYSED AND PREDICTED UTILISING SELF LEARNING HYBRID MODELLING IN REAL TIME

Don Sands [a] and Glen MacElroy [b]

[a] *Technical Director, Synengco Pty Ltd, 82 Eagle Street, Brisbane, Queensland, Australia.*

[b] *CEO, Synengco Pty Ltd, 82 Eagle Street, Brisbane, Queensland, Australia.*

Abstract: Asset managers agree that real-time operational, economic and asset life Key Performance Indicators (KPIs) are essential for world class asset management. In seeking to achieve this, most enterprises, despite advances in information technology, still struggle with the challenge of obtaining valid (a true reflection of what is happening) and reliable (repeated measures having a low error factor) data. Enterprises have developed extensive monitoring and analysis systems that produce more data but have not significantly improved actionable information or reliable measures. As a result they are often unable to reconcile or understand the data, which is being presented at greater speed and in larger quantities. The barriers to achieving world class Asset Management KPIs include data invalidity, incompatible data structures, out of date models, analysis disconnected to the asset operation, information overload and delays in analysis of information. This paper outlines how the use of Hybrid Modelling, model based data validation and operations modelling has overcome these barriers to provide a comprehensive self learning, real-enough-time analysis, reporting and prediction system. The system provides valid and reliable operational and financial measures at all levels of the enterprise to be used for asset management, performance analysis, scenario planning, forecasting and prediction of events.

Key Words: Synengco, Hybrid Modelling, Asset Management, KPI.

1 CONTEXT

The objective of asset management is to maximise the outcome of the asset under management, which requires the optimisation of the cost of constructing, maintaining and operating the asset against the value of the output of the asset, as shown in Figure 1. To achieve optimal asset management disciplines and systems have been developed to help manage and optimise the costs of these individual components. For example Project Management for managing construction and asset modifications and Reliability Centred Maintenance (RCM), Computer Maintenance Management Systems (CMMS) etc for maintenance. Traditionally in referring to asset management emphasis is placed on maintenance systems and in the design element of construction while the systems associated with operations activities have a much lesser focus. This lack of focus by asset management on the operation of an asset occurs not due to the lack of recognition of the significant impact asset operations has on the asset outcome but more due to the lack of systems and frameworks in which analyse the impact of operations on the asset outcome and the other elements of asset management.

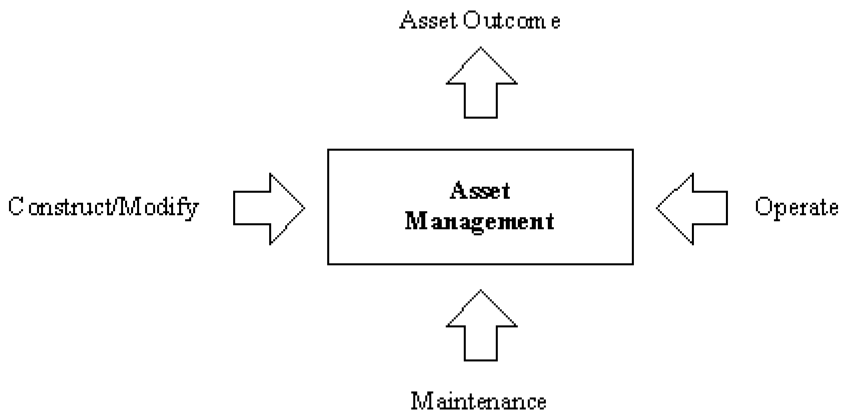

Figure 1: Asset Management Relationship

This paper will outline a methodology and requirements for the analysis of asset operation and how the asset operations is linked to, analysed and optimised with the other inputs into Asset Management. The paper is broken into three parts:

1. The characteristics of a good operations asset management system;
2. The way in which SentientSystem achieves the characteristics of a good operations asset management system; and
3. Case studies illustrating the application of SentientSystem to specific client issues.

2 CHARACTERISTICS OF A GOOD OPERATIONS ASSET MANAGEMENT SYSTEM

2.1 Asset Management

Asset management is the long-term management of an asset and generally covers the entire life cycle of the asset from concept to disposal. Effective asset management systems consider the following long and short term aspects of asset management in an integrated manner:

- ***Long term asset management issues*** include plant design, commissioning, plant degradation, staff turn over, replacement and refurbishment decisions.
- ***Short term asset management issues*** include short term production requirements, plant unavailability, critical incidents and planned and unplanned maintenance requirements.

A balance has to be struck between the long and short term aspects of asset management. This balance can be achieved through detailed knowledge of the asset and its workings over the short and long term. Support systems for asset management should use the available knowledge (see below) to provide a systemic long-term management system.

2.2 Asset Knowledge

Effective asset management uses knowledge (often captured over many years) of the plant and similar plant to decrease the life cycle cost, increase production, decrease risk and ensure the sustainability of the business. Over the life cycle of an asset, the following sources of knowledge, can be used for more effective asset management decisions:

- Plant design knowledge
- Commissioning knowledge
- Operational knowledge (long and short term)
- Maintenance effectiveness knowledge (of actual and similar plant)
- Overhauls/refurbishment knowledge
- Benchmarking knowledge
- Plant degradation knowledge (of actual and similar plant)
- Plant improvement knowledge (of actual and similar plant)
- Reliability knowledge (of actual and similar plant)
- Environmental impact knowledge (of actual and similar plant)

Effective asset management should, therefore, have a framework to manage the many and disparate sources of knowledge relating to the assets.

2.3 Precise Information

Many large cost decisions are required during the life of a large asset. These decisions are generally made based on information presented to a decision maker at the time the decision is required. Typically:

- ***maintenance and refurbishment*** decisions are based on how a plant is degrading and the impact maintenance and refurbishment activates have on the asset.
- ***abnormal operation and early warning for critical incidents*** decisions are generally related to how fast an asset is changing and the time to when this change will have secondary influences.
- ***optimisation*** decisions are based on how much the asset changes as a result of small changes to controllable inputs.

Precise information regarding changes (meaning small changes that are detected and repeatable) is required for all of the above decisions. As a result it is detecting and quantifying the change rather than the absolute value which is most import from a decision making process particularly from the operational asset management aspect.

It is also important that conflicting information be identified as early as possible. Unresolved conflicting information can have a major detrimental impact on decision making quality. Resolved conflicting information can often assist in the quality of the decision making process.

In summary information presented for use in effective asset management decisions must be precise with conflicting information clearly identified.

2.4 Abnormal Operation Detection

The abnormal operation of plant and processes is a leading cause of economic loss and critical incidents and an extremely important part of asset management. Industrial statistics estimate the economic impact due to abnormal operations and situations to be around $20 billion in the petrochemical industry alone (Nimmo, 1995). Abnormal operation analysis is traditionally associated with large complex processing plants (such as in the petrochemical and power generation industries).

There are considerable technical challenges in developing the systems necessary to achieve the early detection of abnormal situations and the identification of the root causes of these situations including:

- the complexity of process dynamics
- lack of adequate models
- incomplete and uncertain data
- diverse sources of knowledge
- amount of effort and expertise required to develop and maintain the systems
- the large operating ranges that the processes are subject to under normal operating conditions

Any mechanism that detects abnormal operations, predicts failure and provides root cause analysis for the detected or predicted events is a useful tool for improving asset performance.

2.5 Continuous and Discrete Processes

Asset management involves both continuous and discrete processes. Product production generally involves a continuous or semi continuous process while maintenance and refurbishment processes are generally a discrete process. Effective asset management therefore requires a mechanism to allow the integration of both continuous and discrete processes within the same decision framework.

2.6 Modelling

Modelling is an effective mechanism to capture knowledge. A great deal of historical scientific research is captured in fundamental and empirical models. Models provide a mechanism for providing predicted outputs based on given inputs allowing cost effective deployment of knowledge that may have taken many years of research to discover and test. Modelling also allows complex processes to be broken down into smaller more easily understood components.

The two basic forms of modelling, fundamental and empirical based models, and their advantages and disadvantages are discussed below.

2.6.1 Fundamental Models

Fundamental models are based on processes. In its simplest form a fundamental model could be a simple equation that represents a fundamental relationship like Power = Current x Voltage.

More complex fundamental models include thermodynamic models, network models, chemical reaction models etc. These rely on the mathematical relations that exist between variables and a consistent model tries to express these relations in a closed form. Model are developed using first principles – heat, mass, momentum balance, reaction kinetics etc. or input-output data and can be dynamic, static, linear or non-linear.

The major advantages of using fundamental models are that the system only requires small historical data sets to allow operation and deviations can be deterministically analysed.

The implementation of these systems is, however, problematic due to the difficulty of obtaining accurate and stable process models, the susceptibility of the outputs to the drift and failure of the inputs, the sudden process reconfiguration under normal operating conditions as well as the expected degradation and renewal of the process through maintenance activities. Further the models may not account adequately for the dynamic performance of the system and therefore produce a large number of fault detections (false positives) which are, in effect, normal dynamic behavior. Another disadvantage of using fundamental model systems are that they generate large amounts of data and hypotheses, which require large amounts of time and expertise to analyze. As the models are based on process fundamentals they also tend to be unique solutions for that process and resulting in high cost and little transportability.

Fundamental models are a powerful tool for stable slow changing systems and can provide excellent early detection, diagnosis and fault discrimination. They are, however, susceptible to process changes, multiple faults and may not prove very robust in an industrial environment where the input data is often noisy and unreliable.

2.6.2 Empirical Models

Empirical models are based on data. In its simplest form an empirical model could be a simple curve. More complex empirical models include neural networks, Bayesian networks etc.

The primary advantages of empirical models stem from the fact that little or no knowledge of the fundamental principles of the process are required to apply the techniques. These models can, therefore, be applied to any process and at a reasonable cost. The system outputs are generally readily understood and interpreted, at least at the superficial level, making the system readily actionable by a range of personnel.

The disadvantages of the system are that they require large data sets both in process points as well as history. These data sets provide a technical challenge to manage and process in real time. The training data (base line) may result in the system masking faults as the data may include the fault or such a large range of operations that the fault is indiscernible with the normal operation of the plant. A further disadvantage of these systems is that they do not inherently provide a diagnostic methodology to identify the root cause of problems.

3 SENTIENTSYSTEM

With the characteristics of an effective asset management system in mind, Synengco developed SentientSystem. SentientSystem is a system that brings the key aspects of effective asset management into an integrated framework. It is designed to be used over the whole of life for an asset from initial concept, commissioning, operation, refurbishment through to disposal. It can be used for design, performance monitoring, abnormal event detection, root cause analysis, risk management, knowledge management and short and long term production costing. It can be used on a single plant or to integrate a portfolio of plant. Its focus is on precision and reconciliation of information used for operational asset management decisions.

The SentientSystem framework allows for traditionally disparate data and analysis systems to work together in a synergetic manner. As more data, information and knowledge is available it can be applied in a consistent manner, reconciling the new information and knowledge with existing information and knowledge. The system provides a consistent mechanism across the data for extracting features from a massive amount of collected and generated data, detection of change from variable “normal” operation and a consistent mechanism for alerting personnel when a notifiable change is detected.

3.1 Knowledge Management

A large amount of knowledge is generated during the life of a large asset. During the design process many fundamental models are developed and optimised to deliver the most cost effective solution for the predicted future environment. During construction knowledge is generated on construction costs, plant changes, shortcuts taken and designs that could not be implemented. During commissioning there is traditionally a large amount of parametric testing conducted. Operations generate knowledge of the market, plant issues and raw materials issues. Disposal generates knowledge of asset worth and disposal costs. Traditionally much of this knowledge is captured but is not readily available to other parts of the life cycle. SentientSystem provides a mechanism to capture this knowledge and also similar knowledge from other plant, benchmarking studies and research and deploy it in real time.

SentientSystem captures knowledge generated from construction, commissioning and operations and checks whether there is a conflict with existing knowledge.

3.2 Hybrid Model

We found from experience that fundamental and/or empirical models were not effective on their own for asset management. Fundamental models are excellent for design purposes but are difficult to maintain operationally and do not cater for normal plant degradation over time. Empirical models lose a lot of available knowledge and miss important characteristics. They do, however, allow for self learning and are much easier to maintain.

As a result, the basis of SentientSystem became a hybrid modelling framework using a mix of fundamental and empirical modelling techniques that can handle both continuous and discrete processes in a systemic and auditable framework. This allows knowledge to be associated with the model in many different ways, from fundamental and empirical knowledge sources to rules of thumb and captured prediscovered cases. The model allows for self-learning of fundamental models characteristics using empirical techniques but still utilises fundamental knowledge to provide rapid learning and the ability to check the validity of the data being presented.

SentientSystem’s hybrid modelling technique was also designed for robustness and precision meaning that the information is reconciled as part of the solution using residuals. Residual based techniques are used within the fundamental models to improve precision and robustness of solutions by ensuring that the models are manipulated to achieve a solution that provides the lowest practical residual within the fundamental model to get the closest solution that represents the data presented. This technique not only ensures a highly repeatable result but also increases the early detection of faults through monitoring residual amounts for each solution. The residual techniques can also provide strong diagnostic capabilities in analysing a failure as it assists in identification of the component elements that required manipulation to obtain a solution. Online reconciliation has increased the precision of a solution, ensures the solution is feasible from a fundamental aspect and that small changes to the process are able to be determined in a repeatable and accurate manner despite noise on the input signals. This allows small and subtle changes to be detected early.

When developing the fundamental model, a review is conducted of the process to identify where accurate fundamental models can be applied for components within the process. These components are then built. Where fundamental models are not available or are unreliable, statistical models are built in conjunction with fundamental models for these components. Both the fundamental and statistical component models are then integrated to complete a total process model.

Many of the challenges of the application of fundamental models to industrial and commercial applications lies not within the identification of the appropriate mathematical model, but the identification of the system parameters for this model. The SentientSystem fundamental model uses a self-learning framework, which matches the mathematical model to the process data and self learns the system parameters. These self-learnt parameters are then validated within a process knowledge set to prevent solutions being realised that are not congruent with the process.

This self-learning framework continues to operate throughout the life of the system providing an adaptation mechanism such that the model accurately reflects the process as it changes with time and use. Analysis of the changing system parameters is itself a highly useful diagnostic tool.

The fundamental model also provides the structure and data hierarchy to improve the ease with which process and components can be analysed.

3.3 Virtual Instruments

Virtual instruments are a derived piece of information that is not available in a raw form but is closer to the decision making process. A common example of a virtual instrument is the fuel efficiency figure for modern motor vehicle where a fuel consumption (l/hour) and speed (km/hr) is translated to a l/100 km which is closer to a decision of should I increase or decrease speed to improve efficiency. A virtual instrument may also be a measurement within processes that cannot or does not have any instrumentation. However, by using other instruments within the same process and a model of the process, the virtual instrument value can be derived. An example could be a virtual instrument of the mechanical power output from an electric motor using electrical measures on the power supplied and a model of the electric motor.

SentientSystem provides a mechanism to allow virtual instruments to be added to any part of the process. The virtual instruments have a model (empirical, fundamental or hybrid as appropriate) associated with them. There can also be multiple virtual instruments generated from a single model (multiple inputs and multiple outputs). Virtual instruments can also be used for prediction.

3.4 Data Validation

Data validation is possibly one of the largest reason for actions not occurring as a result of diagnosis and analysis of real-time data sources. Generally there is a large amount of real-time data upon which to make the decision. The data is, however, sometimes incorrect due to instrument errors, incorrect data entry and/or deliberately misleading information. The SentientSystem framework allows data to be validated as soon as it comes into the system through many different mechanisms. One of the more powerful data validation mechanisms is the ability to check the relationship of the data with other sources of data associated with the same process using virtual instruments. This provides for real-time reconciliation and data validation which is extremely important in any asset management system.

3.5 Key Performance Indicators

Key performance indicators are basically virtual instruments on the key measures that indicate the health of the business process. Sometimes there are direct measures but more often the key performance indicators are an aggregation of a number of measures and algorithms and provide a mechanism to compress lots of information into a much small number of KPIs. Traditionally, due to the data compression mechanism, a change in a KPI is difficult to root cause without further analysis. SentientSystem provides for root cause analysis as indicated below for deviations in KPI.

3.6 Monitoring, Abnormal Event Detection And Root Cause Analysis

Within SentientSystem there is a vast amount of data available for analysis. It is typically in a hierarchical plant model and includes all the current raw data, the virtual instrumented data and historical data (sometimes over many years). Monitoring and abnormal event detection is achieved in multiple ways. The first is to generate virtual instruments (expected behaviour) for the process parameter being monitored and compare it with the actual instrumented value. If there is a significant deviation between the virtual and actual instrumented value an alert can be sent out. The other methodologies are based on a comparison of the current data signatures with historical data signatures. If the current data signatures deviate significantly from the baseline signatures, then an alert can be sent out. Root cause analysis can be achieved by comparing the current data signature with the signatures of known problems. There are many techniques available for developing signatures which are based on advanced analysis, classification, machine learning, statistical and data mining technologies.

Each of the following techniques can be implemented, depending on the evaluation of the particular process and detection and diagnosis required.

Principle Component Analysis (PCA): PCA carries out a statistical analysis on 'n' variables over a given time period, at a given interval, and transforms the 'n' process variables to be represented by 'm' principal components (which are dimensionless components that describe the variation between the relationship of process variables). There is a statistical link between the principal components and the process variable but this is not readily observed in the analysis of only the principal components.

The power of the PCA is that for a sensible set of data (data derived from an underlying process), the majority of the variance (>85%) is displayed in the first and second principal components. It allows you to study the variance of a process containing hundreds of variables by observing the changes to the first two principal components from a PCA study. This technique has been refined further by calculating the ellipses that contain 95% and 99% of the points and then repeating the analysis on a test set. By observing the instances that fall outside the target ellipses we can detect instances in time when the process was no longer operating as per the base case. This results in a technology that can easily detect abnormal operation.

PCA studies have more recently been utilised to also determine root causes, as the pattern of the PCA plot is characteristic of the root cause giving rise to the abnormal event. Development in this area is the focus of many organisations using PCA.

While the detection of events using the PCA is useful, additional techniques were developed to compliment the PCA to assist in root cause analysis of the out of control events. These techniques include Hotellings T^2 (TA^2), Partial Least Squares (PLS) and Squared Prediction Error (SPE). The TA^2 analysis provides a time series analysis of all the elements of deviation to allow a time analysis, the PLS is used to assess the significance of the deviation and the SPE provides a check that the analysis of the first 2 principal components is valid.

Slow Feature Analysis (SFA): This analysis is applied to remove the impacts of fast transients which can mask the slowly moving underlying drivers of a system. This technology was originally developed for the analysis of biological systems to determine the drivers for population increases and decreases and has been applied by SentientSystem to industrial processes to identify slow moving changes and provide early warning to these slower changes. This technology enhances abnormal event detection by removing the transients that provide false positives as well as providing early warning of process and plant degradation.

Independent Component Analysis (ICA): ICA looks for the statistical independence of the data and identifies the independent components that represent the raw data. This technique has been used extensively for blind source separation, where signals from various sources can only be measures as a mixture of the signals (an example is multiple conversations occurring at once with the microphones only able to measure the signals mixed together). ICA is used to separate the signals into their independent components. This means that the value of any one of the independent components gives no information to the value of another of the independent components (one conversation gives no information to the other conversation). By monitoring the independent components we can effectively monitor the source of the signal (one conversation), not the measurement of the signal (the microphone), and detect any changes that occur at the source.

Within an industrial process there are many sources of disturbances impacting on the measurement of the process such as ambient conditions, incoming material quality and plant degradation. The monitoring of the process may be through process variables such as pressures, temperatures, mass flows, etc. Through the application of ICA, it is possible to monitor the source disturbance instead of the raw measurement, account for known disturbances and monitor unaccounted disturbances. The monitoring of the unaccounted disturbances provides a mechanism for abnormal event detection.

Neural Networks (NN): This advanced multidimensional curve fitting technology is useful for providing a statistical representation of processes, which are difficult or impossible to create a fundamental model given the state of the model knowledge or the availability of data. The system statistically fits a multidimensional curve to the input and output data of the component under analysis. The curve is then available for simulation or predictive analysis where actual results are monitored against the prediction and deviations monitored and alerted to detect changes in process performance.

Partial Least Square Prediction (PLS): This advanced multidimensional analysis technique provides for the development of predictive models based on statistical relationships learned from historical data. The prediction of measurements compared to the actual measurements provides a mechanism to detect changes in the process and a method of abnormal event detection.

Classification Models: Classification is a method of data reduction and is used to classify information into distinct clusters that have certain characteristics. SentientSystem includes many classification techniques that can be applied to different problems. Use of classification is useful for abnormal event detection within a dynamic process through development of known operation classifications. This builds up classifications for known operations and anything that cannot be classified into known operation becomes unknown operations and the basis of abnormal event detection.

Time Series Analysis (TSA): TSA involves the analysis of data within a time dimension and is focused on trend and seasonal analysis. Seasonal analysis is the repeated cyclic information that has many different time periods from seconds to months or even years. Trend analysis is the long-term changes that do not have a cyclical nature. By identifying the individual trend and seasonal components, the underlying and independent phenomenon can be extracted, predictions of the time series variables can be achieved and abnormal events can be detected as a result of changes to the seasonal and trend components or as a deviation from the predicted and actual results. SentientSystem utilises a range of techniques for TSA.

3.7 Simulation and Optimisation

Simulation of the models is a powerful asset management tool. Through the manipulation of the input variables and model parameters (such that the predicted outputs match the actual outputs), a rapid diagnosis of possible fault states can be obtained. Simulation allows for optimisation by manipulating controllable parameters such as maintenance, component replacement and day to day operations, such that a more desirable outcome is achieved. Simulation can also be used to simulate plant failures and develop plant fault signatures for root cause analysis without having to experience the fault first hand. The SentientSystem simulator utilises the same fundamental and costing models that are used to monitor the process ensuring that the predicted values from the simulator are based on the self learnt system parameters reflecting the current process reality.

3.8 Costing

In prioritising and assessing fault detection, operating regimes, asset degradation for further analysis and action, the costing model provides key information that is actionable by all users. The costing model is integrated with the fundamental model such that an integrated financial and process solution is obtained. This ensures that any change to the asset has an integrated engineering/physical and financial analysis. This provides for the system performance to be monitored via either domain, financial or process, and allows for resource allocation and prioritisation to be made across the organisation.

The costing analysis can be componentised into a range of costs including conversion cost, capacity, asset consumption, maintenance, service quality, environmental and regulatory costs.

3.9 Outcomes and Benefits

The benefits for Asset Management from using a tool such as Sentient System are:

- ***Data Validation:*** With effective data validation decisions can made quickly and effectively without having to worry about if the data is correct.
- ***Early Warning of Problems:*** This prevents collateral damage from plant failures and reduces the cost of failure. It also allows planning to take place before a failure, thus reducing the cost and time to repair.
- ***Key Performance Indicators:*** Key performance indicators provide a means of measuring the overall performance of the asset and allow the monitoring of the effectiveness of asset management strategies.
- ***Optimisation:*** Optimisation results in reduced asset consumption and maintenance requirements while improving production.

4 APPENDIX A: CASE STUDY SENTIENTSYSTEM OPTIMISATION

The following shows how the SentientSystem™ Optimisation can be used to improve asset life and reduce failures. A plant in the US was experiencing plant failures from to the size and frequency of thermal excursions on critical metal components due to cleaning activities. This thermal cycling was contributing to metal fatigue and failures. SentientSystem was used to monitor, optimise and control the cleaning activities.

A number of different technologies from SentientSystem were used to address this problem. Due to the arduous nature of the environment, instrumentation to measure the thermal cycles would be very expensive, unreliable and would have required a unit outage to achieve. SentientSystem, instead used existing instrumentation, its precision model and virtual instrument to monitor the thermal cycles.

Once the thermal cycles were monitored, the self learning aspect of SentientSystem was used to characterise the impact that the cleaning action (discrete process) had on the metal temperatures (continuous process). This influence changed with different feed material (semi-continuous process) and different production levels (continuous process). As a result the self-learning aspect had to cater for these "normal" changes within the process and separate out the cleaning influence from all the other disturbances.

With the cleaning characteristic self-learned, SentientSystem optimisation was used to optimise the cleaning regime with the primary objective of decreasing asset consumption and improving reliability. A secondary objective was to maintain or improve the efficiency of the plant. To provide the balance between potentially conflicting objective functions SentientSystem costing was used to weight the influences according to their relative value/cost to the plant. The optimisation then only had to minimise the cost of the solution to achieve the most balanced outcome for the plant.

The outcome for the plant was an improvement of 40% in mean time to failure for the plant, an improvement in the efficiency of the plant and a reduction in the cleaning resources required by 50%.

As a result of using SentientSystem different technologies, this opportunity was realised without additional instrumentation or a plant outage. The resultant low cost and impact of installation meant the project had a true payback period of less then 6 months.

5 APPENDIX B: CASE STUDY SENTIENTSYSTEM EARLY WARNING

The following shows how the SentientSystem™ MSPC can detect a tube leak in a boiler by monitoring the thermal conductances as calculated by SentientSystem™ Process Analysis. The first detection of the leak occurred 4 days and 12 hours prior to the unit coming off line and was over 2 days earlier than the confirmation through the traditional fault detection system.

The timed PCA in Figures A1 to A4 graphically shows how the leak initiated and then propagated. Once detected, Figure A5 shows how the Variable Contribution Tool identified, which process variables are contributing to the abnormal operation. Through knowledge of the boiler layout and that the SSH, PSH and Economiser are all contributing to the variance we can conclude that the element prior to these has the leak as additional energy is being placed into the gas stream which has increased the thermal conductances of the SSH, PSH and Economiser.

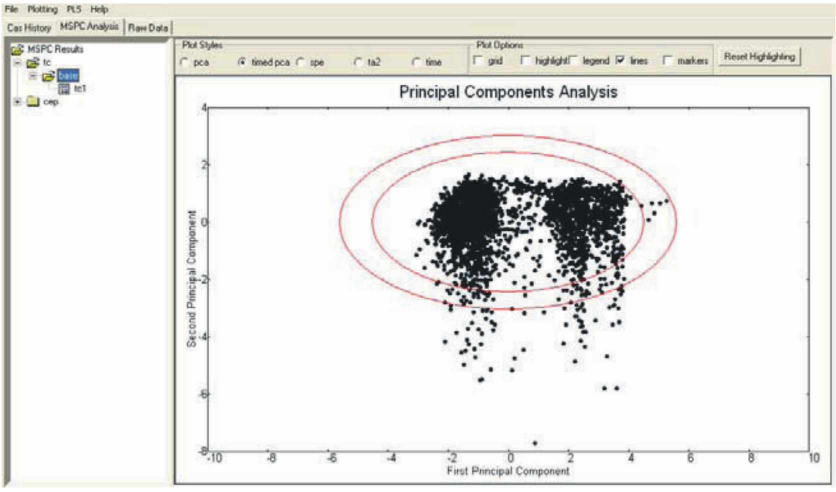

Figure A1: Base case using thermal conductances of boiler

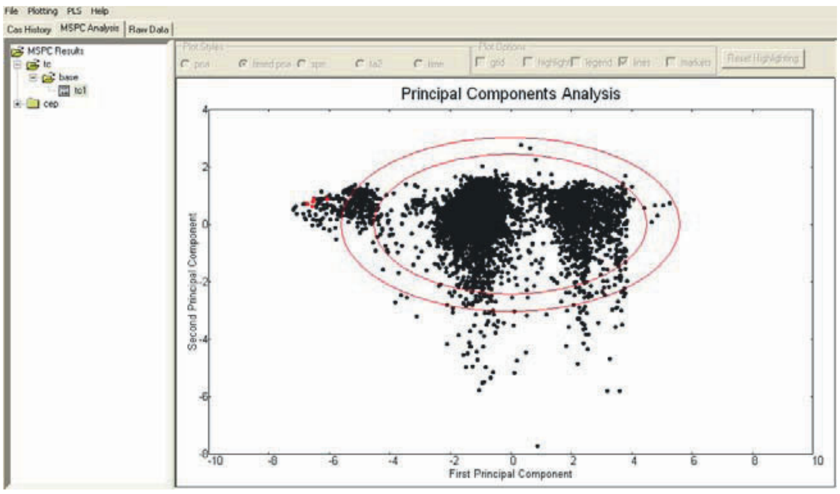

Figure A2: Test case showing start

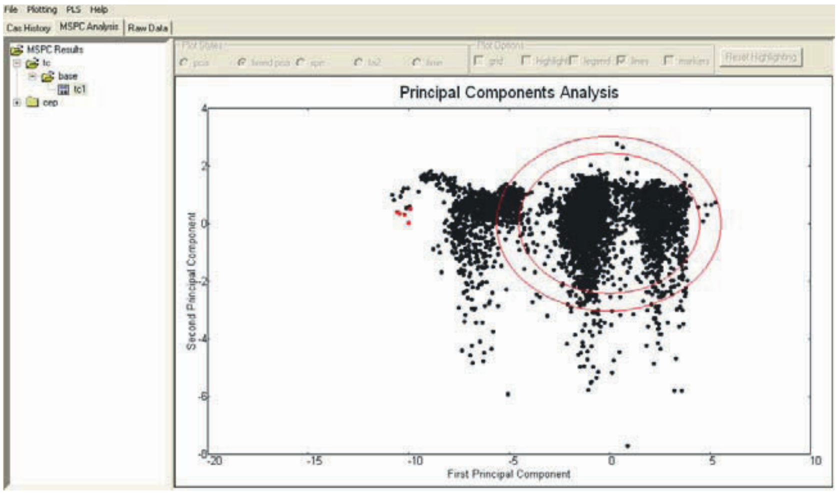

Figure A3: Test case showing start tube leak progression

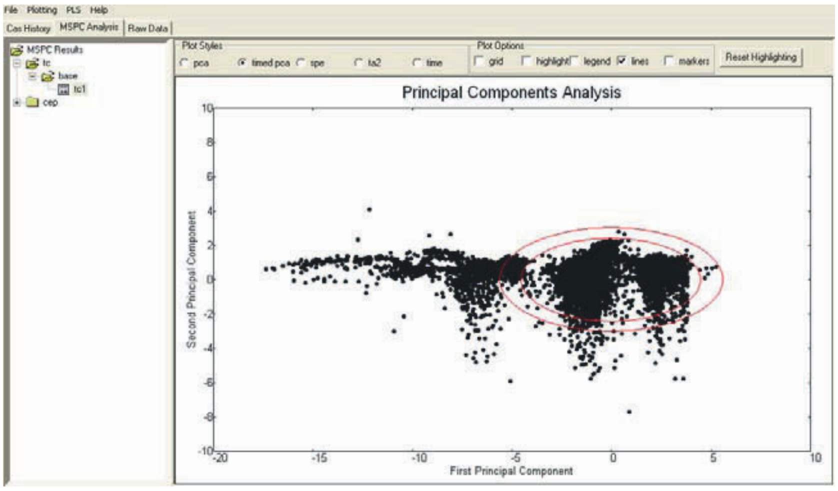

Figure A4: Test case showing final stages

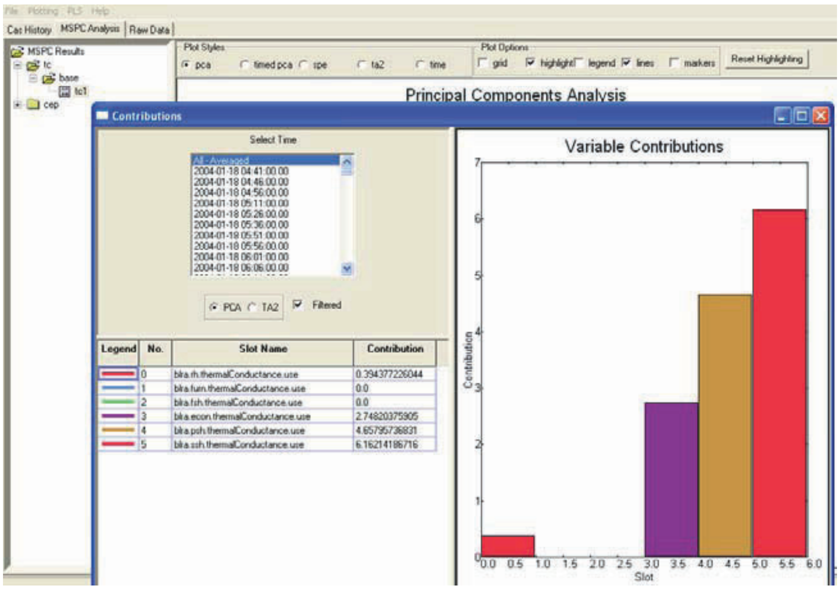

Figure A5: Determining the Process Variables Contribution to the Deviation

Abstract: Complex engineered products are all knowledge intensive. It is crucial for suppliers and operators of such "fleets" of equipment to manage and minimize product costs and risks. Many schedule delays, cost overruns, accidents, excessive operating costs, and premature product failures result from ineffective management of product data, information, and knowledge. This paper reviews solutions based on integrating structured authoring and product lifecycle management systems and data warehousing implemented by a large project engineering and management organization and the development of an alliance organizational form to support the product to reduce costs, risks and hazards through comprehensive and coherent management of project data, information and knowledge.

Key Words: Life cycle knowledge management, complex products, documentation, risk minimization

1 INTRODUCTION

Complex, long-lived products are failure prone and sources of costs and risks for organizations that procure and operate such things or build, supply and support them. Some problems relate to poor management of personal knowledge (Nousala et al. 2005). However, the points of failure leading to visible cost and schedule blowouts, in-service failures or accidents often derive from errors appearing first in project documentation and data, possibly as far back as client requirement development and contract negotiation. One key to minimize unanticipated costs and problems in service is to provide coherent visibility and control of the development of project requirements and their elaboration into documentation for engineering, production and maintenance activities. Another is to integrate lifecycle logistic support considerations into the systems and design engineering processes. A third is to provide engineering configuration control over all aspects of proposed changes to ensure that impacts on associated data and documentation deliverables are carefully considered before any change is allowed to proceed. A final key is to ensure rapid feedback and analysis of problems arising in production and in-service operations. This paper describes how Tenix Defence integrated a range of software into an increasingly comprehensive knowledge management infrastructure to satisfy requirements of production, operating and support organizations to better manage engineered fleet products.

1.1 Project life cycles — What can go wrong?

Almost anything relating to a complex product can go wrong, sometimes disastrously so. Because faults in early documentation development, design and logistics analysis phases "only involve paper", such "latent errors" (Hopkins 2005) can escape notice or be hidden until products are fabricated and put into service. However, the cost and delay to correct mistakes on paper is insignificant by comparison to costs to correct mistakes after they have been fabricated in steel, so the benefits from identifying and remedying such mistakes before they go into production should be high. The construction/ production phase of a large project may span a decade or more. In-service support may span several decades. Examples are ships, commercial and military aircraft, heavy vehicles, infrastructure plant and equipment, where units may be in service for several decades. Knowledge concerning the product must be actively maintained through this lifecycle for periods longer than the normal membership of a person in any the organizations.

By comparison to project successes, documented cases of mistakes and failures can be difficult to find. Many mistakes are covered up, rather than cherished and studied as learning situations (Argyris 1999; Ford & Sterman 2003). Yet, "Those who do not learn from history are doomed to repeat it" (attributed to George Santayana, 1863-1952).

Seeking to improve the performance of large Australian Defence projects with regard to cost and schedule blowout, difficulties with large Australian Defence projects are well documented. (e.g., McNally and Bates 1999; McNally et al 2005;

Brown 2002). One example of a project that has encountered problems throughout its lifecycle is the $A 5 billion Royal Australian Navy Collins Class submarine project to build six diesel powered attack submarines, documented in a report from the Australian National Audit Office (McNally 1997), the McIntosh/Prescott Report (1999) and a Parliamentary Research Paper (Woolner 2001). Many of the problems with the submarines traced back to the contract specifications - where the supplier explicitly followed the contract to deliver against specifications that were inadequate when the products were put into service. Also, monitoring procedures did not adequately highlight the issues prior to delivery of the subs.

Other issues tracing back to problems with knowledge work early in a project may become apparent only as operational failures. If appropriate knowledge doesn't exist, is incorrect, or isn't accessed and used when needed in engineering, producing or operating the product, huge costs can ensue and people may even die. Many equipment failures are resolved with little more than damage to the equipment itself. However, it is the nature of large and complex systems that some failures propagate catastrophically (Bea 2003). Such disasters often begin with engineering and design faults, or faults in maintenance and support. A "minor" equipment failure or operator error may be exacerbated by operators who lack immediate personal knowledge and cannot find explicit knowledge as to remedies that might bring a cascading sequence of failures under control. As failure becomes more extreme the chances that operators will have the necessary knowledge to stem the cascade declines.

Documented examples of these kinds of failures include: Three Mile Island (Kemeny 1979), Longford Gas Plant (Dawson and Brooks 1999), HMAS Westralia. (Yates 2000; Hope 2003; Royal Australian Navy 2004)., Petrobras's P-36 offshore semisubmersible oil production platform. (Rios 2002; Bea 2003; Dias and Valerio 2002), and Chernobyl (Cohen 1990).

A consideration in all these cases is that plant and equipment operators as individuals or teams can only ever be expected to have the knowledge required for their day-to-day activities and reasonably common occurrences in their heads (Hall 2003). And even then, to train the operators to that state of competency to deal with failures outside the normal operating envelope requires production of explicit training activities, technical manuals, simulators and a variety of other explicit knowledge-based materials to guide the training. Thus, beyond training for their common activities, to deal with infrequent, unusual and extreme events, plant and equipment operators require ready access to a much broader knowledge base than can possibly be held in personal memories — especially kinds of events that have the potential to become catastrophes if not dealt with correctly. Appropriate and correct documentation in a rapidly accessible (e.g., semantically indexed, retrievable) format can be a lifesaver — or at least essential to keeping the product in service for an economically long life. On the other hand if the documentation is available, but incorrect, equipment be prematurely destroyed or people die as a result.

1.2 Identifying and remediating project failures close to their sources

Appropriate infrastructure systems for managing and improving project technical knowledge via iterative feedback loops can reduce project risk (Manderson 2000). To try to stop engineering related faults before they reach production or affect in-service operations, the Australian Department of Defence has established a Technical Regulatory Framework (TRF) for major Defence materiel projects (Commonwealth of Australia 2004a) establishing management framework suitable for all kinds of major engineering projects, not just those in Defence. This accepts that engineering decisions involve risks, and establishes a principles-based framework to control and mitigate these risks during design, construction and maintenance. The TRF establishes two kinds of "authorised" agencies, the Authorised Engineering Organisation (AEO) and the Authorised Maintenance Organisation (AMO). Defence organizations such as System Program Offices (generally responsible for a particular fleet) and contractors (whether engineering or maintenance) are all required to obtain and maintain appropriate AEO or AMO certifications for their fleet-related design, engineering or maintenance activities.

An accredited organization is required to comply in four areas (Commonwealth of Australia 2004a), which just happens to summarize the four principle areas of knowledge management as defined in the Australian Standard (AS 5073(Int)-2003): *People*: Individuals within the organisation are qualified, authorized and have demonstrated competence to perform their designated activities. *Processes*: The organisation has, and uses, documented, controlled and approved plans, procedures and processes that conform to the TRF. *Systems*: The organisation has established and maintains applicable management systems appropriate to the type of work being performed. *Data or content*: The organisation uses relevant and authorized data appropriate to the activities being performed. Following Mensforth (2004), Navy's TRF for the engineering organization includes eight major elements:

- Managing risks
- Managing engineering change
- Reporting and investigating defective and unsatisfactory materiel
- Implementing maintenance management systems
- Proper delegations for engineering authority (to ensure that only appropriately qualified people review and authorize engineering changes)
- Proper authorization of engineering organizations (to ensure that it has accredited management systems, appropriately qualified and competent staff, and appropriately qualified management to enforce the integrity of all data)

- Implementation of technical data management system (data integrity, access & IP controls following defense standards, interfaces with other technical processes, procedures and management, interfaces to quality management system)
- Continuous enforcement of compliance with the TRF.

Physically transporting and tracking large volumes paper through the several layers of review approval can be major sources of cost and delay that has inhibited implementing strict TRF type controls. Systems able to electronically manage elements of content within structured documents, to distribute them at light speed and prompt for overdue evaluations or approvals greatly facilitate the implementation of a TRF.

1.3 Meeting product Requirements of the operating/client organization

The fundamental requirement of the operating organization with regard to the engineered product(s) is to have the product capabilities available and functional when needed. To meet this requirement, knowledge must be developed and provided to ensure that products:

- do what they are supposed to do reliably.
- are available for service when needed.
- are readily maintainable.
- are supportable.
- are operable within limits of human knowledge & capacity considering health, safety and operational knowledge issues.

Secondary considerations for the operator are to minimize product costs. For long-lived products such as ships and armored vehicles, support and maintenance costs for the product's life are typically several times the original acquisition costs. Thus, giving due regard to meeting the required capabilities, the product should be designed not only to minimize acquisition costs, but to minimize documentation, support & maintenance costs.

Adequate performance on all the above issues depends on the quality of authoring, management and transfer of technical knowledge from supplier to operators and maintainers. For the fleet operators, this technical knowledge must be:

- Correct in the sense that all knowledge deliverables have been subjected to stringent review and quality control to ensure their technical and operational accuracy in terms of the product's engineering and functional details.
- Consistent across the fleet to facilitate human training and computer systems interoperability
- "Applicable" to the configuration of the individual ship/vehicle
- "Effective" for the point in time re implementation of engineering changes, etc.
- Available to who needs it, when and where it is needed, and
- Useable, both in the sense that it is readily understandable by human operators and maintainers, and in the sense that it can be readily managed and processed in computer systems

To help minimize product costs, besides meeting the operators' requirements expressed above, the supplier has additional goals relating to assemble and produce the technical knowledge package for the product — bearing in mind the contradictions; e.g., to minimize production time (faster), deliver high quality (better), and to complete the work for a low cost (cheaper).

2 TENIX'S ARCHITECTURE FOR MANAGING FLEET DATA, INFORMATION, AND KNOWLEDGE

Tenix Defence is a large defense engineering and project management company that builds and/or maintains fleet "classes" of products or "platforms". The ancestral organization (now the Marine Division) was formed in the late 1970's to bid on the ANZAC Ship Project to build 10 frigates for the Australian and New Zealand Navies. Having won the ANZAC project, Tenix has grown and diversified into an organization of several divisions addressing the whole gamut of Australian Defence requirements, and a wider Group of associated companies covering a wide range from infrastructure engineering and project management to the development and commercialization of high technology and software products. Tenix's divisions now operate across Australia and in several countries overseas. Company success is likely due in part to a proven ability to deliver comparatively unproblematic products on cost and on schedule. At least some of this ability can be attributed to our increasingly sophisticated engineering knowledge management infrastructure.

The ANZAC Ship contract to build 8 frigates for the RAN plus 2 for New Zealand (ships 2 and 4 in sequence) was signed in 1989. The first ship was delivered in 1996. Further ships were delivered at the rate of about one per year, with the last delivered in 2006. The designed lifespan of a single ship is approximately 27 years, requiring ongoing and periodic maintenance support. Given changing strategic environments and rapid evolution of weapons and electronics technologies, major engineering changes will continue throughout each ship's life in service. Although built to similar plans, due to requirements of different clients, lessons learned, supplier changes, changing needs and technologies, and in-service engineering changes, no two ships are identical when delivered or remain static after delivery.

Besides responsibilities to build the ships, Marine was also contractually responsible to provide a comprehensive and highly knowledge intensive logistics support package. Unique aspects of the contract for this particular project are that:

- A stringent "fixed price" was negotiated for all of its aspects including the logistic support package.
- After 10 ship-years of in-service operations (Test, Evaluation and Validation period - TE&V) Marine had to prove to the client's satisfaction that the support package enabled the ships to meet contractual availability requirements for the combat system as a whole and for a number of individual "critical systems". For any shortfalls, Marine had to develop and implement acceptable remediation plans — all within the fixed price.
- A major milestone for the client's acceptance of Ship 5 was acceptance of the complete logistic support package, as summarized above. Failure to meet this milestone would trigger payment of major liquidated damages.

These unique aspects required Marine to develop innovative lifecycle knowledge management solutions that have now been extended and refined across additional projects. These solutions are based on a systems architecture for managing the gamut of information relating to fleet products to address in-house, client and operator needs. Two cycles of systems and architecture development took place in Marine for the ANZAC Ship Project. Lessons learned in these Marine implementations influenced development of a solution in Land Division for the M113 Project (described below), and lessons learned from the Land implementation are now being reflected back into the Marine Division for current projects.

A word processing approach based on structured maintenance documents represented the first of the iterated solutions to manage maintenance knowledge. The contract assumed most technical knowledge would be delivered as manually controlled paper documents. Subcontractors would provide most of the technical manuals, however, Marine controlled the support philosophy for the ships, and was thus responsible to produce all maintenance documentation — especially the knowledge intensive "Maintenance Requirement Cards" (MRCs). As detailed by Hall (2001, 2003), MRCs describe maintenance activities to be performed by ship crew or naval on-shore staff. Besides describing how to perform the maintenance, MRCs include technical metadata on what is to be maintained, when the maintenance is to be performed, spare parts, consumables, labor requirements, tools, special and test equipment, anticipated down times, plus a variety of other data needed by maintenance planners and managers. At the outset, it was recognised that key information contained in the documents could be more readily managed if the documents were structured to include fields tagging this information for computer processing.

Beginning in 1992, MRCs were authored and maintained in WordPerfect's merge table format. Different data elements could be entered in semantically specified merge table fields for later selection and formatting by different merge templates. Merge/macro processes automatically extracted particular information required by the logistics analysts (Hall 2001). This saved much labor in its own right, as selected content could be automatically extracted and formatted for particular needs. Formatting changes only required changes to one template rather than editing content in thousands of documents.

Around 1993 the Navy decided to develop a relationally based Asset Management & Planning System (AMPS) to provide computerized scheduling and data collection for maintenance activities. Once details of the AMPS delivery format were agreed, it was comparatively easy to build a macro process and merge templates to extract the required information from the WordPerfect merge tables to produce electronic transfer files. Only templates and associated processes required development. A rudimentary automatic process also validated key data against standard information held in an ILS database. Although there were unsatisfactory aspects to the merge table approach, the value of structured authoring was amply proved (Hall 2001, 2003) for the production of Ship 1 (Australian) MRCs. Maintenance instructions loaded into the AMPS system would then be printed out by the on-board AMPS system to guide maintainers when the maintenance was to be performed.

When authoring of MRCs for Ship 2 (for New Zealand) started it became clear that the "flat" merge table structure used by WordPerfect could not cope with engineering changes that required commonly used key information to be changed across many routines. A single ANZAC ship requires more than 2000 MRCs, and given that no two ships are identical, each new ship required an additional 2000 to be maintained. In some cases a single engineering change might impact content in hundreds, or even thousands of MRCs, each of which had to be manually edited to apply the change. For example, specifying the wrong ID in an MRC for a replacement part could cause a system failure in maintenance. Even with automated validation, it proved impossible to maintain the MRCs completely consistently with changes to the ILS Database, and it was clear that the WordPerfect platform would have to be replaced by something more robust and easier to maintain. Details within MRCs needed to be managed coherently with engineering changes - preferably at a level of structure corresponding to granularity of the engineering data. SGML object management technology offered a solution, as detailed by Hall 2001.

Figure 1 illustrates the potential semantic linkages between elements in structured documents and a product breakdown structure as maintained in a product data, configuration control and engineering change management ("PDM") environment. The heart of an engineering knowledge management system is the PDM engine, which establishes and maintains one or more hierarchical models of the structure of the product. All other data and document content relating to the product can be linked to the specific components ("parts") in product model or breakdown structure (whether this is physical or systems/logical).

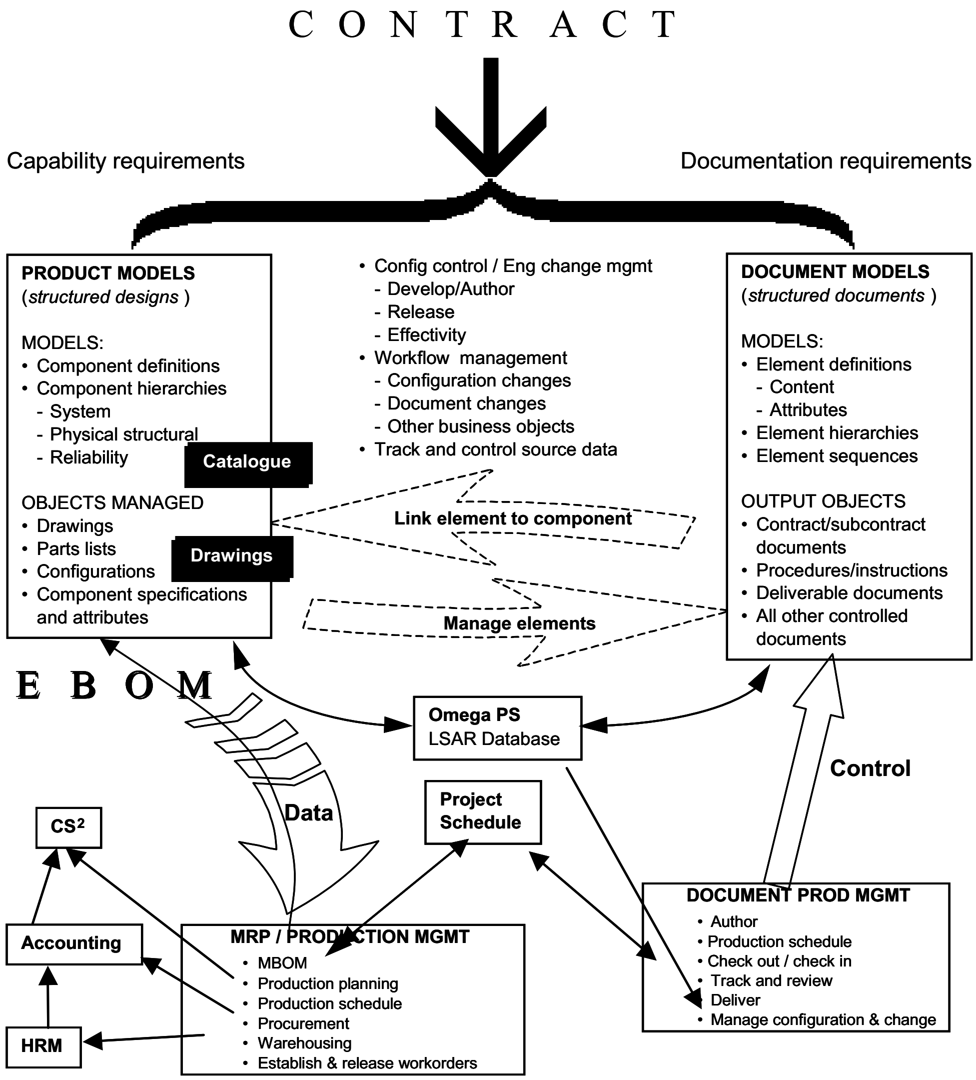

Figure 1. Simplified structure of information, knowledge and control in the fleet production management environment (1997 concept)

Product models are held in a PDM environment. Document models are held in a structured content management environment. Logistic support analysis data is held in an LSAR database. Production control systems include manufacturing resource planning (MRP) and production management, document production management, project scheduling, human resource management (HRM), accounting and Cost and Schedule Control System (CS2). All of this is tracked within a requirements tracking umbrella to ensure contractual requirements are met. The EBOM is the engineering bill of materials for the product. MBOM is the manufacturing bill of materials of the ships as produced.

When new engineering applications were selected in 1998 and 1999, no PDM system recognized document content to a low enough level of structure for document changes to be managed at the same level of granularity as changes to the product model. (PDMs manage document files, but don't see structure within the files). This meant that structured content would have to be managed in a different system from the PDM and the two linked in some way to maintain coherence between engineering and document changes. TeraText, developed by RMIT University (then known as SIM - see http://www.teratext.com.au; Sacks-Davis & Kent 2002), was selected to manage document content. Sherpa Works ("Sherpa" - no longer commercially supported) was selected for the PDM role. Coherence between document content in TeraText and engineering changes in Sherpa was maintained by validating all documents against extracts of key data from Sherpa.

Figure 3 illustrates the system architecture based on Sherpa and TeraText plus other systems forming a complete infrastructure for fleet knowledge management. To collect the operational data to meet the TE&V requirements, Marine developed a software application called OARRS (operational availability recording and reporting system, now known as CSARS) to extract and analyse performance data on the individual ships from the AMPS system. This capability combined with RAN's AMPS and other Tenix systems provide a full lifecycle management capability for the fleet of ANZAC ships.

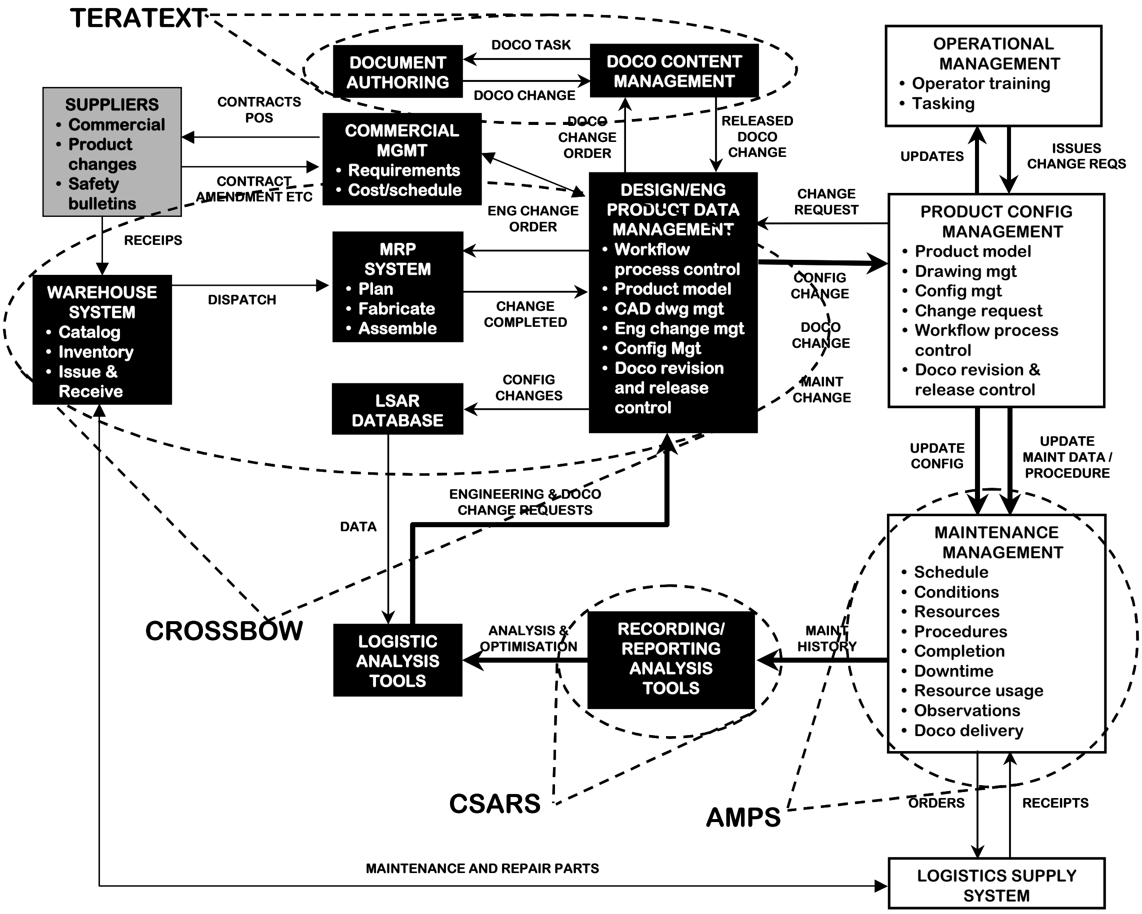

Figure 2. KM architecture for the production and support phases of a fleet project in place by 2002.

The prime contractor's (i.e., Marine) components are shown in black, with white text. The operator's components are shown in white, with black text. Suppliers to the prime contractor are shown in gray. AMPS is the Navy's Asset Management Planning System, CSARS is the Class System Analysis and Reporting System. Crossbow is Marine's data aggregation and normalization engine, and TeraText is the structured content management environment. Sherpa was limited to the Design and Eng Product Data Management role and was also used by the RAN as a configuration management tool. LSAR refers to database applications able to work with logistic support analysis records.

Also, because the ANZAC Project began before integrated enterprise and engineering program management systems existed, Marine developed engineering and ILS technical data in 15 independent software applications (including Sherpa and TeraText). Although text and data were normalized between Sherpa and TeraText, major problems remained to coordinate and normalize key data across many other separate data sources. Tenix addressed this issue by developing a data warehousing and aggregation engine called Crossbow, now marketed commercially (Sykes 2004). Crossbow allowed key technical data to be normalized across all applications and to be visualized in a single user interface (Sykes and Hall 2003; Microsoft Case Studies 2004), for a major cost savings and to eliminate many potential errors in the data that could have surfaced at any time.

Further refinement of architectural concepts for fleet knowledge management then moved to Tenix's Land Division ("Land"). In 2002-3 Land won the project to completely reengineer and upgrade 350 M113 tracked, light armoured vehicles for the Australian Army. The M113 Project was first conceived in 1992 to "upgrade" to the capabilities of a fleet of armored personnel carriers (APCs) first used in Vietnam. As finally agreed, only the bare metal of the original hulls is being reused. Seven major engineering variants will be produced: most hulls will be chopped in two and "stretched", or be even more heavily modified (e.g., to convert what was an armored personnel carrier into a flatbed logistics transport vehicle). Thus, except for parts of the metal hulls, the vehicles are new design and build in every respect (e.g., power trains, weapons systems, electronics, etc.), and require a completely new product technical knowledge package (configuration management, engineering and logistics data, technical, maintenance, and operator's documentation, training materials, etc.). The project is staged, first to build demonstration and "initial production" vehicles for testing and logistics evaluation, with delivery of the first vehicles to an Army company level unit scheduled for 2006. Given that the existing M113's are 30-40 years old, the renewed vehicles are anticipated to have a long life-span in service. Although not required by the project contract, Land's philosophy is that the system for managing technical knowledge should cater for the fact that each vehicle will eventually have its own unique configuration as the result of engineering changes and maintenance activities and that the management system will track the current configuration of each hull.

Land built a highly integrated approach to implement the architecture and data structures illustrated in Figures 2 and 3, as the Configuration Management Information System ("CMIS"). Implementation began late in 2002 with the system in full production by 2004 over all of Land Division's design and production projects. Given that new vehicles are only just beginning to be delivered, the system has not yet been linked directly into the Army's maintenance management environment, although it has been designed with this eventuality in mind. CMIS is based on the Matrix product lifecycle management environment from MatrixOne (see http://www.matrixone.com/matrixonesolutions/index.html; Brouwers 2004). Extending Marine's experience with an earlier version, the latest version of TeraText was used for content management - but in a much more sophisticated integration. In general both Land and the Army operating/maintenance organizations need a PDM capability to know the configuration of the vehicles produced. Land's PDM system maintains three baselines for the product:

- as designed, including the bill of materials (BOM) that guides fabrication of the product within the manufacturing resource planning environment (MRP);
- as built, feeding back details of field changes, parts substitutions, equipment serial numbers, and other information required to be collected in the production process, and
- as delivered — PDM datasets of the physical product(s) as delivered are included in the product technical data deliverables.

The array of product knowledge relating to each component is linked to components in the baselines. The operator's PDM system normally tracks the current configuration state of the product unit as it is maintained in service, and when a component changes, the "where used" approach will quickly retrieve any documentation relating to the change.

CMIS provides a common graphical user interface and electronic workflow environment to control the development, approval, release and publication of all explicit knowledge products for the TLAV project. CMIS is based on MatrixOne's Matrix10 , a complete product lifecycle management system. This provides a graphical workflow environment and master repository able to relate all kinds of business objects to appropriate components in the product breakdown structure; and to electronically progress and control objects through the various business processes of creation, review, revise, signoff, release and fabrication or publication. Through application programming interfaces (APIs), CMIS controls applications in the technical authoring, engineering drawing, logistics analysis and manufacturing areas so all related changes are administered in concert through the one user interface and workflow management environment.

Integration of technical authoring is particularly powerful. To maintain complete integrity of changes to parts and low level elements of document content relating to those parts, document models based on the S1000D standard (TPSMG 2005) are used. TeraText maintains links between particular document elements to specific components in the product breakdown structure in the PDM environment. An engineering change to a part automatically includes all related document elements in the change process. The S1000D standard is specifically designed to facilitate linking document modules to a product breakdown structure — such that a document module relating to a particular component can be reused in a variety of higher level kinds of documents referencing that component. From the standpoint of the end users of the workflow management system, the engineering change process is applied to relevant document components as an integral aspect to changing any other aspect of the information or knowledge linked to a component. Standards for the development of training materials are also being rationalized into the S1000D structure (Shook and Thropp 2004) This ensures that all aspects of knowledge relating to the particular component are considered for change together.

The other aspect of integrating authoring and engineering environments is that it remarkably reduces the risk, effort and cost to perform "impact analyses". A major source of engineering change derives from changes that suppliers make to components they supply or to the data or documentation relating to these components.

In a paper world, when such changes are received, it is a major and risky task to determine what product components or documents may be impacted by the change. Identifying impacts depends on authors' personal knowledge of which parts of which documents are likely to be affected. In general, because supplier changes are often made years after the original documents were written, the authors who wrote the original documents are no longer available. If the analysis misses documents that should be changed, but aren't, this risks an operational failure and whatever consequences cascade from it. Thus, when an impact analysis is performed against a set of paper documents, it may take days or weeks and still be fallible.

By contrast, the TeraText system provides the capability to annotate and link back to the product breakdown structure all component details and source documents used in drafting technical documents (Hall 2003). Impact analyses can be completed automatically in a few minutes to a much higher degree of certainty that all impacts have been identified and assessed. An author still needs to read potentially impacted documents to see whether any changes are required, but this is trivial compared to what is required in the paper world.

Thus, Land Division's CMIS system brings essentially all fleet product related explicit knowledge produced by the supplier organization under a single point of access and control. Controlling all aspects of technical data change, review, and signoff in the common workflow environment, where all associated documentation is linked to the engineering change request/order, ensures all relevant knowledge relating to the change is immediately to hand. CMIS provides the infrastructure to fully support the Technical Regulatory Framework.

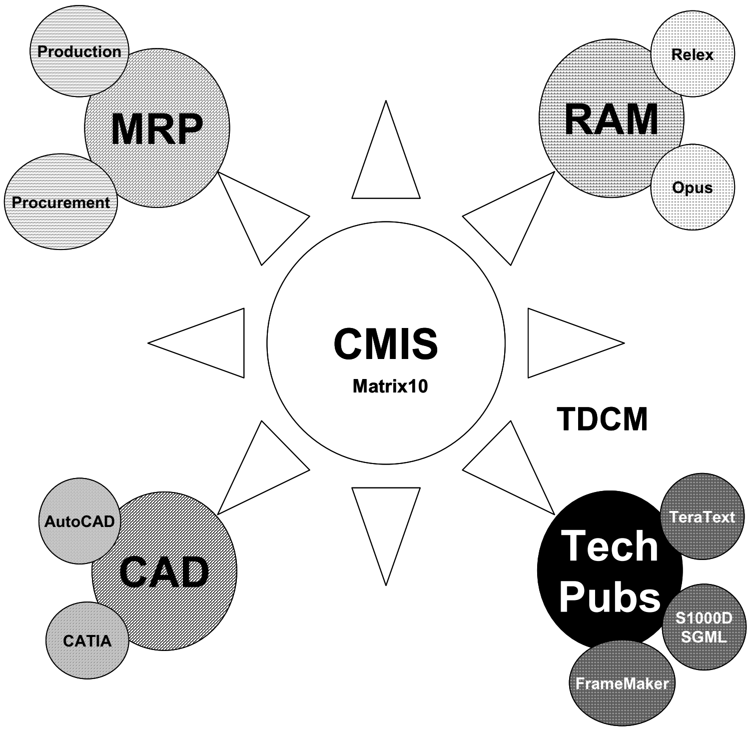

Figure 4.

Fleet knowledge management environment for Land Division. CMIS is the single user interface covering most aspects of the project.RAM includes the logistics tools Opus and Relax for the development of reliability and maintainability information. CAD represents the computer aided design systems, including AutoCAD and CATIA. TechPubs represents the technical authoring environment controlled within TeraText using the S1000D SGML data model and (currently) using FrameMaker as the authoring Tool. MRP represents the manufacturing resource planning environment including procurement and production control.

3 A KNOWLEDGE-BASED ORGANIZATIONAL FORM FOR FLEET MANAGEMENT

Tenix Marine is delivering the last of the ANZAC Ships in 2006, and is now involved in implementing the fourth Tenix iteration of a fleet knowledge management system in a new organizational structure. Responding to the kinds management issues cited by the Auditor General's reports (McNally 1997, McNally and Bates 1999), in mid 2001 the Navy formed a new kind of engineering and support organization for the ANZAC Ships (Bailey 2003). This ANZAC Ship Alliance ("Alliance") is formed from components of the Navy's ANZAC System Program Office ("SPO"), Tenix Marine, and the Combat System Supplier who had been a primary subcontractor to Tenix. The Alliance is a virtual organization formed to manage all changes and upgrades. The aim is to create a high performance collaborative relationship to manage change more effectively than through the use of traditional contracting models.

In the Alliance, Marine provides the primary management systems infrastructure and engineering baseline knowledge. The Combat System Supplier provides its detailed and practical knowledge of the weapons systems and electronics, while the SPO represents the fleet's "owners" and operators. As an organizational entity, the Alliance is responsible to guide and manage engineering and support activities to implement new technologies, optimally maintain capabilities of the ANZAC ships, and to remedy inefficiencies and faults discovered in operation.

An engineering change begins with drafting a change package for circulation to potential 3rd party suppliers for quotations. Installation of a change package is normally subject to open competition. However, better value for money may be gained by allowing the Alliance partners to perform the installation. This decision is based on value for money considerations subject to open book accounting and government probity audits. The Alliance responds to Defence requirements through structured target cost estimating processes. During the estimating process, the Alliance can optimize results by combining features of different competitors' proposals or by trading cost and capability to achieve best mix. The Alliance approach facilitates this optimization while minimizing the ability of any individual commercial partner to unduly influence the outcome (Anonymous 2003). After two years, the Defence Materiel Organization claimed the following benefits to itself and industry as:

- Government's involvement in all Alliance decisions;
- Fewer contract changes, reduced tendering and implementation costs;

- Increased predictability and reliability of forward business; and
- Open communication allowing the strengthening of long term relationships.

The Alliance is currently conducting a "Data Rationalization" project to bring all of the technical knowledge for supporting the fleet under common control within an architecture evolving from that shown in Figure 2. What the alliance is working towards is a more sophisticated and general version of the knowledge testing/improvement cycle illustrated in Hall 2003 (Fig 6) that the Supplier developed during the 10 ship-year test, evaluation and validation phase required under the Warship contract. What is illustrated is an OODA loop (Boyd 1996 - see also http://www.d-n-i.net/fcs/ppt/boyds_ooda_loop.ppt).

- The loop process is seeded with requirements for the operational capabilities to be provided by the fleet product;
- Authors and engineers design and develop a product set that meets the needs and determine knowledge that needs to be provided so the product can be safely and effectively operated and maintained;
- Authors and logistics analysts assemble, write and manage the technical knowledge ("data") package in the document (TeraText DB) and product data (PDM/ILS DB) management systems for internal review and signoff prior to production and delivery to the operators.
- Technical data products are transferred into the AMPS fleet maintenance management system.
- Operators and maintainers use the knowledge embodied in and served up by AMPS in their daily operations and maintenance of the fleet assets.
- Maintainers and operators return observations on results to AMPS, which collects and stores information regarding operations, maintenance, downtimes and any component failures.
- CSARS periodically extracts operational data (observations) from AMPS for logistics and engineering analysis, and provides the analysts with cognitive support highlighting for analysis system components or other factors contributing excessively to operating costs or non-availability of critical systems.
- Helped by CSARS and a variety of logistics analysis tools, logisticians and engineers seek improvements to the engineering of the product or its knowledge base that will resolve the identified problems.
- Recommended changes are circulated for review and signoff by the operator and engineering management, and implemented if approved in the fleet knowledge base.
- Changes to the fleet knowledge base are again downloaded to AMPS and the cycle repeats, to continue through the lifespan of the product,

The Alliance's “Data Rationalization Project”, is currently integrating the architecture illustrated in Figure 1 and Figure 2 within an “umbrella” PDM system like that developed by Land (Figure 3) so all engineering documentation is available to those who need it and so all changes are managed in the one common workflow environment. This is being implemented in the TeamCenter PLM tool offering similar functionality to the Matrix application implemented by Land. Given the proprietary nature of supplier knowledge, Marine and the Alliance will each maintain separate TeamCenter systems, but with the assurance of a seamless interface between the two for those knowledge products needed and used by the Alliance.

We argue that the ANZAC Ship Alliance exemplifies the strategic alliance form of organization (Spekman et al. 1998) based on sharing knowledge and learning (Inkpen 2000) about how to better support the fleet product. Carlile (2004) describes some of the barriers to organizational learning and innovation that boundaries within and between organizations can cause. These take three forms:

- Syntactic difficulties in transferring domain specific knowledge across the boundaries;
- Semantic difficulties in fully understanding and translating the transferred knowledge so it is capable of being used within the new domain; and
- Pragmatic difficulties in evaluating and valuing the effort required to fully transform the knowledge so it can be used in the new domain.

The Alliance's organizational goal is to support the Warship Class using staff and capabilities from three disparate and strongly bounded organizations (two directly competing commercial organizations and a client whose business they compete for) — with the implicit membership of government auditors who represent the ultimate operators and owners of the fleet. Although strategic alliances now represent a well known organizational form, based on a dearth of literature on the topic “support alliance”, this may be a relatively new type of the alliance form. Obvious risks in such an alliance in the fleet management realm would be difficulties establishing process in such a comparatively new organizational form, the potential for impaired engineering and management oversight where processes cross the boundaries of the competing organizations, the propensity to hide errors and mistakes within the partner organization where they occurred, etc. The success of the Alliance depends on the abilities of its partners to break down the boundaries between the disparate organizational groups assigned to carry out alliance activities. It is clear that implementation will benefit from the kind of technological infrastructure described in this paper (Fulk and DeSanctis 1995; Andersen 2004; Huber 1990).

Given that automated workflow is able to progress actions between actors at light speed and effortlessly monitor the progress of actions and activities through the workflows, it should be possible to fully apply the rigorous principles of the Australian Defence Technical Regulatory Framework to engineering change processes within the Support Alliance (and the parent organizations contributing to the alliance). Hopefully, the success of the new organizational form will be demonstrated in Australia, and the spread of its significantly automated cognitive processes to other large engineering projects will be measured by a reduction in the number of engineering disasters around the world.

APPLICATION OF RANDOM FOREST ALGORITHM IN MACHINE FAULT DIAGNOSIS

Xiao Di Tian Han, Bo-Suk Yang and Soo-Jong Lee

School of Mechanical Eng., Pukyong National University, San 100, Yongdang-dong, Nam-gu, Busan 608-739, Korea.

Abstract: The purpose of this paper is to present a methodology by which rotating machinery faults can be diagnosed. The proposed method is based on random forests algorithm (RF), a novel assemble classifier which builds a large amount of decision trees to improve on the single tree classifier. Although there are several existed techniques for faults diagnosis, such as artificial neural network, support vector machines etc, the research on RF is meaningful and necessary because of its fast executed speed, the characteristic of tree classifier, and high performance in machine faults diagnosis. Evaluation of the RF based method has been demonstrated by a case study on induction motors faults diagnosis. Experimental results indicate the validity and reliability of RF based fault diagnosis methodology. Furthermore, an optimized form of RF is also provided in this paper. We employ the genetic algorithm to strengthen RF. The capability of optimized RF algorithm is proved with same experimental data. It is the evidence that RF based diagnosis methodology can generate more accurate outcome by combining with other optimization method.

Key Words: Random Forests Algorithm, Machine Learning, Genetic Algorithm, Fault Diagnosis, Rotating Machinery

1 INTRODUCTION

The rotating machine plays an important role of modern industry, and is equipped in many crucial departments. This situation causes the problem that its breakdown will result in a huge losing. Therefore, fault diagnosis of machines is gaining importance in industry because of its capability to increase reliability and to decrease possible loss of production due to machine breakdown. Efficient and accurate faults categorized have been critical to machinery operated in normal condition. There are several well-known machine learning methods which also named artificial intelligence, such as artificial neural network (ANN), support vector machines (SVM) etc. The new techniques and their extended research increase the intelligent, preciseness and applicability of diagnosis domain. It exhibits the great potential of combining machine learning methodologies and machinery faults diagnosis theoretic. While the passion of developing machine learning based machinery faults diagnosis methods is increasing, there are a number of obstacles in the presence of researchers. That is, the correct diagnosis of the fault is rather complicated. The reasons are listed as follows:

- Different kinds of faults may result in a certain symptom, or feature extracted from raw data.
- Because of the background noise, some faults are difficult to be distinguished in the machine.
- There are a number of subassemblies with rotating machinery and a high level internal interaction between these subassemblies such as bearings, rotor bar and rotor etc.

Hence, the machine learning based fault diagnosis method which is employed to make hypotheses should be powerful enough to category the malfunctions in a correct way. So that, improving the capability of diagnosis is the motivation to inspirit researchers syncretizing existent technologies and exploring new theories.

In this paper, we introduce and investigate a novel rotating machinery faults diagnosis methodology based on random forests algorithm (RF) [1, 2]. It built a large amount of decision trees out of sub-dataset from a unique original training set by using bagging, acronym of bootstrap aggregating which is a meta-algorithm to improve classification and regression models according to stability and classification accuracy. Bagging also reduces variance and helps to avoid over-fitting. This procedure extracts cases randomly from original training data set and the bootstrap sets are used to construct each of decision trees in the RF. Each tree classifier is named component predictor. The RF makes decision by counting the votes of component predictors on each class and then selecting the winner class in terms of number of votes to it. Details of the theory will be represented in the section two RFs.

Since first introduced by Breiman, RF has been employed in various fields such as astronomy, micro-array analysis and drug discovery and otherwise [3, 4]. RF provides good performance in applications in these fields, and it also can be a competitor for rotating machinery faults diagnosis, because of these distinctive features as below [1]:

- Unexcelled in accuracy among current algorithms
- Runs efficiently on large data bases
- Can estimates of what variables are important in the classification
- Has methods for estimating missing data and maintains accuracy when a large proportion of the data are missing
- Computes proximities between pairs of cases that can be used in clustering, locating outliers, or five interesting views of the data
- Generates an internal unbiased estimate of he generalization error as the forest building progresses

Due to these features and its board application, we investigate the performance of RF based faults diagnosis methodology. Furthermore, an optimized RF methodology is also explored in this paper by combining the genetic algorithm. Experimental result shows optimized RF based methodology achieves a very high accuracy by cooperating RF with GA.

2 RANDOM FOREST AGORITHM

RF which derives from decision tree classifier is an assembled method, it grows tree using CART (acronym of classification and regression trees) methodology to maximum size without pruning. RF has greatly improved classification accuracy resulting from growing an ensemble of trees and making them vote for the most promising class. A convenient method to build the ensembles' random vectors generation via random selection procedure from integrated training set. The constituent in this method is that we prepare k random vectors, Θ_k, which is independent of the past random vectors Θ_1, Θ_2, Θ_3, …, Θ_{k-1} but with the same distribution to build the trees among the RF. Corresponding individual classifier is noted by $C(\mathbf{X}, \Theta_i)$. And then they vote for the most popular class. Breiman names these procedures as random forests. A definition drawn from original paper is available here [1, 2].

Definition 1 A random forest is a classifier consisting of a collection of tree structured classifiers $\{C(\mathbf{X}, \Theta_i), i = 1, \ldots k -1\}$ where the $\{\Theta_i\}$ is independent identically distributed random vectors and each tree casts a unit vote for the most popular class at input vector $\mathbf{X}$.

2.1 Two randomized procedures in RF tree building

As mentioned below, RF enhances classification accuracy significantly compared with decision tree classifier. It is the reason that RF applies two randomized procedures when it builds trees. Each tree is built as follows:

Firstly, assuming that the number of cases in the training set is N and the number of variables in the classifier is M. Select the number of input variables that will be used to determine the decision at a node of the tree. This number, m should be much less than M. Secondly, choose a training set by choosing N samples from the training set with replacement. And then, for each node of the tree randomly select m of the M variables on which to base the decision at that node. Calculate the best split based on these m variables in the training set. Finally, each tree is fully grown and not pruned.

The two distinctive randomized procedures exist among four steps below. That is, RF extracts a fixed quantity from training set randomly, or names it bagging process [5]. RF draws one-third of observations from training set with same underlying distribution. This part of data is named out-of-bag data to get an unbiased estimate of the test set error of an individual tree. The rest of data is used to build the single tree classifier. After the bagging processing, the other randomized procedure is emerged in node splitting while tree classifier is built. Different from normal CART like decision tree splitting algorithm, CART within RF algorithm searches only in m variables which are small amount and drawn at random from all M variables instead of entire variables.

The research of Breiman states why these two randomized procedures make classification accuracy increase effectively. Improvement will occur for unstable procedures where a small change in training set can result in large change between component classifier and classifier trained by entire training set. In RF, whatever the bagging processing or the randomly selection of variables to split the node both make difference in individual tree and forests. Therefore, these two sources of randomness are most important feature of RF.

2.2 Convergence of RF

RF adopts an ensemble of decision trees and determines the categorical classes by majority vote algorithm. Thus a serious consideration of over-fitting is necessary to test the performance of RF. Normally an over-fitting will occur where learning is performed too long or where training examples are rare, the learner may be limited in very specific random features of the training data that has no causal relation with target function. But RF can avoid the over-fitting completely, which was proved in Refs [1]. To affirm this point, we define a margin function at first.

Given an ensemble of a series of classifiers $C_1(\mathbf{X})$, $C_2(\mathbf{X})$, …, $C_k(\mathbf{X})$, and with the training set drawn at random from the distribution of the random vector Y, $\mathbf{X}$, define the margin function as

$$mg(\mathbf{X},Y) = av_k \, \mathrm{I}(C_k(\mathbf{X}) = Y) - \max_{j \neq Y} av_k \, \mathrm{I}(C_k(\mathbf{X}) = j) \quad (2)$$

Where $\mathbf{X}$ is the input metric, av_k is the average number of votes at $\mathbf{X}$, Y for the right class and I( ) is the indicator function. The margin measures the extent to which the av_k exceeds the average vote for any other class. The larger in the margin, the more confidence in the classification.

According to this function, the generalization error is given by:

$$PE^* = P_{X,Y}\left(mg(\mathbf{X},Y) < 0\right) \quad (3)$$

Where $P_{\mathrm{X},Y}$ indicates the probability which is over the $\mathbf{X}$, Y space.

Theorem 1 As the number of trees increases, for almost surely all sequences Θ_1, PE^* converges to:

$$P_{\mathbf{X},Y}\left(P_\Theta\left(C(\mathbf{X},\Theta) = Y\right)\right) - \max_{j \neq Y} P_\Theta\left(\left(C(\mathbf{X},\Theta) = j\right) < 0\right) \quad (4)$$

Theorem 1 is proved with the strong law of large numbers and the tree structure. It indicates that it is unnecessary for RF to employ common anti-overfitting methods for instance, cross-validation, early stopping, etc. RF do not overfit when more trees are added, meanwhile it result in a limiting value of the generalization error. This is another important feature of RF beside the two randomized procedure mentioned above.

2.3 Accuracy of RF depending on strength and correlation

In last section, the anti-overfitting characteristic of RF is proved. But we concern more about its accuracy. According to the analysis built in references, an upper bound of RF can be derived for the generalization error in terms of two parameters that are measures of how accurate the individual classifiers are and the dependence between them. These also lead an in-depth view of how RF works. Firstly we define a margin function and raw margin function for RF.

The margin function for a random forest is:

$$mr(\mathrm{X},Y) = P_\Theta\left(C(\mathbf{X},\Theta) = Y\right) - \max_{j \neq Y} P_\Theta\left(C(\mathbf{X},\Theta) = j\right) \quad (5)$$

The raw margin function is:

$$rmg(\Theta,\mathbf{X},Y) = I\left(C(\mathbf{X},\Theta) = Y\right) - I\left(C(\mathbf{X},\Theta) = \hat{j}(\mathbf{X},Y)\right) \quad (6)$$

Distinctively, $mr(\mathbf{X}, Y)$ is the expectation of $rmg(\Theta, \mathbf{X}, Y)$ with respect to Θ. And the strength of the number of individual classifiers $\{C(\mathbf{X}, \Theta)\}$ is:

$$S = E_{X,Y} mr(\mathbf{X},Y)$$

where $E_{\mathbf{X},Y}$ is the expected value of margin function over $\mathbf{X}$, Y space. Then we compute the variance of margin function:

$$\mathrm{var}(mr) = \bar{\rho}\left(E_\Theta sd(\Theta)\right)^2 \le \bar{\rho} E_\Theta \,\mathrm{var}(\Theta) \quad (7)$$

Write

$$\mathrm{E}_\Theta \,\mathrm{var}(\Theta) \le \mathrm{E}_\Theta\left(\mathrm{E}_{\mathbf{X},Y}\, rmg(\Theta,\mathbf{X},Y)\right)^2 - S^2 \le 1 - S^2 \quad (8)$$

Where $\bar{\rho}$ is the mean value of the correlation, $sd(\cdot)$ is standard deviation of $rmg(\Theta,\mathbf{X},Y)$. Considering equations (7), (8) and Chebychev inequality, theorem 2 can be concluded.

Theorem 2 An upper bound for the generalization error is given by

$$PE^* \le \bar{\rho}\left(1-S^2\right)/S^2 \tag{9}$$

Although the bound is likely to be loose, it full fills the same suggestive function for random forest as VC-type bounds do for other types of classifiers. It shows that the two ingredients involved in the generalization error for random forests are the strength of the individual classifiers in the forest, and the correlation between them in terms of the raw margin functions. There is a conclusion drawn from this upper bound, that is the smaller this ration is, the better performance RF provided.

3 GENETIC ALGORITHM

RF is strengthened by a standard genetic algorithm (GAs) [9] in this paper. GA is a simulation of evolution where the rule of survival of the fittest is applied to a population of individuals, or it can be considered as a parallel searches procedure that simulates the evolutionary process by applying genetic operators. Comparing with other search algorithms, GA has been well-known for its superior performance. And a most powerful feature of GAs is the great simplicity of it. They do not need too much code and no differentiability or continuity requirements to be satisfied. The usual GA flowchart and steps are shown as follow:

Step 1: Coding, generate an initial population (usually a randomly string)

Step 2: Fitness evaluation, apply some function or formula to the individuals to get the fitness of each individual.

Step 3: Selection, according to the fitness, individuals are selected to be the parents of next generation.

Step 4: Crossover, it is used to create two child individuals from the parent which pass the selection successfully via exchanging their chromosomes.

Step 5: Mutation, it assigns a new value to a randomly chosen gene and is controlled by a mutation probability.

Step 6: Repeat steps 3 to 5 until the evolved result satisfy the termination criteria, or a certain fixed number of generations are achieved.

4 EXPERIMENT PLATFORM AND MOTOR FAULTS DATA DESCRIPTION

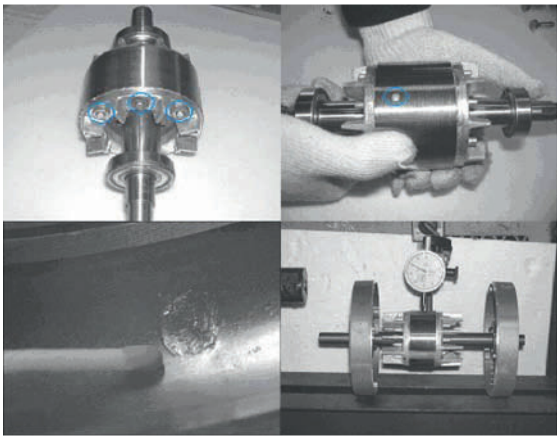

Figure 1. Faults on introduction motor.

The experiments are designed to simulate six most universal categories of induction motors faults which are broken rotor bar, bowed rotor, bearing outer race fault, rotor unbalance, adjustable eccentricity motor (misalignment) and phase unbalance, first four motor faults are shown in Fig. 1 as examples. The load of the motors can be changed by adjusting the blade pitch angle or the number of the blades. The platform of these experiments consists of six 0.5kW, 60Hz, 4-pole induction motors, pulleys, belt, shaft and fan with changeable blade pitch angle.

Three AC current probes and another three accelerometers were used to measure the stator current of three phase power supply and vibration signals of horizontal, vertical and axial directions for evaluating the RF based fault diagnosis system.

After measuring the raw data, a preprocessing and feature extraction are implemented on the data to obtain the most important features for the RF based diagnosis methodology [6]. Finally, there are 63 features left which are prepared for the next procedure, induction motor faults diagnosis by RF.

5 INDUCTION MOTOR FAULTS DIAGNOSIS

In this section, RF was run on the induction motor faults data. The experimental results are given in Table 1. Confusion matrixes for the training data in RF are given by Table 2 which shows the accuracies of each fault class for testing data with 1200 trees and selecting 1 variable every split.

Table 1

Faults diagnosis accuracies based on RF

Trees No.	Split variables	Test accuracy (%)	Trees No.	Split variables	Test accuracy (%)
200	1	88.89	2000	5	73.34
500	1	94.44	5000	5	72.23
1200	1	95.56	10000	5	74.44
2000	1	93.33	200	8	81.22
5000	1	92.23	500	8	83.33
10000	1	92.25	1200	8	82.34
200	5	71.11	2000	8	83.33
500	5	75.56	5000	8	78.89
1200	5	72.23	10000	8	77.78

The experimental results in Table 1 show three characteristics of RF clearly:

First, compared with the number of component classification trees, the parameter, random split number at each node, is more sensitive to the classification accuracy. Hence a prudential searching procedure is necessary to find the best split variables number by an experimental way. Second, if the split variables number is decided, the sum of individual tree classifiers should achieve appropriate quantity to get a better performance. Last one, when we increase trees into a high number, for example 5000 or 10000, there is no over-fitting occurred but a little undulate existed.

Table 2 indicates that incorrect diagnosis of RF based methodology often occurs at certain fault category. So we can apply some assistant diagnosis methods which are function in that specific kind of fault to improve the diagnosis precision. Additional, variable importance is another strongpoint of RF. But in this case, using 18 most important features replacing the all just can get an accurate rate 93.32%, slightly lower than the best correct classification rate. The reason is that replacing all by the important features is able to increase the accuracy only when the data is adulterated with noise at a certain extent.

Table 2

Accuracy of each fault class for test data with 1200 trees and selecting 1 variable every split

Class No.	1	2	3	4	5	6	7	8	9	Accuracy (%)
1	10	0	0	0	0	0	0	0	0	100
2	0	10	0	0	0	0	0	0	0	100
3	0	0	10	0	0	0	0	0	0	100
4	0	0	0	10	0	0	0	0	0	100
5	0	0	0	0	7	3	0	0	0	70
6	0	0	0	0	0	10	0	0	0	100
7	0	0	0	0	0	0	10	0	0	100
8	0	0	0	0	0	1	0	9	0	90
9	0	0	0	0	0	0	0	0	10	100

In general, the normal RF has achieved the satisfied fault diagnosis accuracy. But it should be noticed that two parameters, the number of trees and random split number, which greatly affect classification result are set manually. It means accuracy of normal RF depends on researcher's experience. This situation exists at almost all the applications of RF. So that applying the genetic algorithm to do the parameter optimization is exigent. The effect of this cooperation is proved by using same data. According to the pervious research, the number of trees and random split number are limited in the range from 500 to 1500 and from 1to 10 respectively. In order to reduce executed time of GA program and find the optimized point synchronously.

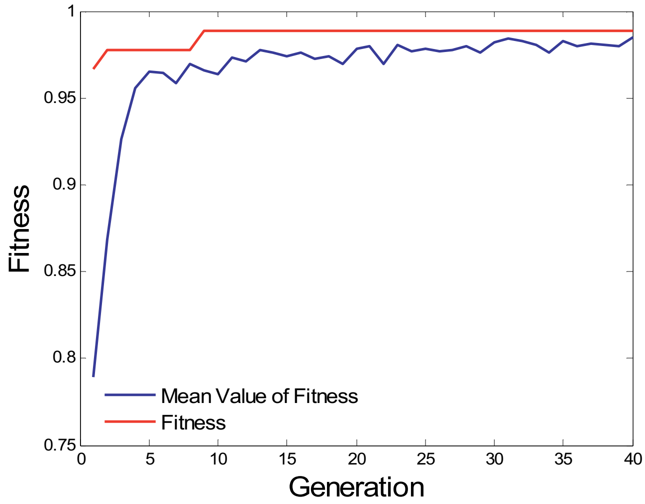

Figure 2. Optimization trace within 40th generation.

Figure 2 shows the trace information of every generation. Fitness adopts the classification accuracy of test data set. The upper curve is the best fitness value and the other one is mean fitness value of each generation. The risen trend of mean fitness value convergent indicates that GA well cooperates with RF based methodology on the motor fault diagnosis, and best fitness value lays out the optimization point which is 908 trees and 1 random split created by 9th generation. The classification accuracy at this point achieves the 98.89%, 3.33% higher than the best value of normal RF. It means GA can enhance the capability of RF algorithm distinctly.

6 CONCLUSIONS

In this paper, the RF and optimized RF based faults diagnosis methodology of rotating machinery were investigated. The performance of two methodologies was proved by the faults diagnosis test of an induction motor. The optimized approach attains a high correct rate of diagnosis, 98.89%. It means optimized RF based method is competitive with other classification method. Especially, the assemble classification trees method and even faster then some of them [1, 7], it is proved by other multi-classes classification applications.

The extended research will focus on decreasing the redundancy of the RF and try other optimization algorithm or more effective voting principle.

EXPLOITING TECHNOLOGY FOR REAL TIME HIGH VOLTAGE NETWORK FAULT MANAGEMENT

Randall Jones and Brett Handley

Powerlink Queensland, PO Box 1193, Virginia, Queensland, 4014, Australia

Abstract: Changes in the electricity supply industry have led to transmission companies being exposed to increased pressure associated with reliability and quality of supply issues. The effectiveness of the fault management process is fundamental in mitigating business risks associated with the impact of faults on the high voltage network. The existence of large volumes of data being captured and stored by intelligent field devices associated with almost all items of high voltage plant and equipment, has resulted in the root cause of network events being able to be readily identified in a post fault timeframe. However, if this data can be accessed remotely, and most importantly turned into "information", in the "real time" fault timeframe, it can be used to make informed decisions about the suitability of faulted plant for service. Using this philosophy, Powerlink Queensland has developed and implemented an innovative fault management strategy, aimed at realising the business goals. This paper outlines Powerlink Queensland's business approach to fault management. In particular, the paper focuses on the key elements of the strategy that have enabled the business goals to be realised. A case study provides an example of the benefits being realised by this innovative approach.

Keywords: Fault Management; Asset Monitoring; HV Networks

1 INTRODUCTION

Powerlink Queensland is a government owned corporation that owns, operates and maintains Queenslands high voltage electricity transmission network. The network extends 1700km from north of Cairns to the New South Wales border – approximately half of Australia's eastern seaboard.

It is common knowledge the electricity supply industry has undergone significant restructuring in the face of deregulation in recent years [1]. Modern power systems have become more complex to operate and control, and transmission infrastructure is being run to the limits of its technical envelope to achieve the demanding performance requirements of Transmission Network Service Providers (TNSPs).

These ongoing changes have forced TNSPs to think outside the square when it comes to utilisation of asset capability.

Powerlink as a regulated electricity transmission company faces a continual challenge to reduce system operation and maintenance costs while increasing network availability and reliability. [5]

The introduction of the Australian Competition and Consumer Commission (ACCC) transmission service standards, and the associated financial penalties and bonuses for transmission companies, have increased the need to be able to make informed decisions about the health of high voltage network plant and equipment.

The key, to allow informed decisions to be made about the suitability of service of high voltage network plant and equipment following an event, is the availability of accurate information.

This paper outlines the ways in which Powerlink Queensland is exploiting the capabilities of equipment technology to obtain this accurate information, to strive for operational excellence in transmission service provision.

2 THE NEED FOR INFORMATION

In November 2003 the Australian Competition and Consumer Commission (ACCC) released transmission service standards guidelines [2]. These standards have had a marked impact on the way TNSPs view network operational performance. According to Powerlink Queensland Chief Executive, Gordon Jardine, being operationally 'just OK' is no longer acceptable for grid customers and other stakeholders. 'Operational Excellence' has since become a key Powerlink business objective with financial penalties imposed upon TNSPs failing to meet the ACCC service standards. [4] There are also monetary incentives offered to TNSPs exceeding the standards.

Financial incentives under the transmission service standards guidelines are attributed according to delivery against predefined operational measures. These include:

- Measure 1 – Transmission Circuit availability;
- Measure 2 – Average outage duration; and
- Measure 3 – Loss of supply event frequency index.

Unfortunately, network incidents will often occur due to influences outside the TNSPs' control. The circuit availability measure, loss of supply frequency index, average outage duration and network constraints are impacted according to the success of the corporate fault management strategy. The success of the strategy hinges on critical accurate information being available, to allow restoration plans to be formulated and resources to be deployed, to reinstate the affected network in the most effective and efficient manner.

3 AVAILABILITY OF DATA

3.1 Plant and Equipment

In the late 1990s, a period of intense capital investment and expansion commenced on Powerlink's transmission network. It was quickly identified that high voltage plant and equipment manufacturers were embracing technology, and supplying products that came standard with intelligent monitoring systems capable of providing data about the health of the device, both in a real-time timeframe and as stored historical trends and records. These monitoring systems were being applied equally to substation plant, such as circuit breakers and transformers, as well as secondary systems including protection, control, and communications systems. As an example, Powerlink has high voltage circuit breakers in service that each host a total of twenty-one intelligent devices on board (seven per phase) performing state of the art monitoring and data provision functions.

This monitoring data generally lives on the item of plant, in an intelligent device, or in the case of secondary systems, within the device itself.

This monitoring data is very detailed and as such not suitable for transmission to the Substation Control System (SCS) or transmission via Supervisory Control and Data Acquisition (SCADA) to Powerlink's statewide network control centre (NCC).

Generally, manufacturers intended for the information to be obtained and analysed by service personnel on site, trained in the use of extraction tools such as laptop computers and trained in the expert assessment of the data, in order to turn it into information.

3.2 Substation Control Systems

In the early to mid 1990s, Powerlink began implementing computer based distributed control system technology as its substation control system (SCS). The SCS was implemented with a Local Control Facility (LCF) that was both a Human-Machine Interface (HMI) and an event capturing and logging system. The event log of the site LCF provides the lowest level detail of substation event information and is crucial to the post fault analysis function of system events.

In the early 2000s, a new and improved substation integrated secondary system was designed by Powerlink to take full advantage of the remote access technologies and infrastructure being implemented. The secondary system provides advanced automation and condition-monitoring facilities, including significant fault diagnosis and alarming features. [6]

4 OBTAINING DATA FROM THE FIELD

With consideration of the business drivers, it very quickly became apparent, and increasingly justifiable, that there were some big advantages to be realised by remotely accessing data that existed at the remote site.

As part of the capital expansion in the late 1990s and continuing into the 2000s, Powerlink's telecommunications infrastructure has been significantly upgraded and expanded. This was necessary to meet the requirements of the National Electricity Rules in the areas of protection and SCADA.

High speed digital communication existed between Powerlinks Brisbane office and remote substations. The site data was available and waiting to be obtained, and a communications infrastructure back to the office was in place. The next step to provide a connection from the intelligent devices to the communications infrastructure was easily justifiable when considerations of the advantages to be obtained were completed.

Powerlink established an asset monitoring strategy to reduce operational and maintenance costs, while seeking to reduce the frequency and duration of system outages. A key aspect of this strategy was the remote monitoring of high voltage equipment to enable rapid diagnosis of incipient failure trends and faults prior to a system or equipment outage. [5]

From this strategy, the justification, design and implementation of Powerlink's Operational Wide Area Network (OpsWAN) for remote monitoring and interrogation of plant and equipment was borne.

The OpsWAN system comprises a number of strategically located computer servers that provide the gateway to plant and equipment located in that geographic area. These servers communicate via an operational Wide Area Network (WAN) comprising of 2 Megabit communication channels.

Powerlink currently has 70 substations remotely accessible from the OpsWAN system, providing remote access to over 1500 intelligent primary plant and secondary system devices from its Brisbane office. Devices connected include:

- Video camera systems;
- Protection relays;
- Battery systems;
- Telecommunications equipment;
- Substation local control facilities;
- Discreet device local control facilities
- Hydran transformer gas monitoring units;
- Power transformer management systems;
- Circuit breaker monitoring systems; and
- Other plant specific plant monitoring systems.

A typical configuration of an OpsWAN installation is shown in Figure 1.

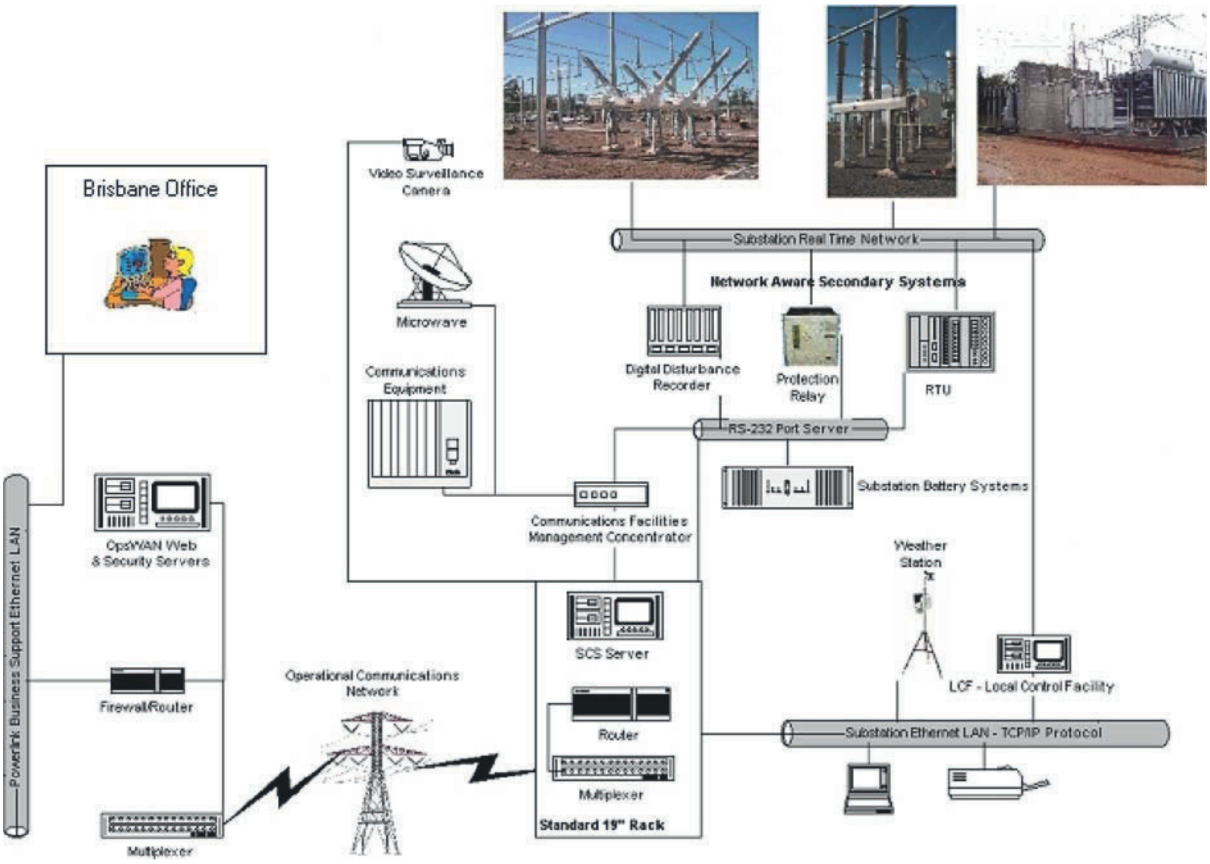

Figure 1. Typical configuration of an OpsWAN installation

5 TURNING DATA INTO INFORMATION

The next part of Powerlink's asset monitoring strategy is to turn this remotely obtained low-level detailed data into value added accurate information. It is this value added accurate information that is critical, to allow informed decisions to be made about the suitability of service of high voltage network plant and equipment following an event.

As part of Powerlink's Asset Monitoring Strategy, an Asset Monitoring Team (AMT) was formed. The AMT has three key objectives associated with the operation and maintenance of Powerlink's high voltage transmission network. These are to reduce costs, minimise exposure to potential liability, and ensure quality of supply. To achieve these objectives, one of the team's tasks is to turn the copious amounts of field data, now available in the office, into value added accurate information in a timeframe suitable for use in real time system event restoration and action plans.

An innovative part of Powerlink's Asset Monitoring Strategy entailed the design of a high level framework for the provision of information from the analysis of raw data.

An overview of the Powerlink Data to Information Framework is shown in Figure 2.

Within the framework, the upper layers draw on and are dependent on the lower ones. For example, prior to data interpretation being done, some level of data management is required. In turn, data management requires an emphasis on communications systems and data capture capability. [3]

The seven layer data-to-information pyramid below summarises this process.

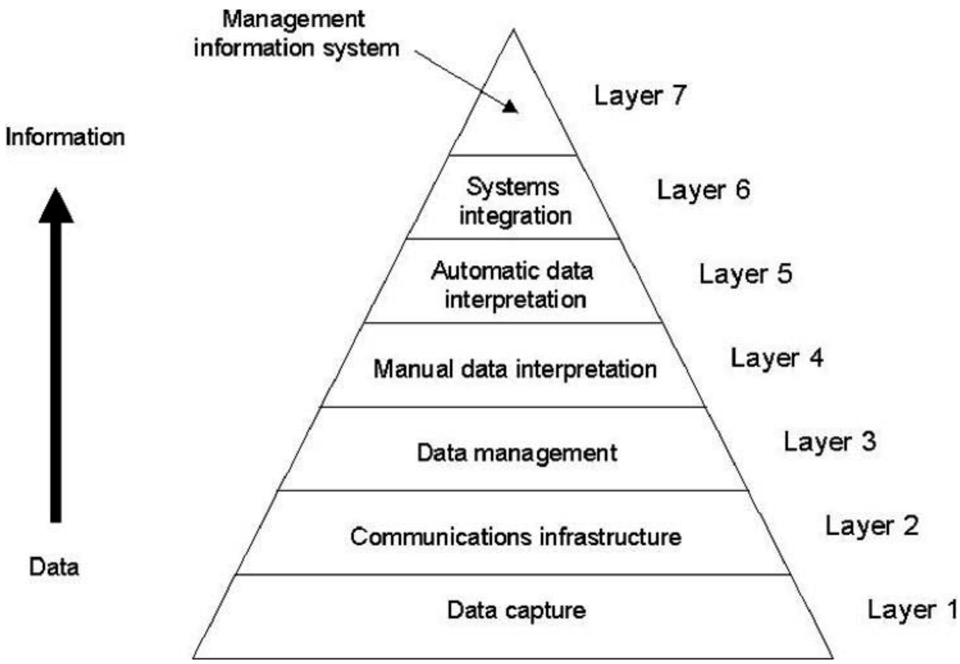

Figure 2 – Powerlink Queensland Data-to-Information Framework

The ability to obtain site data remotely from the office and turn it into value added information in a real time timeframe was achieved. The next step is to integrate this capability into the Fault Management process.

Powerlink's Asset Monitoring Strategy had also identified that changes to the fault management process were required. A review of the fault management process was undertaken and changes made as discussed later.

6 FAULT MANAGEMENT PROCESS REVIEW

To Powerlink's management, it was clear the ability to obtain detailed site data and turn it into valuable information quickly would provide significant benefits from a fault response perspective. The creation of a new role to cover this requirement would also provide significant benefits in exploiting the available data from a proactive condition and performance monitoring perspective. A business case put forward to the Powerlink Executive resulted in the approval and successive formation of the Asset Monitoring Team (AMT) to perform a number of new functions, including fault management. [4]

The AMT needed to interface efficiently with the traditional functions of fault management. The conventional fault management process was modified such that the Network Control Centre (NCC) continued detection of plant and equipment faults via the SCADA system, but then handed over the fault management responsibility to the AMT.

The NCC monitors the network, and, if a fault occurs, transfer the fault management responsibility to the AMT. The AMT are available on-call 24 hours a day, 7 days a week. This single point of contact ensures there is no confusion as to who the NCC controller should call. This hand over process allows the NCC operator to concentrate on their core task of monitoring and operating the high voltage network.

A flowchart of the new fault management process is shown in Figure 3.

The AMT then obtains the detailed data from the appropriate substations via OpsWAN and analyses the data. Once the cause of the fault has been established, the AMT can then assign a priority to the fault and request the Maintenance Service Provider (MSP) attend to the fault immediately, next day, next working day or next opportunity, depending on the urgency of the fault and based on policies set by Powerlink's Asset Manager. A further benefit of this strategy is that the cause of the fault is known up front, enabling appropriately skilled staff with the necessary tools and spares to be sent to site, hence avoiding multiple site visits. In certain circumstances, where technology allows, it is possible for the fault to be repaired remotely avoiding the requirement for MSP involvement.

There are feedback loops between the different parties to ensure everyone is kept abreast of developments as necessary. The AMT also fulfils the coordination role between the various stakeholders.

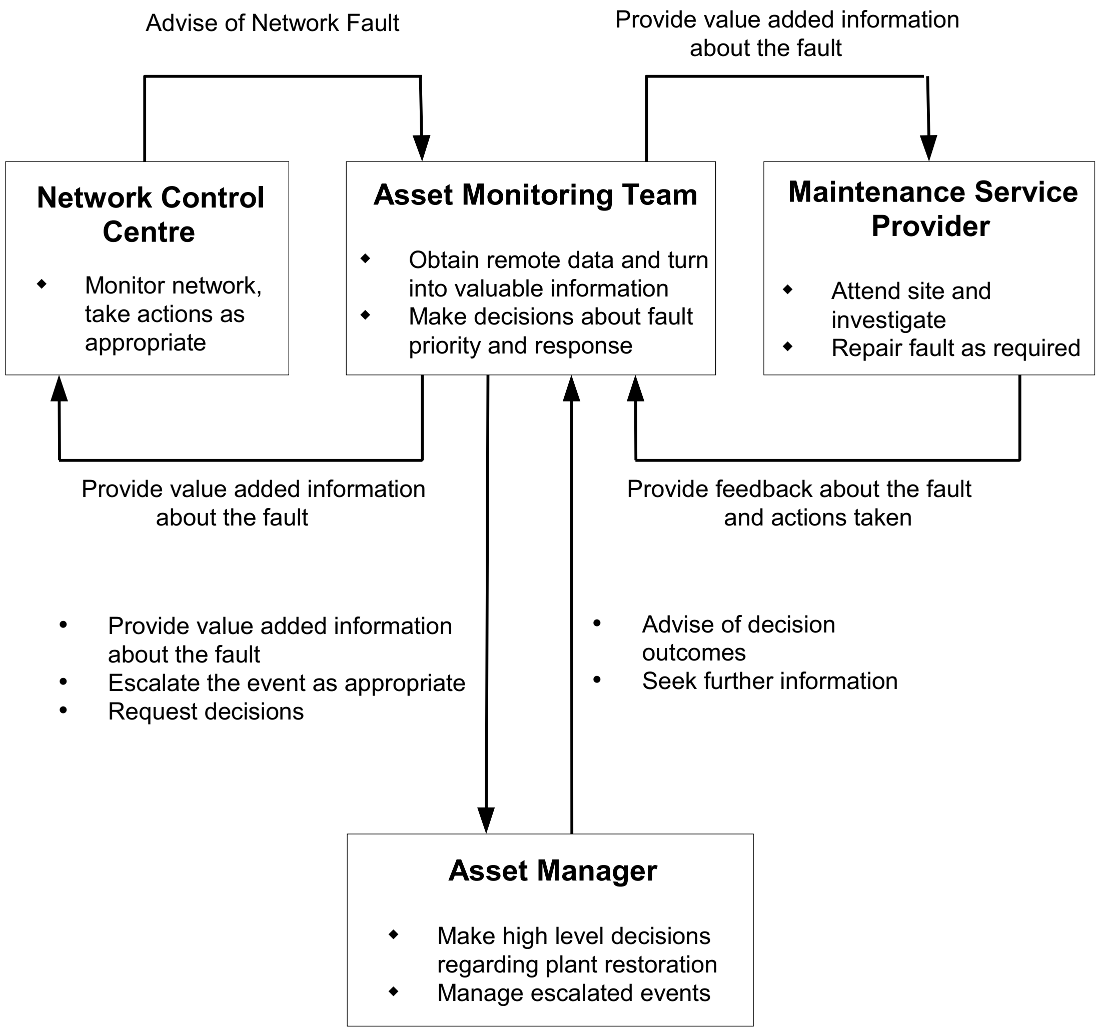

Figure 3. Powerlink's New Fault Management Process

As a result of the new fault management process, the AMT is involved with each fault that occurs on Powerlink's high voltage network. As the AMT is intimately involved in the fault management decision making process their knowledge and experience is made available for every incident. This involvement is also beneficial in post fault analysis to ensure the same fault does not occur again, and in looking for failure trends across the network.

On reflection, the traditional fault management process does not cater for the existence of the AMT. The AMT is necessary to exploit fully the technology and communication capability available. The NCC cannot afford to be distracted from their core business of operating the network, therefore it was decided not to extend the roles of the NCC controllers.

7 ADVANTAGES OF THE NEW ASSET MONITORING STRATEGY

From the perspective of the Asset Manager, MSPs and NCC controllers, significant improvements are being realised in the amount of valuable information being made available. In particular, benefits being achieved by the new process are the:

- application of the Asset Manager policy and procedures in a consistent manner;
- application of the fault knowledge obtained from one component failure across the entire network;
- exploitation of the technology and related infrastructure (this is clearly demonstrated in the following case studies);
- prioritisation of the fault response, so MSPs are not called out unnecessarily;
- realisation that the AMT has the knowledge to perform proactive as well as reactive fault management.

Deviating from traditional fault management practices places Powerlink in a better position to utilise installed technologies to meet the changing business and regulatory body objectives. The combination of technology and efficient process has had a marked impact on the speed of response to power system faults and is progressively eliminating recurring faults through better monitoring and works management. [4]

The combination of these benefits results in reduced cost of fault management activities. Based on operational experience to date using the new fault management processes and the technology available, Powerlink has reduced the number of fault related site visits, to sites connected to OpsWAN, by typically 20% and reduced the requirement for immediate call outs by 50%.

8 CASE STUDIES

8.1 Case Study 1 – Loss of Sulphur Hexaflouride (SF6) insulating gas from a Circuit Breaker

The following case study provides an example of two real network events. Both events occurred at a critical 275/132/66kV transmission substation providing point of supply for distribution company load as well as critical mining infrastructure load. This substation has a modern Substation Control System (SCS) with a Local Control Facility (LCF) that provides low-level detail about the root cause of any alarms initiated from the site. Summary alarms are sent to the Network Control Centre (NCC) to advise of loss of functionality of equipment on site, or priority of attendance required to an equipment fault in line with Powerlink's Asset Manager policies. This substation is located approximately 4 hours drive from the primary maintenance service provider's depot.

Event 1 occurred in October 2003 and was managed under the previous (traditional) fault management model. This event has been provided to allow comparison to Event 2, which was associated with the same circuit breaker at the same substation in October 2005.

8.1.1 Event 1 – October 2003

This event occurred under the traditional fault management model.

At 1440hrs several alarms were received at the Powerlink NCC. The alarms advised of both an urgent and non-urgent condition associated with a 132kV Hybrid circuit breaker. There was no other information available about the alarms from site. The maintenance service provider responsible for this site was advised, with the estimated time of arrival being approximately 1830hrs.

At 1717hrs a protection trip of one of the two 132kV busbars occurred. The busbar that tripped was the one connected to the hybrid circuit breaker that was alarming. Maintenance service provider staff attended site and it was subsequently determined that the cause of the urgent alarm from the 132kV Hybrid circuit breaker was due to a rapid loss of SF6 insulating gas. This was caused by a major leak associated with one of the rupture disks. An internal flashover subsequently occurred when the SF6 insulating gas density could no longer provide adequate insulation for the system voltage. Significant damage occurred to the pole resulting in the need for it to be sent back to the manufacturer for repair.

8.1.2 Event 2 – October 2005

This event occurred under Powerlink's new fault management policy, which incorporates the use of technology to remotely access substation low-level detail data, and a process incorporating the AMT to turn this data into information is a real time timeframe.

At 1543hrs several alarms were received at the Powerlink NCC. The alarms advised of both an urgent and non-urgent condition associated with a 132kV hybrid circuit breaker.

At 1545hrs, the NCC operator called the AMT to advise of the alarms and hand over the fault management responsibility.

AMT staff used OpsWAN to remotely access the site LCF, the device that contains the low-level detailed data associated with the alarms received by the NCC.

At 1554hrs, after remotely accessing the substation LCF, AMT staff identified the root cause of the alarms as a rapid loss of SF6 insulating gas from a 132kV hybrid circuit breaker.

At 1555hrs, AMT staff advised the NCC operator that urgent de-energising of the affected circuit breaker was required to avoid internal circuit breaker flashover, in turn causing a protection trip of one of the two 132kV busbars.

The NCC staff immediately developed a plan to shift load and, with the assistance of monitoring information from the AMT on estimated time to flashover, had remotely de-energised the affected 132kV hybrid circuit breaker by 1639hrs.

No load was lost for the event, a costly hybrid circuit breaker internal flashover was avoided and network constraints and loading issues were significantly reduced compared to Event 1 in October 2003.

8.2 Case Study 2 – Trip of two 132kV Busbars at a critical Central Queensland substation.

This case study steps through the events associated with a forced outage at one of Powerlink's 132kV substations.

The event commenced with the Bus Zone protection trip of two out of the four 132kV busbars. The single line diagram is shown in figure 4. This event occurred outside of normal business hours.

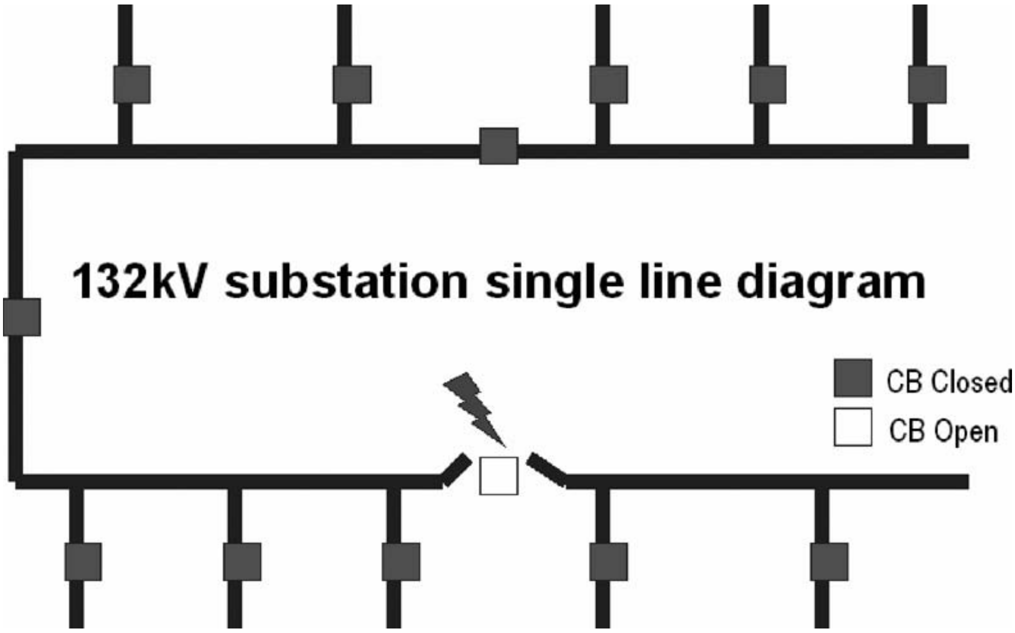

Figure 4. Substation single line diagram after protection trips

A combination of height voltage plant rating issues and network constraints resulted immediately the event occurred. The NCC operator immediately called the AMT and requested assistance and information on what had occurred.

The AMT immediately called the local Maintenance Service Provider and requested immediate site attendance due to the seriousness of the event and the probable need for site attendance.

Within 10 minutes of the event occurring, remote connection to the substation was established and analysis of the substation control system event log was being undertaken.

Within 15 minutes of the event occurring, it had been established that all duplicated bus protection systems had operated on the out of service busbars. Remote access to the bus zone protection relays was established and analysis of the protection disturbance records commenced.

Within 20 minutes of the event, information was provided to the NCC operator that there had been a genuine high voltage fault internal to the bus section circuit breaker, within the overlap of the bus zone protection schemes. The faulted circuit breaker was part of a hybrid switchgear module which included remotely operable isolators on each side of the circuit breaker. A recommendation to remotely open these isolators was provided to the NCC operator to disconnect the faulted plant from the system. While this was being performed, as per Powerlink policy for latched protection systems, consultation with the Asset Manager occurred to brief him of the situation and seek approval to restore the out of service busbars and deloaded feeders.

Within 30 minutes of the event occurring, the NCC operator had remotely opened the isolators to disconnect the faulted circuit breaker from the system. The AMT had remotely reset all the latched bus zone protection relays and advised the NCC operator of Asset Manager approval to restore the out of service busbars and feeders.

Within 45 minutes of the event occurring, the busbars had been restored and feeders reloaded relieving the plant loading issues and system constraints.

At approximately 55 minutes after the event occurred, the local maintenance service provider arrived on site.

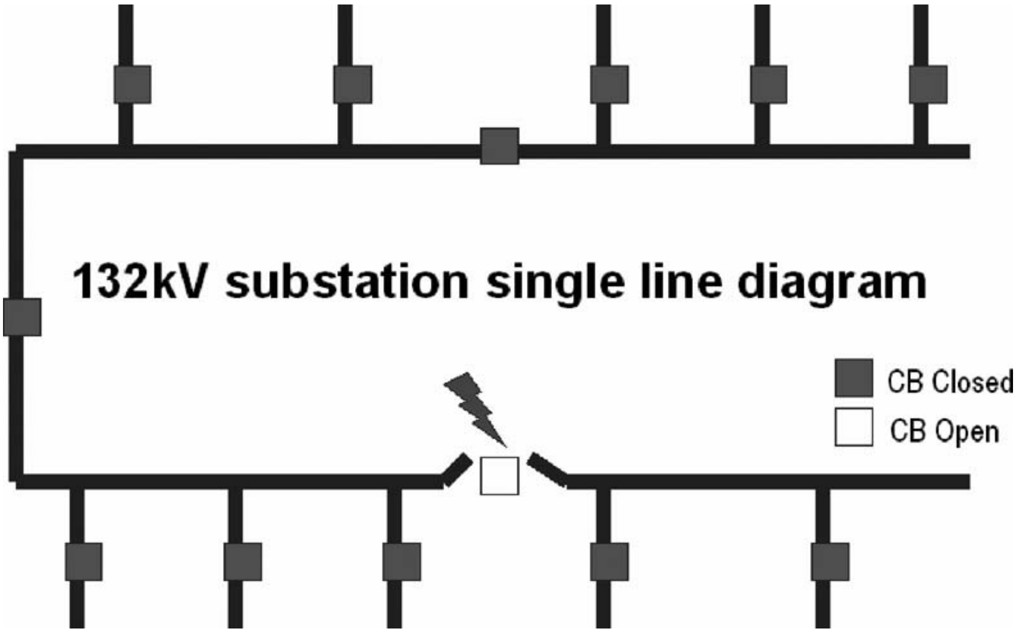

Figure 5. Substation single line diagram after system restoration actions completed.

8.2.1 Case Study 2 Summary

Remote access to the data captured by the secondary systems equipment in the substation allowed the cause of the event to be diagnosed and systems restored as much as possible within 45minutes of the event occurring. The network constraints, and plant loading issues were resolved within 45 minutes of the event occurring.

It is estimated that under the previous fault management strategy the network constraint, and plant loading issues would have continued for at least another two hours until personnel skilled at extracting and analysing data from the intelligent devices attended site and completed these tasks.

9 SUMMARY

Powerlink's Asset Monitoring strategy exploits the advances made in equipment monitoring and communications technology that now allows remote access to intelligent devices in the field from a remote location. Data from these intelligent devices was previously only available by sending suitably trained staff to attend the site, which incurred significant delays in the retrieval and analysis of fault data.

Success of the strategy is not only due to the technology, but the way in which Powerlink has modified its fault management processes to exploit it. The processes are often overlooked in the drive to install new technology. However, unless the processes are modified, the benefits will not be fully obtained.

Powerlink Queensland formed the Asset Monitoring Team (AMT) to implement the data to information framework required for realising the system strategy. The AMT manages the collection, analysis and reporting of information to the business and plant strategy decision-makers. The AMT exists as a small group of engineering specialists, dedicated to the retrieval and analysis of operational data following notification of a network fault. Benefits already being achieved include reducing outage times, exposure to potential liability, fault rectification costs, and, improvements in network reliability and quality of supply.

The new fault management process has been made possible by Powerlink's investment in intelligent substation technologies and communications infrastructure. By accessing substation data from the office, AMT staff are informed about the status of the fault and the health of the plant. Armed with this information, decisions regarding the fault priority, resources required for rectification, and the final decision to return plant to service can be made. These judgments can be made in a short timeframe, in many cases avoiding the need to send personnel to site or before staff arrive at site. It should be stressed however that although the technology is an enabler it is not a solution in itself, as it requires supporting processes as outlined in this paper.

REGULATING ASSET MANAGEMENT THROUGH SERVICEABILITY AND A COMMON FRAMEWORK FOR INVESTMENT PLANNING

Derek Parsons a

[a] Water Services Regulation Authority (Ofwat) 7 Hill Street Birmingham UK B5 4UA

Abstract: Regulation by output (albeit with an associated investment level assumption related to price-cap) rather than input is one of the ways in which the Water Services Regulation Authority (Ofwat), the economic regulator of the water industry in England and Wales, incentivises companies to effective asset management. The paper discusses how such arms-length regulation operates, and considers the appropriate output indicators for such a regime. The paper draws on experience of some ten years of operation and annual monitoring of trends in serviceability indicators, which are the foundation upon which the regulator judges the appropriate financing for capital maintenance at periodic reviews. It describes the UK water industry's risk based approach to capital maintenance planning common framework (CMPCF) jointly developed by companies and regulators in 2002, and Ofwat's approach to its assessment of resulting company business plans. The paper highlights issues arising from the periodic review of prices in 2004 (PR04) and developments needed for the next one in 2009. Companies will need to develop their asset information and analytical tools to enable better forecasting of asset deterioration and the likely impact on service in both medium and long term, to develop a more robust, service driven, risk based approach that delivers economic capital maintenance plans.

Key Words: Ofwat, Water Services Regulation Authority, economic, regulator, serviceability, serviceability to customers, service risk, environment, indicators, trend, capital maintenance, serviceability assessments, service delivered, asset performance, common framework, CMPCF, UKWIR, planning, deterioration modelling, PAS55.

SUMMARY

The aim of this paper has been to broaden understanding of Ofwat's approach to regulating capital maintenance through monitoring of serviceability outputs and its approach to capital maintenance assumptions used for price setting. Inevitably there are references to key documents that mark the sea change in the planning of capital maintenance in the England and Wales water industry since the periodic review of prices in 1999 (PR99) which provide an essential platform for discussion.

Companies not only have to maintain a level of service to their customers and the environment, but demonstrate that service capability of the asset systems is not being compromised for the future. This could happen if performance of key asset groups were to slip through lack of timely investment. Yet it is possible to be over cautious, or inefficiently apply capital maintenance which would elevate prices. So the drive is to demonstrate optimum interventions to maintain the flow of service to customers. The paper tracks recent developments in the regulation of capital maintenance of water companies in England and Wales, (Scotland and Northern Ireland have their own regulation authorities). It sets out Ofwat's approach to annual monitoring and its assessment of business plans at price reviews. The conclusion is that whilst the outcomes of price reviews have been generally satisfactory, there is a need for more transparent, robust deterioration models, coupled with linkage to service delivery and costs to better inform the next price review in 2009 (PR09).

1 REGULATION OF THE WATER INDUSTRY IN ENGLAND AND WALES

Privatisation of water authorities in England and Wales occurred in November 1989, and in setting initial price limits for customers, the UK Government made some broad assumptions about the level of expenditure needed to maintain, or improve and maintain the asset base. At the same time, an independent regulator (in legal terms the Director General of Water Services, but in practice supported by an 'Office of Water Services' or 'Ofwat' was created. His role is to regulate the industry from an economic standpoint to ensure value for money and review and set new price limits at appropriate intervals. In the event, the first price review was in 1994 (PR94) and the two subsequent reviews have occurred at five yearly intervals. Some mergers have occurred, and there are currently 22 companies (plus one with only about 2000 customers) whose prices are set by Ofwat.

Sister quality regulators, now the Environment Agency and the Drinking Water Inspectorate were set up and tasked to set and ensure compliance with standards, and advise Ministers on investment requirements to meet new objectives, mostly emanating from EU directives on potable water and the aquatic environment.

Recent legislation created a corporate structure for water regulation to replace the Director General of Water Services with the Water Services Regulation Authority with effect from April 2006 along with a new duty to contribute to sustainable development. The 'Ofwat' name has been retained for the new organisation.

2 REGULATION OF CAPITAL MAINTENANCE

Ofwat has elected to set price caps for companies every 5 years. Companies are required to submit to Ofwat their business plans for scrutiny which, although focussing on the next five years have a planning horizon for of 15 years (more in some areas). So every five years there is an opportunity for companies to register a need for a change to the planned investment which is then reflected in a new price cap. The price cap is a package encompassing all categories of expenditure and obligations. (There are mechanisms for interim price adjustments, but it is not necessary to digress into this area.)

The main challenges are to:

- monitor and challenge the effectiveness of capital maintenance;
- determine whether there should be a change to past levels of capital maintenance, up or down and by how much; and
- challenge efficiency.

This paper focuses on engineering aspects of optimum capital maintenance assessment. The technical detail of how Ofwat makes the efficiency challenge is a large subject and is beyond the scope of this particular paper, save providing an outline.

2.1 Monitoring and challenging effectiveness of capital maintenance

For a water utility, the principal requirement for capital maintenance is that it is sufficient to maintain service to customers. Ofwat operates arms-length regulation. It does not seek to micro-manage companies because this is resource hungry and ought to be unnecessary in a very mature industry. The regulatory focus is on service to customers. Ofwat, acting on behalf of customers needs to be assured that service level is stable, and is likely to remain so in the future.

Ofwat has developed a set of metrics to monitor company asset systems, and between price reviews it monitors their stability or otherwise through annual review of detailed data returns. These are known as serviceability assessments, which are made at sub-service level (above and below ground asset systems distinguish sub-services). Where a sub-service is assessed as less than stable the company is called to account and is required to set down its proposals to remedy the situation.

The key point here is that at periodic review, the company, in accepting the price cap has also accepted the requirement to maintain (or achieve and maintain) stable serviceability. If the company does this through a set of investments that cost less than Ofwat has assumed, it can retain the financial savings as part of its efficiencies. On the other hand, Ofwat expects a company to invest to maintain stable serviceability, even if this may require more expenditure than assumed at price setting. Thus the specific price limit accepted by each company contains both a profit challenge and downside risk.

The mechanisms to resolve issues are beyond the scope of this paper, suffice it to say that:

- price reviews provide for a timely 'course correction' in funding assumptions (including penalty for failing to deliver, or 'shortfall');
- between price reviews the companies have a financial incentive to maintain stable serviceability efficiently; and
- a company's prestige can be threatened by failure, because Ofwat publishes its annual serviceability assessments.

2.2 Determination of changes to historic levels of capital maintenance

At the 2004 periodic review Ofwat adopted a four stage approach to challenge each company's business plan:

Stage A: Adjustment needed to maintain stable serviceability from a historical perspective.

Stage B: Is the future different?

Stage C: Scope for efficiency

Stage D: Take account of overlaps between capital maintenance and enhancement programmes.

In 2004, the English and Welsh companies 'asked for' over £9.4 billion capital maintenance for the period 2005-2010. Price limits include £8.4 billion. This paper focuses on Ofwat's challenges at Stages A and B. Stages C and D are subjects in their own right and their approach is only outlined in sections 3.3 and 3.4. The remainder of the paper explains and develops the ideas behind Ofwat's Stage A and B challenges and issues that are emerging for resolving at or by the next periodic review.

Stage A is essentially a long term historic average cost, corrected for price base. Companies were allowed to make adjustments in their business plan submissions for whether or not this was typical and whether serviceability could be maintained (see section 8). Ofwat made its own assessment, and where the company view was greater expenditure than Ofwat's view at Stage A, the difference received further scrutiny by being fed into Ofwat's Stage B analysis (see section 9).

Stage B is essentially Ofwat's way of considering the validity of a change from the past rate of expenditure into the next period(s). In most cases, companies tend to seek more going forward. But how robust is the engineering business case?

2.3 Stage C - Efficiency challenge and incentive mechanism

Ofwat commissioned several studies and reviewed contemporary work of others to come to a view on the **scope for efficiency**. This is the amount of capital expenditure that the water industry in total can be expected to save through capital efficiencies of one sort or another in the period 2005-10. Ofwat uses a carrot and stick approach, whereby the scope for efficiency is divided into two parts. It removes one part on behalf of customers (stick), leaving the other part as an incentive for the company (carrot). The size of the carrot and stick for each company depends on how near it is to the efficiency frontier.

Relative capital expenditure efficiency: this is the (percentage) difference in efficiency that has been observed using historic (and forecast) data between the capital expenditures of all the companies. The company with the lowest measured capital costs (in a specified category or basket of indicators) becomes the 'benchmark' company. Ofwat assesses relative capital expenditure efficiency in two ways:

- using econometric modelling of total capital maintenance expenditures (averaged over a number of years) and various explanatory variables – this is known as the Capital Maintenance Econometric Analysis; and
- measuring the differences in company's capital scheme unit costs (procurement costs) – this is known as the Capital Expenditure Cost Base Analysis.

The company is allowed to keep its out-performance for five years. The details of the econometric models and cost base unit costs are set down in the 2003-04 issue of Ofwat's Water and sewerage unit costs and relative efficiency report. It covers both capital and operating costs, which also use benchmark econometric modelling. The impact at PR04 was to shave some £0.5 billion from capital maintenance assumptions across the English and Welsh companies, which makes it a big subject.

2.4 Stage D –Adjustments for Enhancement Expenditure - Benefit to Serviceability

Stage D is the final adjustment made to derive the required level of capital maintenance expenditure going forward. The Stage D adjustment allows for the impact on future serviceability from planned expenditure on enhancement projects, whilst taking into account any change in proportional allocation of enhancement expenditure to capital maintenance going forward.

3 ECONOMIC CONSTRAINTS TO LIMIT THE PRICE PAID BY CUSTOMERS

Ofwat holds the view that prices, which support maintenance of the vast asset base, should be no higher than they need to be to limit the price paid by customers. In the 1999 Periodic Review of Prices (PR99) the Director General of Water Services judged that the water companies had not moved sufficiently in their business practices towards a more efficient approach to capital maintenance. After setting prices for the period 2000 – 2005 he wrote, in April 2000 an open letter to Managing Directors of the water companies of England and Wales, MD161 [1]. He recognised that companies had put much effort into improving systems of information for asset management, resulting in more effective direction of capital maintenance activity. But the key message was that the companies' economic analyses fell short of expectations. Thus he wrote:

3.1 Extract from letter MD161 to Managing Directors, April 2000

'Each company needs to demonstrate how the flow of services to customers can be maintained at least cost in terms of both capital maintenance and operating expenditure recognising trade off between cost and risk, whilst ensuring compliance with statutory duties. Appraisal of capital maintenance, operating expenditure and risk can be compared using discounted cash flows. All such appraisals would need to be set in the context of the framework of maintaining serviceability to customers. Such an approach should have been used to justify the future levels of capital maintenance included in the business plans.

It would have been helpful to include commentary on the material elements of the economic appraisals undertaken such as the:

- Cost of any potential loss of serviceability to customers, including consideration of risk scenarios and their probabilities as well as illustrations of how serviceability to customers would decline, if the activity was not undertaken;
- Impact on operating costs of capital maintenance activity, before and after assets are renewed;
- Circumstances surrounding the timing of asset replacement;

- Impact of obsolescence and newer lower cost technology; and
- Any terminal values and the discount rates assumed.

This list is not exhaustive. The economic appraisals would also need to be balanced and justified against a strategic top down approach used to assess, for example, the impact of alternative scenarios on company financing, including an analysis of past and prospective accounting charges. Setting out examples of economic analysis in this way would go a long way towards demonstrating why companies have taken the view that the levels of capital maintenance since, say 1980, have been sub-optimal. This approach could also indicate the extent to which levels of capital expenditure should change, up or down, for future capital maintenance to be economic.'

So Ofwat puts the customer, not the engineering, centre stage. Exponents of PAS 55, take note of these stakeholders!

4 MAINTAINING THE FLOW OF SERVICES TO CUSTOMERS: 'SERVICEABILITY'

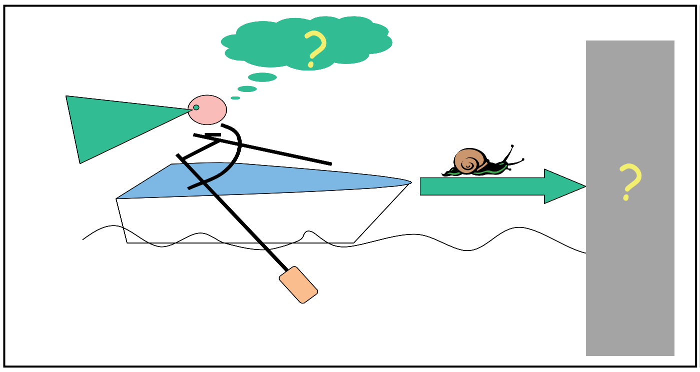
Specifically, the term used by Ofwat is 'Serviceability to customers'. This is NOT the same as serviceability of the assets deployed to deliver service – but there are close relationships between what service the customer wants and the ability of the assets to deliver it. Maintainers of assets sometimes find it is easy to forget why the assets are there in the first place.

The term encapsulates the concept of the continuing capability of a company's asset systems (and the associated operational activity) to maintain the level of service experienced by its customers and, where relevant, the receiving environment. The regulatory focus is on delivery of customer needs (both now and in the future) and not on maintenance of the assets to a specified state for their own sake. The 'right state' should essentially be determined by economics, albeit the default position in the absence of robust economic argument for change should reference to a suitable historic level.

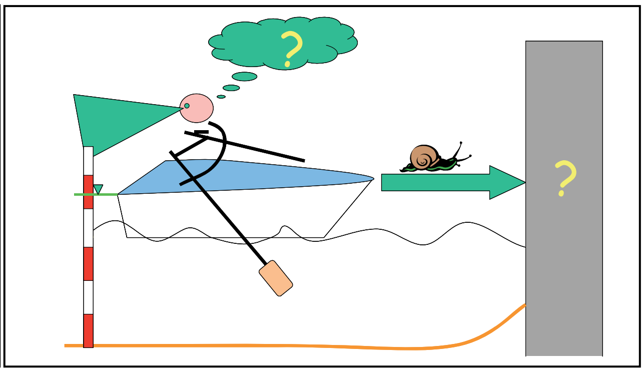
4.1 Assessing serviceability: Anticipating future problems from an historical perspective

Regulatory serviceability indicators have come in for a good deal of adverse criticism in the UK, cited as being 'backward looking'. The author contends that just about everything that can be forecast about the future is based on past experience or past observation, and therefore invites the reader to re-consider whether they are, after all, useful by considering the following thought experiment.

Suppose you are in a lake, rowing a boat, alone. You are facing backwards and have no view of the boat's forward, but slow progress.

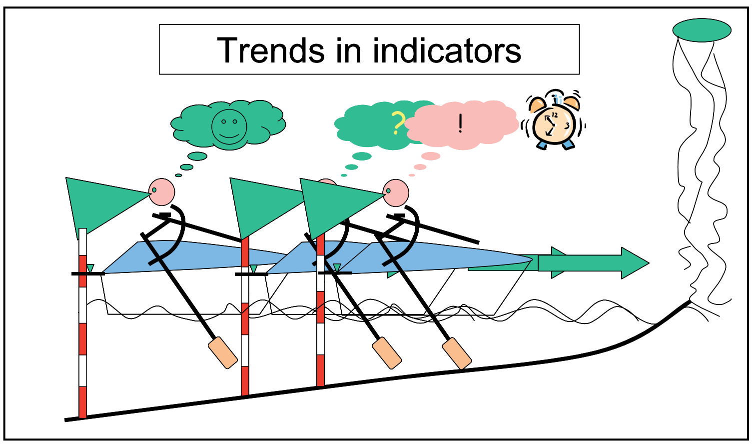


How might you anticipate arriving at the shore?



Perhaps measuring the depth might give you some idea?

At intervals you make a series of depth observations. Perhaps monitoring the trend in the depth provides warning of your arrival at the shore? The conclusion is surely that rearward view of appropriate indicators, monitored at regular time intervals does indeed reveal useful information about change. (The analogy can, of course, be trivialised, because all you do is look over your shoulder. If only looking into the future was that simple!)



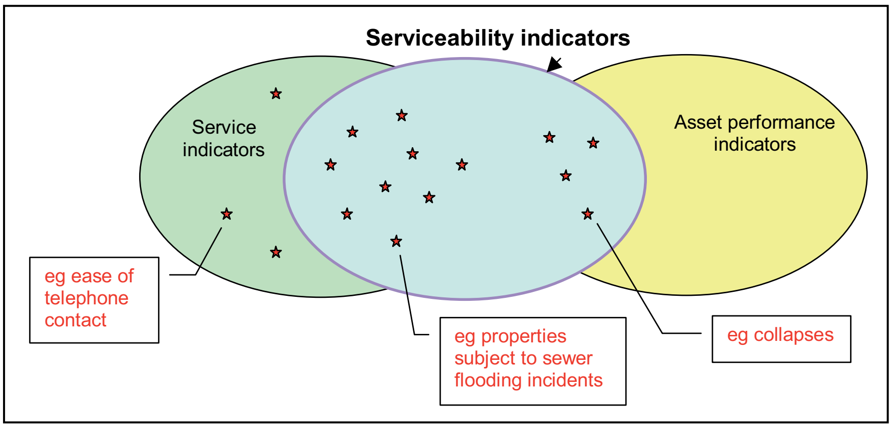
Put in its simplest form, such indicators provide the basis of assessing whether or not there has been change. And, stepping right away from the row-boat analogy into asset management, consider next what the inputs have been to maintain the status quo or cause change to our suite of indicators (a suite because more than one is required, as will be explained later).

Serviceability is considered at company level, by sub-service. The aim is to ensure that the trend in serviceability remains at least stable, or if the start point is less than stable, then to achieve and then maintain stable serviceability.

Note the key word is **trend**. Absolute values of indicators are not important, although it is useful to compare and contrast each company's performance and to build a national picture. The assets being considered have relatively long service lives, and deterioration is relatively slow. Thus annual monitoring provides the opportunity to take timely corrective action.

5 APPROPRIATE SERVICEABILITY INDICATORS

The figure below illustrates from where indicators of serviceability are drawn - courtesy of United Kingdom Water Industry Research (UKWIR) Report 02/RG/05/3 [2]



Clearly, a service indicator such as ease of telephone contact has little direct connection with capital maintenance needs. The basket of serviceability indicators comprises a selection of measures of service delivered and asset performance. A basket of measures is needed due to the complexity of asset systems and interdependencies. A combination of service and asset performance indicators is needed in order to capture current and likely future service capability. Each type as has certain characteristics and limitations:

5.1 Service indicators are influenced by operational activity, and trends are to be assessed with caution. They inform on the capability of asset systems in the shorter term. The expectation is that trends are stable or improving.

5.2 Asset performance indicators inform on capability over the longer term, that is whether the current service delivered is likely to be sustained. The expectation is that, whilst trends are stable or improving, they may deteriorate to a degree that does not compromise economic provision in the long term. In practice, the default trend for asset performance indicators is stable or improving. Asset performance indicators may have a direct or indirect impact on service delivered. They tend to be symptomatic of the state of the assets, but still can be influenced by policy on operational activity, for example increased leakage control activity in the case of water mains burst repairs.

5.3 Examples of serviceability indicators

Service indicators: properties with extended supply interruptions, properties receiving low pressure, properties flooding from sewers, pollution incidents. Compliance, such as the proportion of treatment works that are out of compliance.

Asset performance indicators: burst water mains, sewer collapses, mean time between failure. Sub-threshold indicators that indicate potential underlying problems but where the works has not failed. Examples are events where a threshold value, say half the permissible value has been crossed.

5.4 Issues around serviceability indicators

A very important point is that it must be the same data that is collected, that is, to the same definition, over the period of time which is assessed. This must be watched closely, because both the Levels of Service and financial data which are essential for the historical perspective analysis are collected for other uses, and there is often a desire to 'improve' them for those uses.

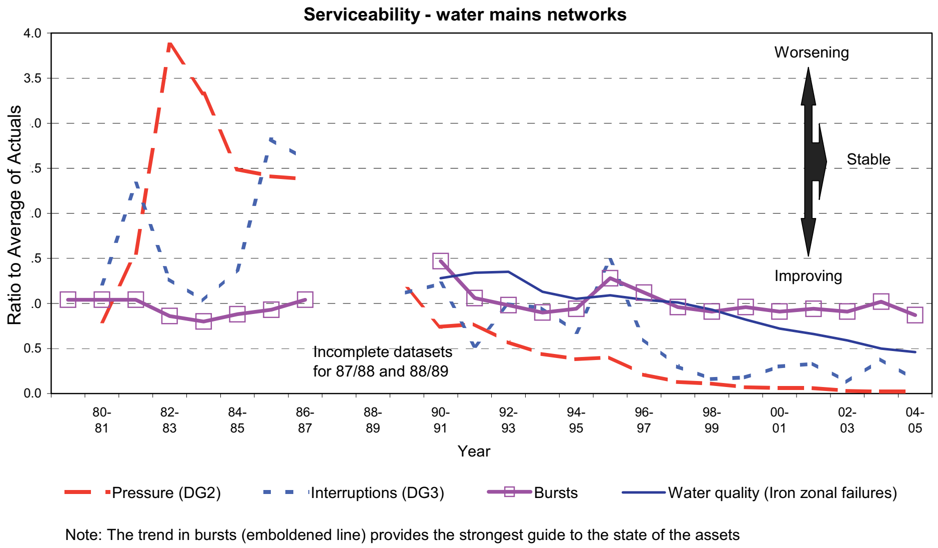
But of course a change in definition invalidates a time trend, and reliable and defensible time trends are the essence of the historical perspective analysis.

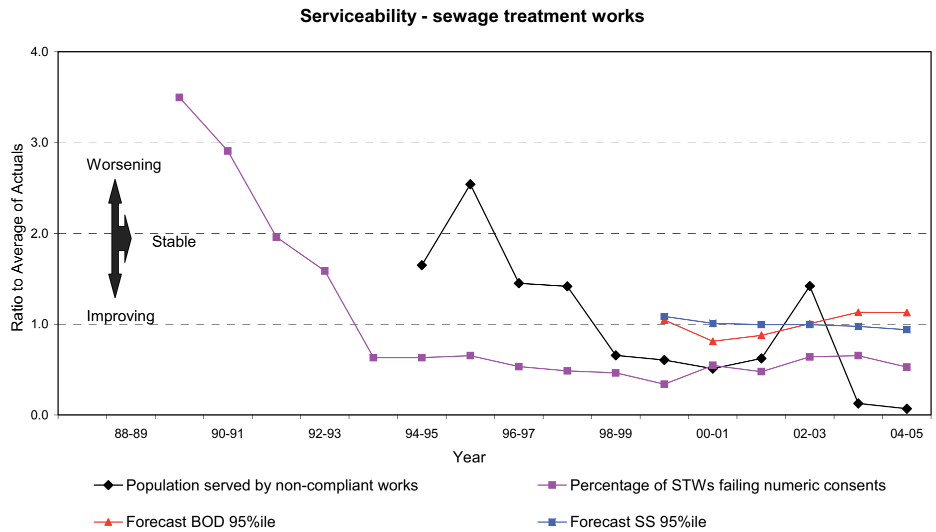
Although there will always be interplay between capital and operational maintenance it is assumed that the deferment of capital maintenance by increased operational maintenance will not be effective over many years. Nevertheless, for surface assets it is wise to look at the pattern of operational maintenance alongside the graph of capital maintenance. It is also important to check companies' explanation of recorded treatment failures. These are generally few in number and experience in the 1999 price review was that companies explained many of them as due to short-term events which had been quickly remedied. In fact they argued that capital maintenance had been adequate even though the serviceability analysis may have indicated otherwise. A conclusion Ofwat was pleased to accept.

From 2003 Ofwat added a limited number of additional indicators that aimed to inform future performance and to widen coverage of asset types [3]. It planned a further review after PR04. The review has now been carried out by UKWIR (2005-06), with Ofwat represented on the steering group. The report is imminent and Ofwat will shortly respond to its findings.

6 ASSESSMENT OF SERVICEABILITY

Ofwat's initial assessments are published annually in August/September in its 'Financial performance and expenditure of the water companies of England and Wales' (FPE) report. Below are examples of Serviceability Graphs at Industry Level for England and Wales, for water infrastructure and sewerage non-infrastructure sub-services respectively.

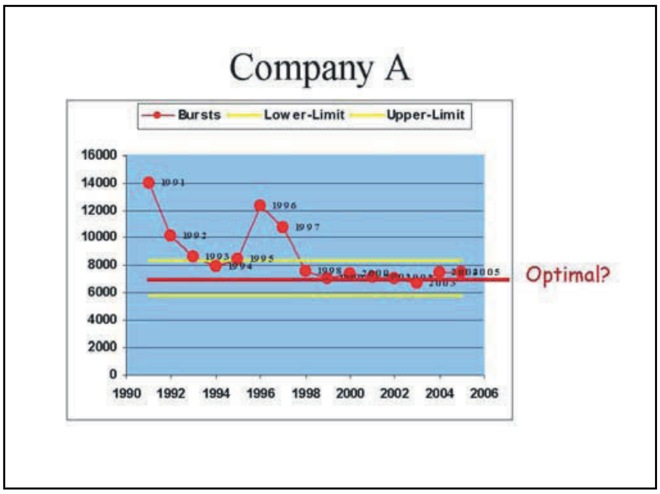




6.1 Assessment marks

The current marking scheme for serviceability trends is, best to worst: Improving, Stable, Marginal, and Deteriorating.

Data is inherently variable, often due to weather effects and care needs to be taken when considering what a normal range of operation is. Because underground assets in particular deteriorate slowly it is not easy to pick out underlying trends. Ofwat uses a suite of statistical tools to help inform its judgement. The statistics toolkit is not a substitute for judgement, simply an aid. It also provides a platform for discussion with companies on their view of the optimal levels for a particular indicator.



6.2 What is meant by 'stable' serviceability?

Serviceability is deemed to be stable when the assessment of trends in a defined set of service and asset performance indicators demonstrates that service is in line with the reference level of service and, by inference, is likely to remain so into the future. Note that there is no implication that the standard of service to customers or asset performance is satisfactory. These are separate issues, which should be addressed through a change in expenditure for improvement or economic argument.

The reference level of service is determined from a specific sub-set of public health, environmental and customer service indicators. Service indicators reflect the degree of compliance with statutory regulations, regulatory and company standards and customer preferences.

Asset performance indicators, measured at system level, are drawn from a specific sub-set of measures that inform current and future levels of service. Stable serviceability normally requires that asset performance is in line with the reference level of asset performance. Unless demonstrably sub-optimal or atypical, the reference levels of service and asset performance are taken as the best historic levels achieved by the company.

6.3 Issues around achieving and maintaining stable serviceability

As the reader may imagine, things begin to get interesting for regulator and regulated when a company begins to fail to deliver stable serviceability. The serviceability assessments enable Ofwat to provide feed back to companies on how it thinks they are doing. Annual monitoring is normally sufficient for Ofwat's purposes, and, despite the indicators being high level, the process has, on occasion uncovered underlying shortfalls in asset management practice. It has thus become a powerful tool.

The assessments enable a regulatory response where companies are beginning to fail, and can provide evidential support for financial penalty or other legal sanction in the most serious of cases of shortfall. This provides motivation for companies to intervene with more effective monitoring and intervention (capital or operational expenditure), and yet still allows the company to decide what to do.

In section 3 it was explained that the periodic review of prices provides scope for a 'course correction' if it is deemed that funding from customers should be changed to facilitate an economic level of capital maintenance. And once prices have been determined, and the company accepts (if not it can appeal to the Competition Commission for a new determination), it is up to the company to deliver stable serviceability. This is irrespective of cost to the company (subject to a high ceiling), since the company accepts this as a risk. But note that the 'course correction' at periodic review does not necessarily cover the cost of recovery to stable serviceability where there has been a shortfall in previous periods. The change is primarily to reflect what funding is needed by an efficient company to maintain stable serviceability going forward.

The risk to serviceability accepted by the company at price review is to some extent a shared one. This is because there is incomplete knowledge, for example in the behaviour of assets and in the economic level of capital maintenance, and serviceability might in any case be changed by events that might render a rapid return to previous service levels impracticable.

In the past, companies have not been overtly penalised, for example where they have spent above Final Determination assumptions and still failed to maintain stable serviceability. Companies are expected to improve their knowledge of their asset base, for example through an improved application of risk based principles espoused in MD161 in the period to 2010. This should lead to better assessments of need by the companies; and Ofwat will be less tolerant of serviceability shortfall.

Where a company is beginning to fail to deliver on serviceability, Ofwat deploys a staged approach to effect corrective action by the company, including in appropriate cases a requirement for setting down action plans with milestone dates for activities aimed at achieving and maintaining stable serviceability. Both the historic level and new information may inform the degree of recovery of serviceability that is required following a period of deterioration. And in the absence of robust justification to the contrary, the historic levels provide the reference level for serviceability.

This low level but firm regulatory action is aimed at bringing defaulting companies to heel and to prevent a situation developing that could cause a general or catastrophic failure of service.

7 CAPITAL MAINTENANCE PLANNING – A COMMON FRAMEWORK (CMPCF)

In 2002 the UK water industry, through UKWIR, responded to MD161 with the development of the capital maintenance planning common framework (CMPCF)[2]. Ofwat regarded the CMPCF as a large step in the right direction, and redrafted its reporting requirements for PR04 business plan submissions to align with it.

The common framework is essentially a three-step process (similar but distinct from Ofwat's 4-Stage A, B, C, D business plan assessment):

A. A Historical assessment, comprising an expenditure and service & asset performance review.

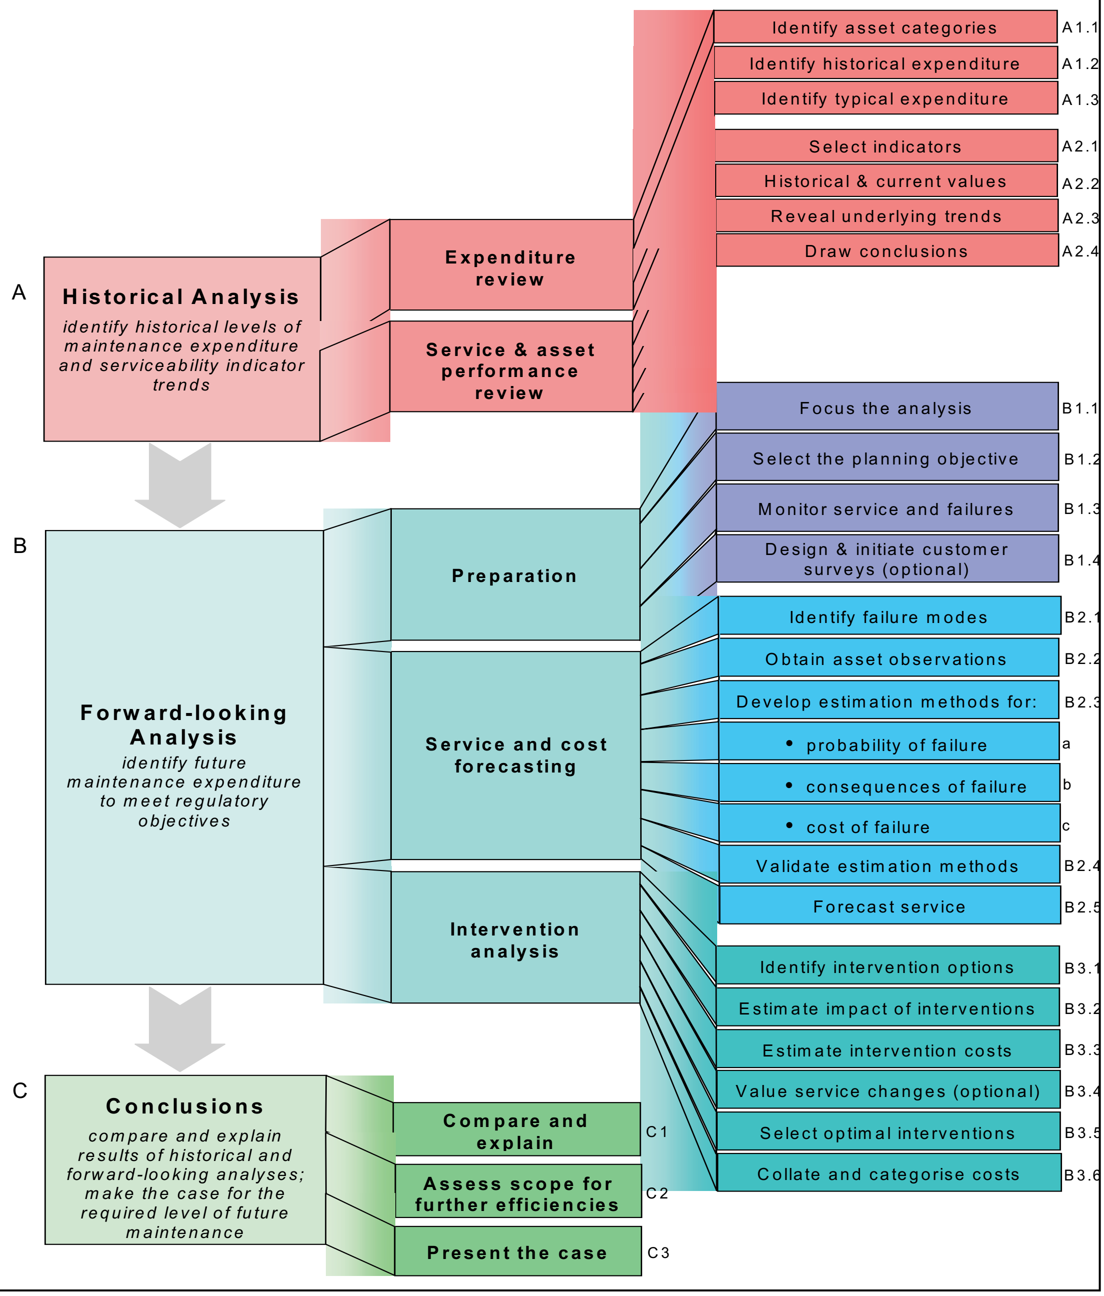
B. B Forward look, considering service risks and cost forecasting to develop optimal interventions.

C. C Comparison of the two approaches, drawing conclusions, look for further efficiencies and make the case for the required level of capital maintenance.

Application of the CMPCF includes two alternative planning objectives – a cost-effective approach or a cost-benefit approach. The cost–effective objective aims to provide steady or improving service to customers at minimum cost to the water company. The cost-benefit objective aims to provide the level of service to customers that represents an economic balance between the value to customers of the service provided (perhaps in terms of willingness to pay) and the associated costs to the water company (and thence its customers).

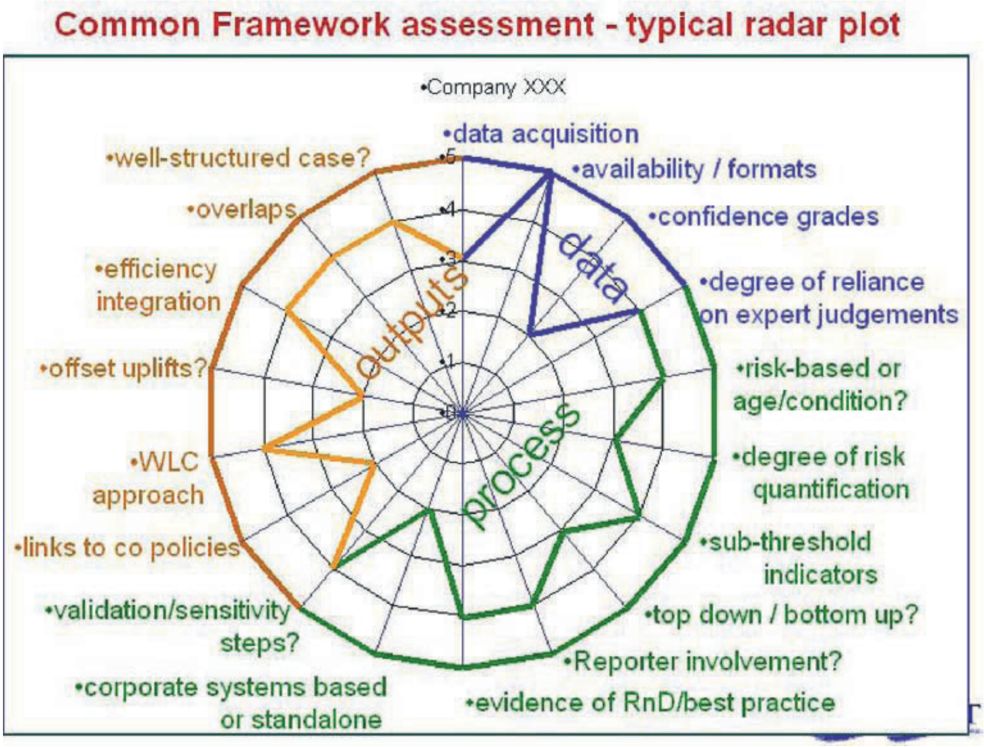
In fact there are over twenty steps at the detailed level, as the figure below shows. The main innovation is in the second step, 'B' that uses the analysis of risk (that is the probability and consequences of asset failure) to inform the economic analysis. Previous practice in UK water industry has been to attempt to convert condition and performance grades (captured with the asset inventory) into remaining asset lives and hence capital maintenance needs. The problem with that approach is that the grading approach tends to be over subjective, generalised and asset centric. Under the CMPCF companies must look to identify specific failure modes by asset type, and at an appropriate level of granularity, obtain the relevant asset observations, including historic failures, consequences and costs, then develop robust estimation methods for probability of failure and consequences for customers. These, together with service valuation studies for the cost-benefit approach, are developed into service and cost scenarios to inform the optimisation of interventions. By evaluating in this manner, expressed in economic-risk measures, the analysis is better focussed. The best exponents can locate where investment will be most effective and may build the programme of works at the time of drawing up the business plan. Unfortunately, in the short term sufficient data is not always available and judgement is needed (nor will judgement be entirely eliminated) in place of a history of asset observations. The process gives a powerful framework for the company to identify what asset observations it needs to improve its forecasting to facilitate optimum interventions.

Capital Maintenance Planning Common Framework (CMPCF)[2]



8 ASSESSMENT OF THE APPLICATION OF CMPCF PRINCIPLES

Ofwat's four stage approach provides a means of evaluating the application of a company's application of CMPCF principles. To challenge stage B uplift over past expenditure levels Ofwat assessed each company's final business plan against 18 criteria. The criteria reflected the aspirations of MD161 and the agreed CMPCF. The criteria cover the three broad areas: data quality, forward-looking analysis process adopted and the approach to outputs. The criteria assessment became known as the 'Common Framework Assessment'. As with serviceability, this was done by sub-service. There are 64 sub-services in total among the companies – 10 water & sewerage co.'s x 4 (water/sewerage above & below ground) plus 12 water only co.'s x 2 (above & below ground).



The criteria were weighted by pair-wise comparison of relative importance. Sensitivity analysis showed that total scores were not overly sensitive to the weights. For each sub-service, the 'score' was allocated into one of five ranking bands ('Leading' to 'Trailing'). The bands determined the factor applied to the uplift in Stage B expenditure (post screening to exclude exceptional items assessed on their own merits). The main problem for companies at PR04 was their inability to find suitable data, leading to more 'expert judgement' than desirable, and the inability to adequately identify operating costs at plant level to be able to get at whole life cost of ownership.

Band	Description	Score range	Factor	Number of sub-services
A	Leading	>= 70%	100%	5
B	Above intermediate	60 – 69%	75%	22
C	Intermediate	50 – 59%	50%	29
D	Below intermediate	40 – 49%	25%	7
E	Trailing	< 40%	0%	1

A 'leading' company will understand the risk profile of its assets and be able to assess the investment needed to manage this risk in the future. A company assessed as 'trailing' will have failed to demonstrate a robust risk-based approach for future investment in this sub-service. Companies with scores close to band limits were reviewed to confirm their position.

At the periodic review of 2004, this challenge on the quality of business plans was limited to the companies' forward look, that is (broadly) what companies wanted in addition to what they'd had in the past. And even then after exceptional items were excluded. So only around 20% of company's capital maintenance expenditure was subject to the test.

8.1 Issues around CMPCF

The impact of Ofwat's challenge at stages A and B amounted to some £0.5 billion, mostly at stage B. UKWIR has reviewed the CMPCF application [4] and outcomes post PR04, as has Ofwat. As always, Ofwat consults with the industry [5] and, at the time of writing this paper, is doing so again [6]. The Ofwat view is that there should be a stronger challenge to historic expenditure, to develop a fairer playing field. Options include simply improving understanding of reported historic expenditure, econometric benchmarking to cap Stage A, assessing part or all of historic expenditure in the Stage B challenge, analysing asset stocks and condition and age profiles. Econometric benchmarking has implications for the efficiency challenge and would need to be considered in conjunction with revisiting stages C and D.

The challenge for Ofwat is to encourage appropriate behaviours in business management; to challenge old habits and drive efficiency. The evolving approach gives companies strong incentives to use sound asset management processes. Ofwat will do this by strengthening the incentive through its assessment processes. Ofwat also believes that the CMPCF approach, whilst it has been developed for capital maintenance could potentially inform a more general application to all capital investment drivers. This is because of its focus on service to customers and risk in order to plan the scale and scope of investment.

8.2 CMPF and PAS55

Both CMPCF and PAS55 are risk-based approaches to maintenance. In the view of the author the key difference between PAS55 and CMPCF is that PAS55 is asset centric, whereas CMPCF is overtly centred on service to customers. In the water industry this is particularly important, because there are so many facets to the service arising from the need to maintain product quality as well as continuity of service.

Ofwat uses its assessment of how well companies applied CMPCF principles its determination of price cap in respect of capital maintenance. Ofgem, the UK energy regulator, in contrast, has used PAS55 for re-assurance and not directly to influence its price review judgements. PAS55 is seen by Ofgem as good practice to aspire to. Interestingly, Ofwat's idea to use radar plots to compare current business practice was 'borrowed with pride' from Ofgem. Ofgem prefers to use other tools for price setting, due to a quite different regulatory environment. For example, competition exists on load (demand) in the electricity sector which strongly influences price. Therefore, for the moment at least, there seems not to be an incentive for Ofgem to further motivate electricity and gas companies develop their application of the principles in PAS55. It will be interesting to monitor developments.

9 THE FORWARD LOOK – GAINING CONFIDENCE IN DETERIORATION MODELLING

At PR04, Ofwat's four stage approach provided for both a historical review (Stage A) and a forward look (Stage B). The forward look embraced the CMPCF, and encouraged companies to demonstrate what is different from the past, going forward. Whatever approach is taken, some form of forecasting of asset behaviour is needed, in order to distinguish either a change in the rate of deterioration from no change, or a change in the volume of assets needing renewal. It is also essential to link asset behaviour (and failure modes) to service delivered. Some software tools were developed of varying complexity for company business plans at PR04. But all such tools are vulnerable to the axiom 'rubbish in equals rubbish out'. The drive now is not so much to develop new models, though the current initiatives through UKWIR are welcome, particularly on deterioration of sewers, but rather to gain confidence in deterioration modelling and application as a process. The need is to:

- expose the assumptions in the models to rigorous scrutiny;
- broaden the understanding of models and modelling techniques;
- peer review the models;
- define criteria for good data for the particular model;
- do a gap analysis and look for solutions to fill them;
- carry out sensitivity analyses on model outputs;
- validate the models by recognised techniques; and
- demonstrate the application of the models
- link 'failure' to service failure and customer preference

Whilst there is a degree of commercial interest that constrains this approach, the models earn their keep best when Ofwat has been convinced of their reliability, and, paradoxically their limitations. At the end of the day, judgements still have to be made, since, like the man in the rowing boat in the thought experiment he cannot see into the future. There is always an element of faith.

10 CONCLUSIONS: ARE THE OUTCOMES OF PR04 SUSTAINABLE?

It is evident from successive periodic reviews of prices that, on the whole, companies have put forward in their business cases more expenditure than was, in the event, actually needed to maintain stable serviceability. But it does not take a genius to wonder, in the case of infrastructure whether the amount assumed is sustainable. The simple manipulation of figures - annual investment divided into the asset value gives an alarming view that the infrastructure assets will need to last for several hundred years. How is this right? Is it right?

The quick answer is, for the moment probably yes, based on the experience of today. 'It ain't so broke, so why fix it?' And, due to the well founded belief that infrastructure assets tend to deteriorate slowly, the capital maintenance assumptions can be ramped up over successive price reviews if deterioration in serviceability is detected. Also, some of these assets will outlive their usefulness due to redevelopment etc, and therefore, there is no need to think that every pipe is going to need replacing anyway.

The more measured answer is that the companies are managing the asset base quite well in an increasingly proactive way between price reviews. There are concerns, particularly for those companies with less than stable serviceability, which they are required to correct by 2010. These are being monitored closely. There is a more general need for companies to get a better understanding of what any ramping up of future expenditure might need to be, and whether or not the problem will remain manageable without earlier pre-emptive investment. It is this nagging uncertainty that drives the need to develop deterioration models for an aging (but generally adequate) underground infrastructure. And there are similar uncertainties surrounding the renewal requirements from the new above ground/non-infrastructure assets constructed since privatisation. These have very different characteristics from the earlier assets that they either replaced, or were built as new/advanced processes to meet higher standards. Thus for these assets, historic expenditure may not be the best guide going forward, a point well recognised by the introduction of the CMPCF. Companies will need to develop their asset information and analytical tools to enable better forecasting of asset deterioration and the likely impact on service in both medium and long term, to develop a more robust, service driven, risk based approach that delivers economic capital maintenance plans.

All assets should be there for a purpose, and do not need to be maintained for their own sake. So whatever modelling of deterioration of assets is done, there has to be recognition that the risk to service from asset system failure is the prime concern. So the need for PR09 is to show how models for asset deterioration link to service consequences of failure and associated costs (remedies and impacts) in order to demonstrate that the company has identified robust optimal restorative interventions.

Ofwat works with and encourages the industry to develop its approach. The Ofwat website: www.ofwat.gov.uk provides a wealth of information through its publications and public consultation processes, much of which is referenced in this paper.

DELIVERING RELIABILITY IMPROVEMENT & EFFICIENCY THROUGH EMERGING DIAGNOSTIC TECHNIQUES AT POWERCOR.

Kieran Skelton

Asset Manager, Powercor Australia.

Abstract: This paper outlines some of the benefits achieved at Powercor Australia through the evolution of asset management methodologies and their application. It considers recent history and the knowledge gained throughout the journey with particular emphasis upon efficient work packaging through improving diagnostic techniques.

Key Words: Asset Management, Diagnostic Techniques, Methodologies.

1 INTRODUCTION

Powercor has an electrical network valued in excess of $2.2B and supplies electricity to over 620,000 consumers across Western Victoria in the South East corner of Australia.

In 2001 Powercor reviewed its Asset Management Strategy objectives to bring a greater emphasis onto the need for a rapid reliability improvement in the operating of the electrical assets. This improved reliability was to take the form of a reduction in the planned and unplanned outages (breakdowns) that impacted upon the assets.

Preceding this review the organisation was based a process related structure that focused largely upon the standardisation of processes and tasks undertaken. Specific benefits that were targeted related to short term financial gains and prudent capital investment. The objectives during this phase were to largely deliver a reduction in costs to consumers following disaggregation and privatisation of the industry in Victoria.

From 2001 until 2004 the revised Asset Management Strategy Objective was to deliver a step change in reliability performance with a relatively minimal step change in capital investment. This is a challenging objective that is compounded in terms of difficulty when attempted in a capital intensive industry such as electrical distribution.

This paper describes how the benefits of emerging diagnostic techniques such as corona detection, and thermography can be used as inputs to a structured Asset Management framework to improve reliability performance and efficiency of resource and capital on a large dispersed asset such as an electrical distribution network.

It also considers some of the next generation of benefits that are being targeted, and the process to move towards best practice, over the next five year period.

2 COMPANY PROFILE AND VISION

Powercors vision is “To be a leader in the distribution business in Australia with outstanding performance. We strive to excel in financial performance, productivity, supply reliability, customer service and community perception”. This translates to the delivery of increasing benefits to shareholders, customers and the communities we serve until we are leaders in each category.

Powercor Australia is the largest of the five Victorian electricity distribution networks in terms of geographical service area and customer numbers. Powercor services some 620,000 customers over an area of 150,000 km2 stretching from the Western suburbs of Melbourne to the South Australian and New South Wales borders. It has assets of $2.2B and is jointly owned by the Cheung Kong group from Hong Kong and Spark Infrastructure Limited a publicly listed company in Australia.

The assets largely comprise of 512,000 poles, 76,000 km of overhead lines, 6,000 km of underground cables, 74,000 transformers and 63 zone substations which are used for electricity distribution.

Figure 1: Powercor Distribution Network Coverage

With the move to a privatised and deregulated electricity industry in Victoria the need to consider both commercial and customer service needs as a measure of a company performance are key drivers for the electricity companies. Since 1995 the industry has progressively been separated into a market driven retail and generation component as well as a regulated transmission and distribution component of which Powercor is a part of the latter.

3 REGULATORY ENVIRONMENT

Companies owning a regulated distribution system, or electrical network as it is often called, are required to obtain and operate within a distribution licence which is linked to various operating and performance standards. These standards are legally binding and legislated within the Victorian electrical distribution code. The Essential Services Commission (Government Regulator) has a charter to ensure compliance occurs by all distributors and oversees the distribution code. The regulator reviews the code every five years to reset the allowable distribution tariffs, and customer service levels, electrical distributors are required to meet in the next review period. The 2001 to 2005 review was completed in October 2000 and the amendments adopted by the regulator required a step improvement in the levels of reliability presently being delivered followed by a level of incremental improvement equating to 20% over the next 5 years as shown in figure 3. In addition to these reliability improvements there was to be a tariff reduction of approximately 20% directly impacting upon revenue.

4 POWERCOR ASSET MANAGEMENT STRATEGY EVOLUTION

The original Asset Management Strategy (AMS) and model already in place at Powercor had been developed with Price Waterhouse Urwick's assistance as an implementation partner in 1997. Underpinning the strategy at that time were 63 Asset Maintenance Policies that had been developed by using the Reliability Centred Maintenance II (RCM II) methodology which was very successful in contributing to Powercor's reduced maintenance and asset inspection costs over the following years.

Powercor had implemented SAP R/3 integrated business software utilising the SAP Plant Maintenance module. The Plant Maintenance module in SAP performs a Works and Asset Management function and was a key factor in the successful implementation of the original Asset Management Strategy. With the implementation of SAP R/3 a process structure was used as the organisational hierarchy to deliver a standardisation of tasks and processes.

The Asset Management model as shown in figure 2 was designed to look at assets and determine how performance improvement through a whole of life approach can be maximised. This goal is reflected in the Asset Management "mission statement" and objectives as follows.

"Asset Management is the structured and systematic approach to acquiring, managing, maintaining and disposing of assets so that Powercor's customers' and business needs are met, and its obligations to share holders, the community, government and regulator are satisfied.

Asset management will address:

- *reducing the need for new assets by adoption of "non asset" solutions where it is cost effective ;*
- *ensuring that existing assets are effectively and efficiently monitored, maintained and utilised;*
- *optimising total life cycle cost of assets from acquisition operation, and maintenance, to disposal; and*
- *establishing clear accountability and responsibility for assets and their performance."*

Between 1997 and 2000 the AMS had delivered a financial benefit and contributed to a reliability improvement trend that was positive although incremental at best. Similarly the process structure in place had delivered significant benefits in the standardisation of processes and bringing consistent and common levels of reporting and data acquisition into the company that previously did not exist. It was appropriate for the regulatory targets and shareholder objectives that were set at that time.

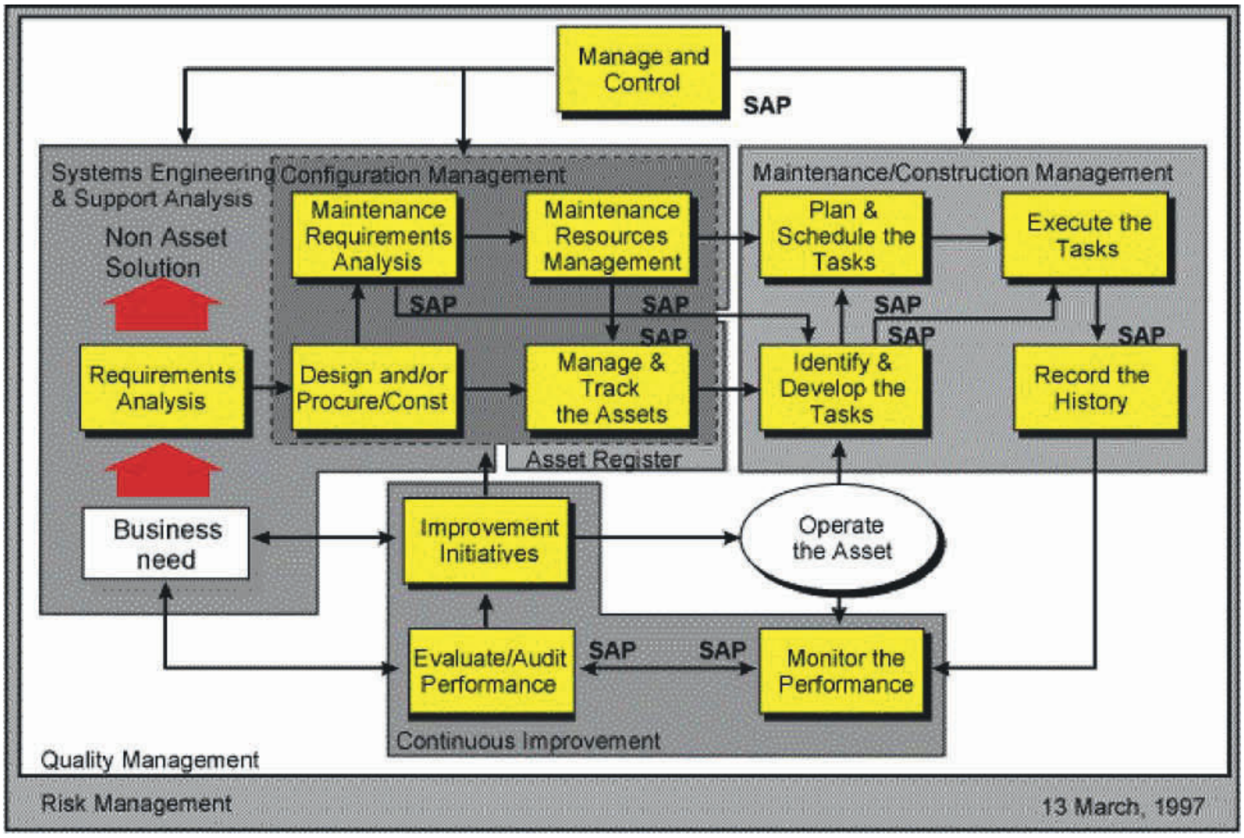

Figure 2:Asset Management Model

In 2001 with new owners and a new regulatory period came new challenges. The new shareholder influence and vision required a step forward in reliability performance with very prompt and financially efficient implementation path.

The Asset Management model was seen as a sound platform having served its purpose well over the previous 3 years and was retained. The mission statement and objectives were reviewed to reflect the new regulatory period and increased emphasis on reliability performance. In addition a much broader framework was introduced to capture many of the existing documents and formalise their input into the Asset Management Strategy. This was to be a fundamental aspect of the cultural change needed to move forward. A clear objective of the changes that was learnt from the previous structure was to re create the visible link between each employee's effort and the delivery of a common divisional goal. This transparency was designed to capture employee ownership and input and ensure it was seen as being valued. It was also seen as a way of restoring some of the employee satisfaction lost in the preceding years under the process structure where many skilled employees felt they had simply become production line workers rather than strategists or maintenance engineers.

By far the most significant change undertaken was to aggregate the key functions of the Asset Management Model into a single strategically focussed Asset Management division (Powercor Network Division) to ensure a consolidated view on the asset whole of life cycle prevailed when making decisions. The consolidation of a single management focus upon assets occurred. A lack of local ownership of the assets was becoming an emerging issue also at the time. A reliability audit undertaken by the Regulator also confirmed this was an emerging behavioural trend across the company. To address this issue and provide a level of local asset ownership six new Regional Asset Management roles were implemented. These roles also had a geographic responsibility to ensure all the Asset Management policies were being applied consistently and correctly. This also led to beneficial feedback being obtained and fed back into the policy reviews with a minimum of bureaucratic processes and paper work.

In any analysis of the value of maintenance programs the organisational structure needs to facilitate the continually linking of reliability performance to maintenance programs as an initial, and fundamental, step. To support this throughout the structure additional training in RCM II analysis and methodologies training has commenced for many Asset Management staff to strengthen the linkage between all activities undertaken and the delivery of reliability improvement outcomes. Currently the reactive nature of breakdown costs and preventative works could be substantially improved by being performed in a proactive and a planned manner. Breakdown works to restore electricity supplies presently incur an additional cost in the order of 120 %

to 175 % due to their unplanned nature and the inefficiency this introduces when compared to performing the task as a planned maintenance activity.

Significant reliability and employee satisfaction benefits were able to be delivered by addressing the cultural paradigm that was present and had evolved from separating all resulting output benefits of the maintenance program and maintenance engineers who were implementing the work schedule. The process structure had introduced an unpalatable scenario that needed resolution from a work ethic viewpoint. If employees feel their contribution towards maintaining the system is treated equally, regardless of the achievement of any assessable benefit or improvement, a large de-motivating and counter productive culture can, and in fact did, emerge. In this instance neither incentive nor recognition occurred for performing the maintenance program well. The return to a structure that linked tasks with outputs and measured benefits through actions that had been analysed and implemented as a part of a broad strategy delivered significant step improvement benefits as can be seen in figure 3.

Often engineering based organisations have difficulty in harnessing the full potential of their employees. Many believe their staff is their greatest asset yet the pursuit of employee satisfaction and consultation on items that would provide greater motivation for staff is seen as "softer" supporting functions rather than the core to delivering engineering excellence. Figure 3 below shows the impact of the revised structure and evolved Asset Management strategy upon reliability performance in 2001 through 2005. These results challenge the view that employee and structure related topics are soft and suggests that perhaps they should be viewed as more "core" engineering issues.

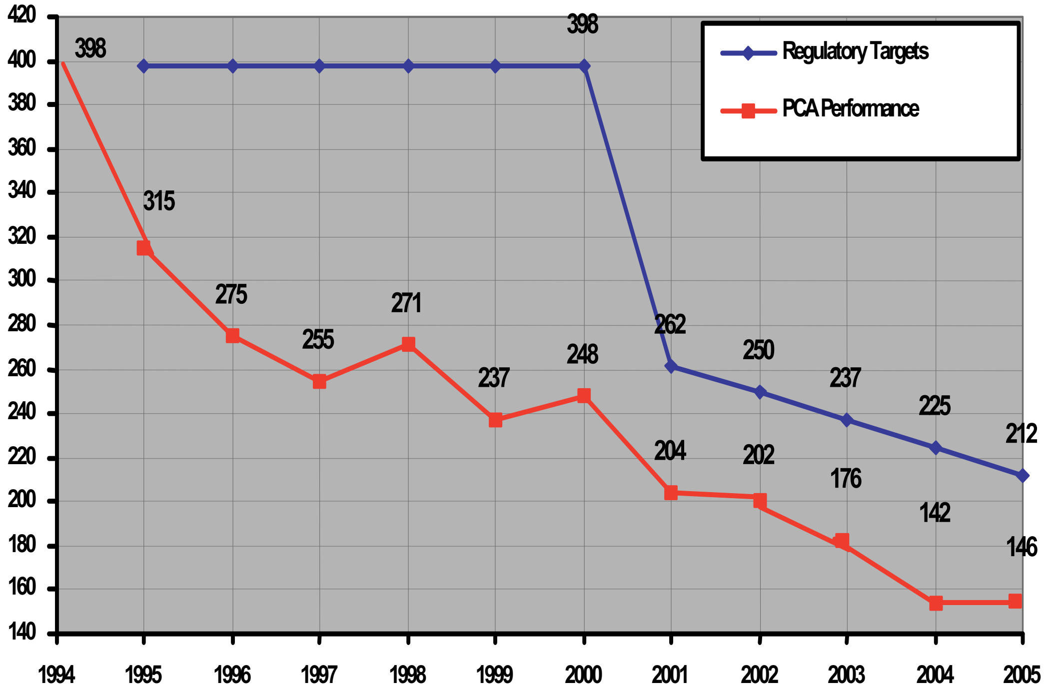

Figure 3: Powercor performance and targets

2001 - 2005 Step improvements and performance

Reliability performance 42% improvement on 2000.

Customer complaints down 50% from 2000

National leader in electrical industry in health and safety with a lost time injury frequency rate of 0.5 (per million man-hours worked).

A strong financial performance was delivered with better than of targeted performance in both Capital and Operation areas.

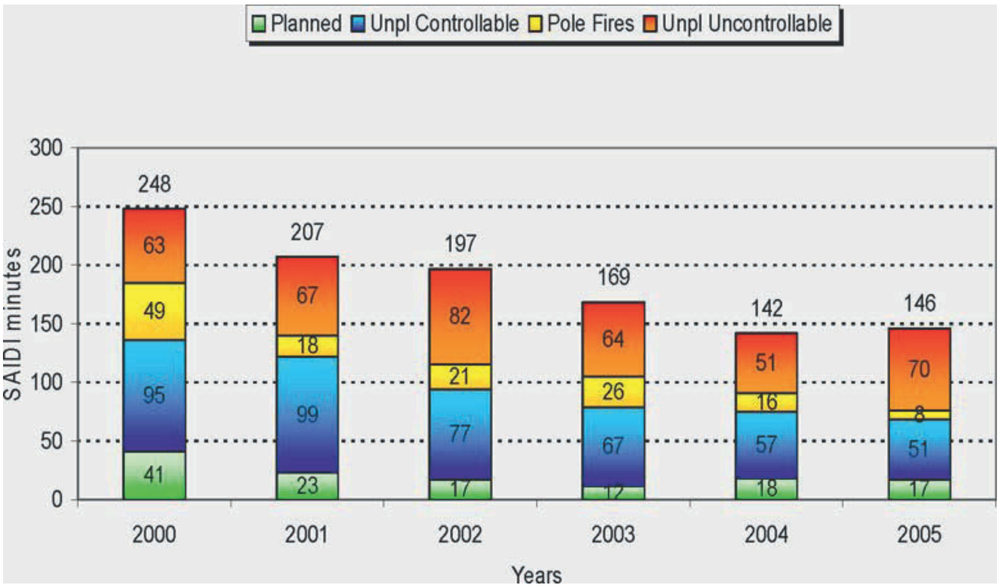

Figure 4: Powercor Reliability Performance 2000 vs 2005 by Cause and SAIDI Impact

2004 Consolidated Asset Management Delivery

Development of the Asset Management Strategy to date has largely focused upon preventing outages as a result of asset failures. In moving forward the efficient deployment of resources and completion of maintenance tasks needed to become a key consideration. This largely relates to the plan, schedule and execute the task activities as undertaken in the Maintenance / Construction Management module of the Asset Management model. (figure 2) Powercor's asset inspection and maintenance process is based around a rotating 5 year cycle.

The analysis of failures and considerations of the costing of undertaking work on a geographically dispersed asset has enabled Powercor to conclude that the efficiency gained through bring forward maintenance will be more than offset by the reduction in site visits and reduced break down attendances. Contrasting the present inspection process assets will continue to be inspected in a rotating 5 year cycle, however all works will be completed in year one with no further maintenance works required for the remainder of the cycle.

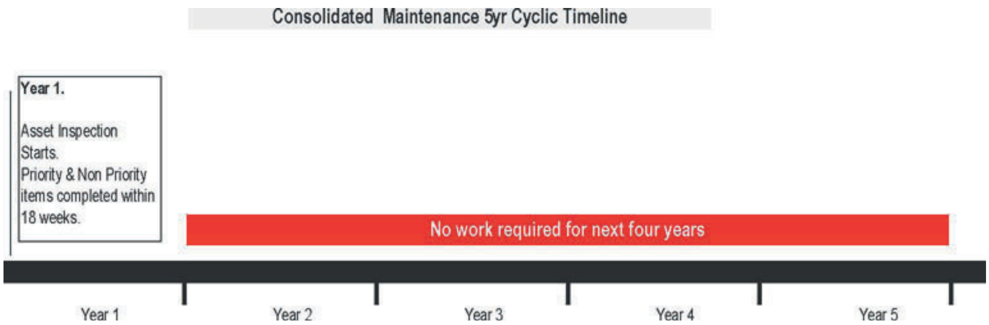

Figure 5: Powercor Proposed Consolidated Maintenance Practice Timeline

4.1 Improvement in the application of Diagnostic tools

A key component of the asset management model that it has an inbuilt allowance for flexibility and innovation in the improvement initiatives step of Continuous Improvement module (figure 2). Powercor has reviewed the reliability outputs delivered (figure 4) and recognised if an improvement in diagnostic techniques was possible then the sites of potential pole fires could be identified and preventative maintenance work undertaken prior to the failure occurring. If this additional work was undertaken simultaneously with normal consolidated maintenance process, as explained above, then an efficient solution to delivering the reliability improvement benefits would be achieved.

Pole fires can occur as a result of a pollutant building up on an insulator or cross arm surface. This build up may become conductive in the presence of moisture such as mist or light rain which in turn will provide a for leakage currents to flow from the energized conductors to earth. These currents, or tracking as it is commonly known, can flow on the surface and within a cross arm and will frequently concentrate on the un-earthed metal bolt that attaches the cross arm to the pole. This leads to the bolt becoming hot and a smouldering fire to commence leading ultimately to the cross arm failure and a power outage.

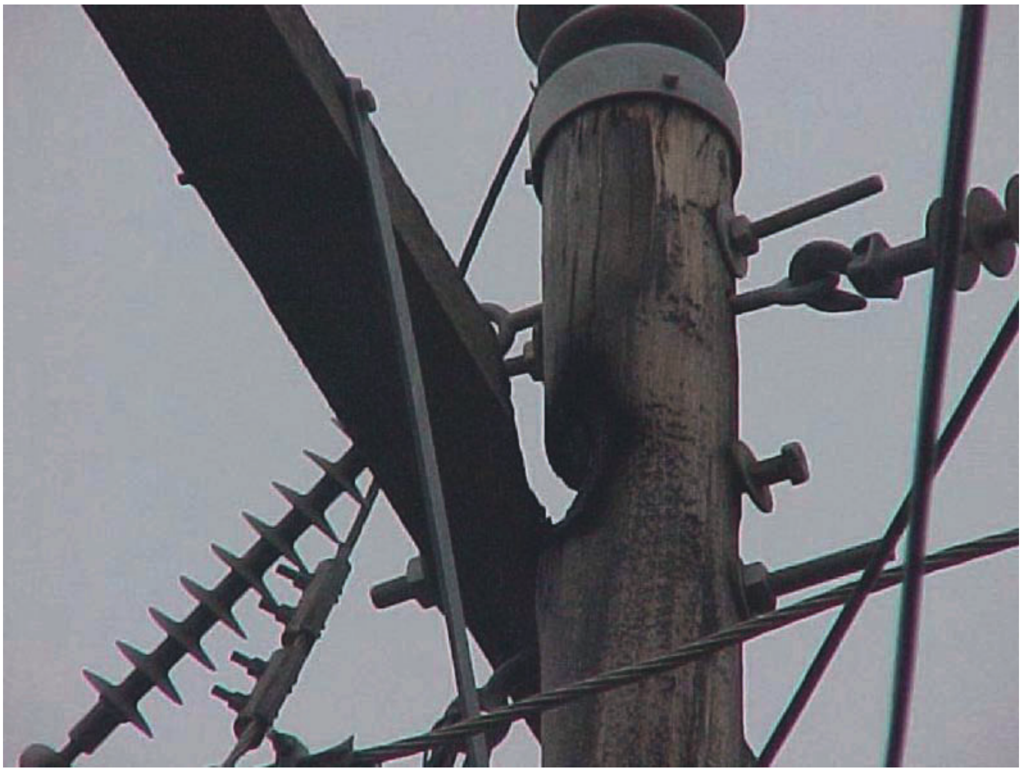

Figure 6: Pole fire

In 2004 Powercor evaluated the corona camera as a tool for detecting potential pole fire locations and other maintenance items. It was assessed that the camera had significant potential for detecting defective assets and in conjunction with thermographic inspection supports routine ground based asset inspection programs to mitigate the risk of earth leakage faults, television and radio interference and in particular pole top fires. A 3 year corona camera inspection contract was initiated. The technology is based on the detection of corona discharge via high resolution video camera "corona camera". The camera detects UV emissions from discharges resulting from ionisation of air caused by leakage current. This activity may also result in audio noise or radio interference which provides a greater breadth of scope for the diagnostic tool to perform additional functions as a part of customer initiated enquiries or complaints. The camera is able to detect severity of leakage current from the corona discharge, its location and potentially the likelihood of pole fire ignition or insulation failure. A sample report from the camera is shown below where the corona is clearly visible. (corona appears as white discharge around insulator)

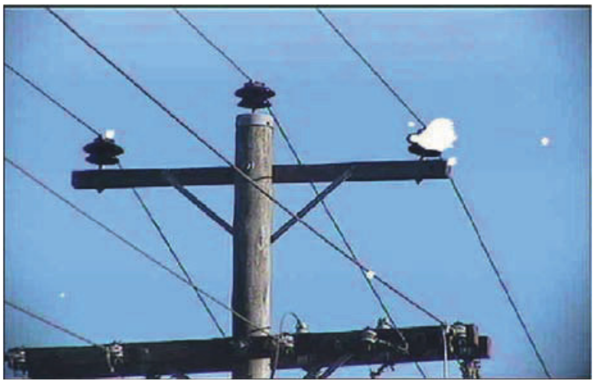

Figure 7: Sample Reports and Associated Analysis

Figure 8: Sample Reports and Associated Analysis

EQUIPMENT POLE No21 LIS No4-22317 FDR CDN3

OBJECT 22KV FOG INSULATOR	Road side phase
DAMAGE Ionisation Cloud	20mm diameter
CAUSE	Cracked Insulator

ANALYSIS

Possible Cause

The level of corona discharge on this insulator compared with the companion insulators would indicate a damaged insulator rather than a pollution issue. If pollution was the cause, corona would be expected on all 3 insulators to varying degrees; however this can only be confirmed by a close inspection of the insulator. The damage to the insulator could be as obvious as a cracked or chipped shed or just deterioration in the insulator surface glazing which would only be detected by close inspection. In addition, the insulator has a lean which indicates a loose fitting on the cross arm which will increase the risk of pole fire.

Priority

Pole and Cross arm condition looks good therefore the risk of pole fire ignition would be low in this case, however as the cross arm deteriorates with time this is a potential pole fire risk location. In addition the insulator may generate TVI and under damp conditions the pole may become alive due to tracking.

Recommendation

It is recommended that the pole top structure be replaced as a priority 2 defect and the insulator retained for closer inspection.

As can be seen from the above sample report an accurate assessment can be made as to the likelihood of a pole fire occurring and an associated risk level can be applied to program the cross-arm for replacement. This pro active diagnostic technique has been implemented at Powercor and the benefits delivered in proactively managing pole fires can be seen in the reliability performance table shown in figure 2. Additional benefits have also been delivered through an improved ability to detect radio and television interference enquiries that are frequently raised by customers.

OPTIMISING FLOOR SPACE DURING RETROFITTING OF HIGH-RISE OFFICE BUILDINGS

Chintha Perera[a], Sujeeva Setunge[a], Arun Kumar[b] and Tom Molyneaux[a]

[a] *School of Civil and Chemical Engineering, RMIT University, GPO box 2476V, Melbourne, Australia.3001.*

[b] *CRC for Construction Innovation*

Abstract: A need for an efficient decision support tool for planning of office building refurbishment is emerging due to the significant increase in the number of ageing buildings in the world. In order to meet this need, all the aspects of building refurbishment projects such as waste minimisation and management, structural strengthening and floor space optimisation, estimation of residual life and construction management issues need to be integrated. Whilst there are number of such tools reported in the literature to cover other parameters in relation to re-life of buildings, they do not include evaluation of the optimising of rentable floor space and corresponding structural strengthening needs. This paper discusses the methodology for development of decision support frame work to compare and assess options available to the design team of a re-life project in optimising rentable floor space. The issues to be addressed during floor-space optimisation have been identified and prioritised through a Delphi process. These issues are then mapped against the life cycle of a refurbishment project and consolidated. Decision tool developed as a matrix to map existing as well as innovative structural strengthening techniques to strengthening needs is presented to demonstrate the application of the proposed model.

Key Words: Retrofit, Office buildings, Structural strengthening

1 INTRODUCTION

The significant growth in the construction of new commercial office buildings over the past 30 years has left a large stock of ageing buildings. The repair and maintenance expenditure of aged buildings is expected to increase due to the structural deficiencies and functional obsolescence. In such situations, the owner of a building has to decide the most judicious moment to undertake refurbishment to extend useful life of their buildings and improve their overall value or to replace them with a new building.

Over the past 5 years, an increasing number of projects are exploring the advantages of retrofitting of aged buildings and therefore, office building retrofitting market has seen considerable growth. The followings explanation of this paradox is given in Literature [1]:

- the life span of office buildings is much shorter than residential buildings;
- users' requirements have considerably changed in terms of office equipment, communications, automation, quality of use and comfort;
- buildings that do not offer all the amenities for comfort and flexibility are difficult to sell or rent;
- retrofitting a building costs much less than demolition and reconstruction;
- office buildings are classified amongst the buildings presenting the highest energy consumption.
- With the changes in legislation, approval of a new development of the same user capacity may not be permitted within the envelop of the old building

In developing a strong business case for re-life rather than demolition and re-build, a major issue to be addressed is maximizing of rentable floor space, which often puts a re-life project at a disadvantage. In increasing usable floor space, options available to the client include removal or adding floors and partitions, relocating services, cutting openings or extending floors and relocating lift wells etc. In each case, innovative strengthening schemes have much to offer when considering upgrading of the existing structure.

For a retrofitting project to be successful, the owner has to establish a suitable retrofitting plan of action. If a client makes inappropriate choices, the outcome may be a time and/or cost overrun and general dissatisfaction. Nowadays, a number of decision support tools are available to the owners to assess the current condition of their buildings with respect to deterioration, functional obsolescence, energy consumption and environment quality, before making a decision to retrofit their buildings. Those decision support tools also help to choose appropriate retrofitting actions and to estimate the cost. However, the available decision support tools do not cover the building structure. Consequently the "Floor space optimisation" strand of Re-life project funded by CRC for construction innovation is looking into the development of a management decision support tool that assists the owners in selecting an appropriate strengthening scheme during optimizing of floor space in a re-life project.

2 OPTIMIZING OF FLOOR SPACE DURING RETROFITTING OF BUILDINGSS

It is a significant challenge for engineers to satisfy the clients' requirements during retrofitting; specially optimizing the usable floor space. Usable floor space of existing building can be optimized by modifying the layout of an existing building such as removing or adding of floors and partitions, relocating services, cutting openings or extending floors and relocating lift wells etc. In these situations, innovative structural strengthening schemes could be implemented to strengthen the existing structure. Strengthening of an existing structure may also become necessary under the following circumstances:

1. When buildings are exposed to harsh environments such as de-icing salts, chemicals or air-borne salt spray, or have inappropriate details, the structures may experience significant deterioration in the form of steel corrosion, concrete cracks and spalls [3]. Such deterioration may result in structural inadequacies that adversely affect the structure or its members,
2. In situations where the building owners make decision to change the usage of a type of building depending on the business demand in the current market environment. As a result, the existing structure of a building may or may not be strong enough to withstand the new loading,
3. Structures constructed in early days may have been designed to carry loads that are significantly smaller than the current needs, possibly due to increase demand usage [3],
4. . Structural inadequacies may arise due to errors in initial design or construction and changes of design standards.

By carefully implementing appropriate structural strengthening methods, re-life of buildings can be justified/achieved rather than adopting demolishment and re-building

3 STRUCTURAL IMPLICATIONS OF OPTIMISING USABLE FLOOR SPACE

In situations where the use of the office floor requires changes to services such as lift wells air ducts, ventilation, lighting and the type of loads applied on it, load transfer mechanism of the building structure may require strengthening or re designing and re-building.

Selection of an appropriate strengthening method is dependent on the materials of construction. Structural elements of existing buildings are commonly constructed of concrete, steel, timber and masonry. Concrete is the most commonly used building material and widely used in the forms of in-situ concrete, precast concrete and post-tensioned concrete.

The structural strengthening can be achieved by section enlargement, external post tensioning, external bonded steel elements, bonded advanced fiber reinforced polymer (FRP) composites, span shortening, or a combination of these techniques [2,3,7,9,12-26]. No matter what strengthening technique is used, the ability to perform as an integrated system can be obtained only by providing an adequate bond between the existing member and the repair/reinforcement to ensure monolithic structural behaviour [2]. Stress concentrations resulting from added material should be investigated as they may cause a localized failure.

Unfortunately, there is no specification or design that covers all repair/upgrade scenarios and engineers, architects, and contractors must be innovative and thorough, in their design details, specifications, and applications.

4 MANAGEMENT SUPPORT TOOLS AVAILABLE FOR RE-LIFE PROJECTS

A good retrofitting action plan will lead to the success of a re-life project. With the aid of decision-making tools, it is possible to select the most suitable retrofitting action [3, 4, 5, 27, and 28]. A number of such tools have been developed for office buildings with TOBUS, MEDIC, EPIQR and INVESTIMMO being the most commonly reported in the literature [3, 4, and 5].

The decision-making software tools, EPIQR (for apartment buildings) and TOBUS (for office buildings) have been developed for the assessment of retrofitting needs of buildings in European countries. The use of these tools can facilitate a quick and accurate diagnosis of the condition of the existing building in terms of its major area including construction, energy performance, indoor environmental quality, and functional obsolescence. The main advantages of using these tools are the ability to evaluate various refurbishments and retrofit scenarios, and cost of induced works, in the preliminary stages of a project [1, 6].

In EPIQR and TOBUS, deterioration of building materials and components are described by the use of a classification system with four classes. The prediction of the period of passing into the next deterioration state is of high interest as this is directly connected to higher refurbishment costs. The prediction of qualitative deterioration states are important and correspond to key moments in the element's life where some refurbishment action has to be taken [1,6].

European countries have used another software tool entitled MEDIC to predict the future degradation state of building. MEDIC is intended for use with EPIQR and is based on a subdividing of the building into 50 elements. MEDIC calculates the remaining life span of a building element not as a deterministic unique value but as a probability distribution. It can help the owner of a building to decide the most judicious moment to undertake refurbishment to achieve his short and long term financial needs [3, 8, and 29].

Following the footsteps of EPIQR an TOBUS, a decision-making tool for long term efficient investment strategies in housing maintenance and refurbishment – INVESTIMMO has been developed in European countries. It has been aimed at evaluating housing maintenance and refurbishment options, which covers expectations of tenants, housing market, and quality of building upgrading and environmental impacts in addition to the factors identified in TOBUS [6].

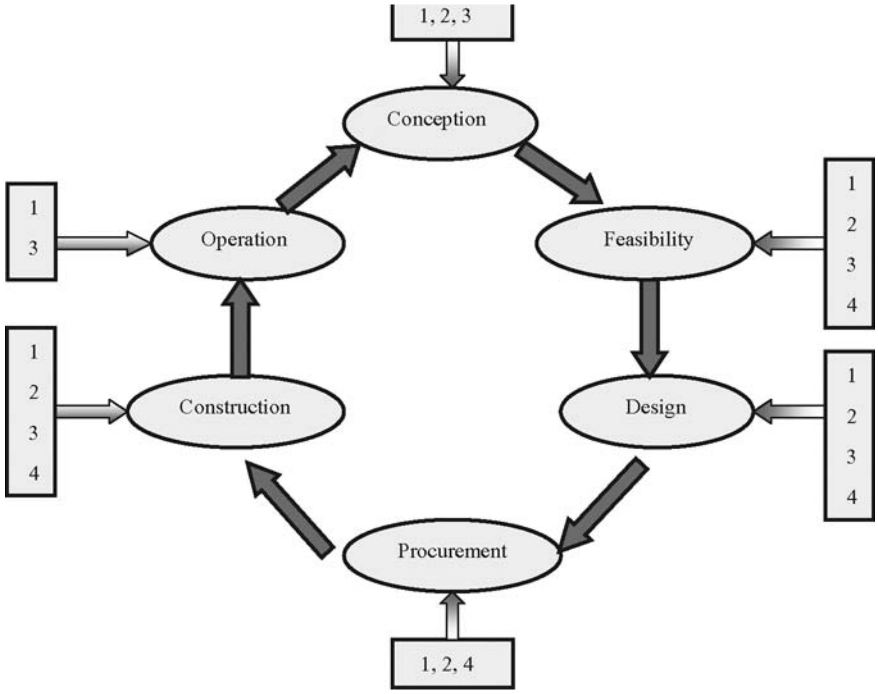
From the review of literature, it was clear that these tools can be used to evaluate the general state of buildings with respect to some of the aspects of building re-life projects such as service life, functional obsolescence, energy consumption and environment impacts. However, no reported work presents a decision support tool, which can be used to compare and assess options available to the design team of a re-life project in optimizing rentable floor space.

5 INTEGRATED FRAMEWORK FOR DECISION MAKING

In order to develop a decision support tool for selecting the most appropriate structural strengthening scheme during optimizing of floor space, the preliminary objective was to identify the clients' requirements and problems associated with structural strengthening. Through the review of literature and based on the experience, a list of issues, which may influence strengthening work has been compiled. Consequently, Delphi process was utilised to rank them based on the importance in refurbishment projects [10, 11]. The following issues were identified as important by the experts engaged in research/practice in the field of building refurbishment:

1. change of use of floors,
2. cutting openings in floors and extending floors,
3. relocate/renew services,
4. structural appraisal prior to refurbishment and
5. safety reliability issues in structural strengthening.

The next challenge faced by the research team was integrating the issues specific to structural strengthening with other issues such as construction management, estimation of the residual life and managing waste and recycling. This was achieved by mapping the issues against the project life cycle as shown in Figure 1, established through an industry workshop with the partners of the project. This identified the input parameters required at each stage of the project life cycle. In this paper we are focussing on the floor space optimisation and structural strengthening during building refurbishment. Detailed mapping of issues to different phases of the project are captured in Table 1



Where 1, 2, 3 and 4 are the inputs from main aspects of building refurbishment projects

1 - Construction management issues,

2 - Structural strengthening and floor space optimisation,

3 - Estimation of residual life,

4 - waste minimisation and management.

Figure 1: Life cycle of a building refurbishment project

Table 1: Mapping of floor space optimisation issues to different stages of the project life cycle

Phases of life cycle of a building / Issues Associated with optimising floor space and structural strengthening	Conception	Feasibility	Design	Procurement	Construction	Operation
Structural Appraisal	√	√	√			
Change of use of floors	√	√	√			
Relocate/renew services	√	√	√	√	√	
Impact on structural strength		√	√			
Safety issues for structural strength		√	√			
Cutting opening/extending floors			√		√	

6 INPUT PARAMETERS TO THE LIFE CYCLE OF BUILDING REFURBISHMENT

Expanding the issues presented in table 1, researchers identified detailed decision parameters required at each phase of the project life cycle to achieve an optimised solution for usable floor space. These were identified through extensive industry consultation complemented by a review of published work. Decision parameters are given in Table 2. For example, at the project conception stage most important parameters are remaining life of the building, structural capacity of the existing building, and structural constraints in the existing building such as flexibility in altering the structure, changes to loads or load transfer mechanisms and structural requirement in relocating services. These issues are identified by studying in-detail the refurbishment reports of two case-study buildings: Council House 1 of Melbourne City Council (CH1) at little Collin Street in Melbourne and Health building at George Street in Brisbane. The two case study buildings covered two distinct refurbishment scenarios. CH1 building refurbishment was driven by a need to arrive at 6-star energy rating to match that of the adjacent council building CH2 which is a state-of-the-art green building. This required drilling through the flat slab floor to relocate services, opening up of light wells to improve natural lighting and ventilation and changes to the windows. George St. building in Brisbane has utilised a concept of integration of two adjacent buildings to optimise the floor space. Through the integration, floor space has been optimised by removing two sets of service cores and demolishing a stair well and using a common lift lobby. For both case study buildings the evaluation methodology for the parameters given in table 2 has been compiled by the research team. This information can be presented as a decision support tool, which will allow the project team to establish typical values for each of the parameters and ascertain the feasibility of a given floor space optimisation option. A typical example is given in table 3 and explained in section 7.

Table 2: Parameters to be considered in developing guidelines for optimising floor space and structural strengthening of a building

Phases of life cycle of a building	Parameters to be considered developing guide lines for optimising floor space and structural strengthening of a building
Conception	● remaining life of the existing building ● structural capacity of the existing building ● structural constraints ● change in load conditions ● change in load transfer mechanisms ● possible options for floor framing and relocation of services ● services to be considered for relocating or renewing ● structural requirements to support relocation of services
Feasibility	● cost of different structural treatment options, floor framing and relocating/renewing services ● availability of technology and expertise for structural appraisal, change of use of floors and relocate/renew services ● reliability of structural appraisal ● environmental issues on structural appraisal and change of use of floors ● user comfort due to relocate/renew services ● consider innovative options for relocating/renewing services ● integrate or evaluate structural options with other issues ● structural safety margins
Design	● calculation of residual structural capacity of existing building ● specialist evaluation techniques ● calculation of structural capacity with new loading condition ● consider innovative options for relocating/renewing services and cutting openings/extending floors ● consider all possible safety requirements ● consider floor framing option which has a relatively low effect on overall structural strength
Procurement	● availability of expertise for relocating/renewing services ● Availability of expertise for structural strengthening ● contractual terms for relocating/renewing services ● reliability of relocating/renewing services
Construction	● proper planning of relocating/renewing services ● techniques adopted for cutting opening/extending floors ● Structural strengthening
Operation	–

Table 3: Matrix of mapping solutions to problems (Contd.)

Structural Strengthening Solutions	Application Projects	Characteristic	Possible Applications	Issues Associated with the solutions	Companies/Contractors
1. **Externally bonded composite system** **- Fiber Reinforced Polymer (FRP)** **- Hardwire® Steel Reinforced Polymer (SRP)**	• Utility tunnel at a University in South Florida • Restoration of swimming pool roof structure, Kalmthout, Belgium	• speed and ease of installation • lower cost • aesthetic appeal • light weight • non-corrosive • excellent fatigue behaviour • non-conductive • can be used for flexural, shear, and axial (confinement) upgrading and crack control • due to thin profile, r/f can be easily run in two directions for two way slabs • allow for carpet, tile, and other flooring finishes to be installed over the system without any significant change in floor elevation	• concrete slab, beam, column and wall • wooden beam, column • masonry	• can damage the externally bonded composite • problematic in flooring applications when used on cracked concrete slabs as these cracks may allow reflective cracking throu' polymer topping.	• VSL International Ltd • Structural Preservation System (USA) • Edge Structural Composites (USA) • C.A. Lindam Companies (USA) • Watson Bowman Acme Corp. (USA)
2. **Section Enlargement**		• relatively easy method • not good in harsh environment. Possible corrosion of embedded reinforcing steel. • can increase load carrying capacity or stiffness • additional concrete can be placed in the form of an overlay or jacket	• concrete columns, beams, slabs	• Increase the weight of existing structure. weight can be minimised	• VSL International Ltd • Structural Preservation System (USA)
3. **External Post-tensioning**	• Two-span steel truss bridge (48-48m) over River Aare at Aarwangen, Switzerland • Pier 39, Parking Structure San Francisco, USA • Double-tee stems on an overpass located on the premises of a University in Washington. Damaged due to overheight truck.	• Possibility of controlling and adjusting the tendon forces, inspecting corrosion protection and replacing tendons. • can be used for both reinforced and prestressed concrete • minimal additional weight to the repair system • ecconomical • requied less time to complete • can be used for flexural , shear and axial (confinement) upgrading	• Applicable for structural steel, composite steel-concrete, timber and masonry structures. e.g. building with masonry walls, girders in buildings, roof structures, circular structures such as silos, reservoirs and large masonry chimneys. • great success to correct excessive deflections and cracking in beams and slabs, parking structure and cantilever members. • due to minimal additional weight of repair system, this is effective and ecconomical for long span beams • existing concrete structures against fatigue and cracking	• vulnerable to corrosion, fire and vandalism. However, improved ductility & fire proofing can be achieved by placing reinforcement in ducts that can grouted after stressing of tendon. Protection can also be achieved by encasing the post tensioning system in concrete or by using shotcrete. • Externally bonded bars can be damaged by traffic. However, that can be prevented by installing the system in grooves made in existing member. • requies access to sides and sometimes ends of member	• VSL International Ltd • Structural Preservation System (USA) • C.A. Lindam Companies (USA)
4. **Bonded steel element**	• Quatier des Celestines, a 19th century building in Namur	• Steel element can be steel plates, channels, angles or built-up members • steel elements can be bonded with epoxy adhesive. In addition to epoxy, mechanical anchors can be used to ensure steel element will share loads in case of adhesive failure. • can improve shear and flexural strength	• Steel plate bonded to tension face of concrete beam can increase flexural capacity, flexural stiffness and in deflection and cracking decreases • Steel plate bonded to side of the member can improve shear strength of concrete beam. • install structural steel beams on the underside of structures and steel brackets at column heads. • long-term solution for structures subjected to aggressive environment	• influence to corrosion and fire.Suitable corrosion protection system and fire protection system can be used. • due to their restrictive length, steel elements need to be spliced which complicate the design and construction operation • existing reinforcement can be damaged while placing the anchors. Considerable site work is required to accurately locate existing reinforcement. • Expensive false work is required to maintain the steel work's possition during bonding. • Adding strengthening material under existing structure may redue the usable headroom	• VSL International Ltd • Structural Preservation System (USA) • C.A. Lindam Companies (USA)

Table 3: Matrix of mapping solutions to problems

Structural Strengthening Solutions	Application Projects	Characteristic	Possible Applications	Issues Associated with the solutions	Companies/Contractors
5. **Span Shortening**	• Shortened span in Parking Garage	• reduce the force in overstressed beam • increase the load carrying capacity • best material for this application is steel, which is quick to install.		• result in loss of space and reduced headroom. • New footing for new column is expensive less expensive approach is to install diagonal braces that extend from the bases of existing columns	
6. **Hybrid strengthening method** eg. steel/CFRP	• Strengthening of a roof system of an elementary school in New Jersey. They wanted to install skylight on existing roof slab. • Transformation of former school building to library • Roof structure of warehouse at Brussels in Belgium (due to calculation error,capacity of main supporting beams are not suticient)	• less expensive • aesthetically pleasing • fast application	• slab with opening • rib slabs		• Structural Preservation System (USA)
7. **Removing existing concrete and casting with lightweight concrete overlay (with steel wire mesh or steel bar)**	• Baltimore's historic Hippodrome Theater renovation -France	• increase bending capacity by increasing effective depth of existing bottom r/f • at support, embedded steel steel r/f in overlay increase the bending capacity • r/f in overlay limits cracking of overlay	• concrete slab and beam	• adequate surface preparation is required to ensure the bond between overlay and existing structure • overlay replace existing topping and therefore small increase in dead load, which offset by using lightweight concrete.	• Structural Preservation System (USA)
8. **Hardwire**	• Baltimore's historic Hippodrome Theater renovation -France	• hardwire made of ultrahigh strength steel wires twisted together to form reinforcing steel cords wires bonded to existing structures with epoxy adhesive • hardwire works as additional r/f to provide tensile strength	• reinforced and prestressed beams, girders, and slabs to provide additional flexural strength. • can be used on sides of beams and girders to provide additional shear strength. • can be used on structural elements to increase their capacity.		• Structural Preservation System (USA)
9. **Hardwire steel belt with polymer flooring system**	• Leading national home improvement warehouse • multi-story warehoue/ distribution facility for a large automative parts distributor in illionis	• hardwire does not replace today's polymer flooring system. However, additon of hardwire dramatically strengthens retrofitflooring design capabilities. • combination of polymer flooring with these thin steel belts creates a system with the ability to increase structural capacity, blast resistance and general toughness of concrete • ability to integrate with multiple polymer and cementitious materials	• heavy trafficked warehouses, manufacturing slabs, elevated slabs, slabs on pile construction, and slabs that are structurally deficient from improper design or construction • viable solution where emission and odors are an issue.		• Structural Preservation System (USA)
10. **Replacing existing wire system with encapsulated monostrand post tensioning system**	• Parking Garage in New York	• existing structure to be post tensionned system • time and cost effective			• Structural Preservation System (USA)
11. **Epoxy mortar**	• Timber floor in a castle	• can be used to strengthen old timber structures. excellent material to repair wood because it has strong bond to wood and MOE is nearly equal to wood.	• Timber - A large groove was sawed on top side of the beam. Steel r/f has been placed in these groove. Then grooves are filled wth epoxy mortar.		

7 EXAMPLE OF A DECISION SUPPORT MATRIX FOR STRUCTURAL STRENGTHENIGN ISSUES

Table 3 demonstrates a typical matrix developed to provide decision support for structural strengthening issues at the conception and feasibility stages of a re-life project. The matrix covers possible structural strengthening solutions, typical application projects, characteristics of the strengthening method, possible applications and issues and the local expertise availability for a typical scheme. This allows the project team of a re-life project to identify possible strengthening solutions and feasibility of these prior to engaging a consultant for a specific issue. The complete tool covers other information such as typical costs and sample calculations for a typical strengthening solution. This matrix has been calibrated using data from the two case study buildings mentioned earlier: CH1 building in Melbourne and 63 George St. Building in Brisbane [30]. Similar matrices are currently being developed to cover parameters identified in table 2 such as options in improving energy rating using relocation/renew services, façade and window treatment and improved ventilation, integration of structural issues with other issues such as waste minimisation and construction and procurement methods.

8 CONCLUSIONS

The paper presented the challenges faced by engineers in decision making during re-life of buildings. It then presented a methodology for identifying major issues affecting optimisation of floor space and structural strengthening of buildings during a refurbishment project. A method for mapping major issues identified as influencing re life of buildings to different stages of the project life cycle has been presented. This model presents decision makers with valuable guidance at different stages of the project life cycle of a re-life initiative. An example of a detailed decision support guideline developed to cover one major parameter has been presented to demonstrate the application of the model. This guideline given as a matrix in table 3 has been validated with data from two case study buildings and other published work.

CRITICALITY IN ASSET MANAGEMENT

Healy Dr. J.A.

JAHCon Physical Asset Management Pty. Ltd.

Abstract: This paper discusses the development and application of a systematic and auditable risk based Criticality Ranking for use in complex plant (both equipment and systems) and is based on work carried out for several organizations in Australia.

Criticality is often mentioned in texts and conferences dealing with Asset Management and Maintenance however little discussion takes place about its uses and applications and the important role it plays in facilitating many Asset Management functions. Limited resources and increasing consequences of failure in modern plant make objective and auditable Criticality assessment of known and likely failures increasingly important.

The Criticality assessment is a fundamental component of effective Asset Management and if not formally developed and implemented, an informal ranking will be applied by individuals even if it is not recognised as such.

A well developed Criticality ranking is beneficial to the organisation if it impacts positively on decision making and provides an objective guide when establishing appropriate responses for various end-user scenarios.

This paper outlines the development and implementation of a Risk based assessment of Criticality and discusses the application of Criticality in day-to-day Asset Management and Maintenance activities.

KEYWORDS: Criticality, Priority, Asset Management, Maintenance, Effectiveness, Efficiency, Reliability

1 1. INTRODUCTION

In the words of Russell Baker "The role of inanimate objects is to resist man and ultimately defeat him". Unacceptable outcomes from system or equipment failures usually arise from a lack of appreciation of the risk associated with operating these systems or equipment. The likelihood and consequences of a potential failure are considered in many instances only after a significant failure (or near miss) triggers a retrospective assessment of a risk the organisation had been living with for some time, often in complete ignorance. Rarely do these failures occur as a result of malicious damage therefore blaming employees or staff for failing to consider these possible outcomes is more of an indicator of poor management than poor employee performance. The only practical approach available for a modern organisation is to carry out a planned and structured assessment of the known and likely risks associated with the operation of the plant and instigate risk management strategies to limit the negative impact of these events.

Criticality based on risk assessments have application in many areas of the organisation and while this paper discuss the application of Criticality Assessments to Maintenance and more broadly to Asset Management, it is important not to overlook the need for similar studies in other areas of the organisation.

Starting from the premise that there is no way to completely eliminate all risk from the organisation, we must address the potential for negative impacts in a systematic and scientific way rather than wait for an event to occur to draw our attention to the risk. While the range of risks in a modern plant is enormous, fortunately not all are of equal significance and usually only a relatively small percentage requires the highest level of risk management to control them. In practice, only about 10% of the assets will have 'High' criticalities with the bulk of the assets having 'Medium' and 'Low' level criticalities. This does not mean that we need only assess the 'High' criticality items as we have no objective way of identifying which are the 'High' Criticality assets until we have assessed them all. This means that the Criticality assessment has to be carried out for all assets and systems in the area of interest before the 'Critical Few' can be identified from the rest.

Without a structured and systematic approach there is little likelihood of addressing all major risks in a useful time. Some of the potential risks will have limited impact on the organisation should they occur and therefore can be managed in a way that accepts some failure occurrences. Other failures can lead to injury or death or complete failure of the business and therefore have to be managed in a way that prevents all occurrences. The varying levels of risk identified by the assessment will require a range of responses commensurate with the risk level identified. Clearly a 'One-size-fits-all' approach is unlikely to be either cost effective, or effective in managing the risks identified.

2 CRITICALITY ASSESSSMENT

Criticality assessment is a structured methodology that provides a proactive approach for the assessment of risks in the organisation. Different approaches are possible while all have the same desired outcome – namely a relative or absolute ranking of the systems and/or assets by their 'importance' to the organisation. A comprehensive Criticality assessment would provide a ranked list of systems and/or equipment (a Criticality Ranking) identifying possible failure mechanisms, underlying failure rates, likelihood of impact from the failure and the consequences of the failure. The outcome of the assessment would typically lead to risk management strategies for equipment which would benefit most from the application of a particular management, operating or maintenance strategy. Criticality ranking also assists in making decisions about which equipment is most important for planning and scheduling maintenance work as well as document control and other management functions.

Criticality assessments can be carried out using various techniques varying from the 'Wild Guess' to the fully 'Quantitative Risk Analysis'. The more common systematic approaches to identifying and representing Criticality include 'Qualitative Assessments', 'Semi-Quantitative assessments' and 'Quantitative Assessments'. Within each of these broad groupings a wide range of approaches are often used. Each approach has its merits and disadvantages and should be clearly understood by those undertaking the study before committing to a specific approach. For an initial assessment of criticality, or where information is limited upon which to base the assessment, a Qualitative or Semi-Quantitative approaches is likely to be the most practical and can give effective results if well implemented. It is likely that the initial assessment would highlight the lack of suitable data as being a risk factor and the management of that risk may involve improved data collection and analysis in the future.

Quantitative assessments rely heavily upon historical data, or well based experience, to 'calculate' the rankings assigned to the equipment or failure mechanisms being assessed. These calculations typically include Probability of failure and Cost of each failure event. Obtaining the necessary data can be very difficult and often the data has to be pre-processed to get it into a form suitable for the analysis and any pre-processing must be understood and carefully carried out to prevent distortions of the final outcomes. It is obvious that where the failure mechanisms do not lend themselves to easy quantification that the Quantitative approach can be unsuitable. This is especially so when assessing the Consequences for Safety and Environmental failure mechanisms and despite claims to the contrary, quantifying a human life or serious injury or for that matter serious environmental damage, is unacceptable to the wider community and is impossible to defend to reasonable people.

It is important to select an assessment approach in keeping with the needs of the organisation as use of a too basic approach can result in insufficient resolution or rigor to implement the necessary risk management responses while an overly detailed approach can increase the cost and time for the assessment and result in a lot of redundant or unnecessary data being generated.

The following steps outline the practical audit process.

1. Consider each asset in its operating context – what it does & where is it?
2. Develop an equipment failure description – i.e. how can it fail?
3. Estimate the consequences of each failure – i.e. what happens when it fails?
4. Determine likelihood of each failure – i.e. how often is it likely to happen?
5. Calculate the Risk from the Likelihood & Consequences.
6. Sort the risk scores in decreasing order of importance.
7. Map the maximum risk score for the unit onto the 'A', 'B', 'C' scale (optional).

Individual systems or equipment can have more than one Criticality Ranking depending on the number of criteria being considered in the assessment. The choice of criterion is crucial as omission of important criterion can result in some significant failure mechanisms being left un-assessed [1]. While there are many criteria that can be included in a Criticality assessment there is also a need to minimise the criteria considered to keep the assessment workload within reasonable bounds. In practice, some common Criticality Ranking criteria include:

- Safety
- Environment
- Asset Damage (secondary damage)
- Production Loss
- Company image

By considering these (and possibly other) criteria and assigning a Criticality Score to the various failure mechanisms for each criterion it is possible to build up a Criticality Profile for the system or machine being assessed. In practical applications it is common to use the highest Criticality Score for a system or machine to represent the Criticality Ranking of the system or machine as a whole. The overall 'Criticality' of the system or machine can be used to support decision making throughout the organisation including projects, maintenance, operations, management etc.

In practice, the scale/s used for the assessment are more detailed than the final Criticality Ranking scale and therefore the 'Criticality Scores' can be 'mapped' onto a lower resolution 'Criticality Ranking' scale (typically 'A', 'B', 'C' or similar) to make it easier to use the Criticality Ranking on a day-to-day basis. The 'mapped' scores are then inserted into the CMMS to allow Criticality to be assigned to jobs for planning and other equipment management purposes.

Depending on the level of detail included in the Criticality Analysis, the results allow many Asset Management decisions to be made on objective criteria and also provide an audit trail for future review and updating. Some of the applications of the criticality analysis results include the following.

- *Provide a common communication tool.*
- *Process system design.*
- *Redundancy – equipment and systems.*
- *Maintenance programs.*
- *Work management based on known risk.*
- Identify spare parts requirements.
- Target maintenance budgets.
- Identify training requirements.
- Identify skill based risk.
- Quantify the maintenance commitment KSF's, KPI's.
- Provide a basis for system modelling.

3 CRITICALITY ASSESSMENT PROCESS

A Criticality Analysis can be carried out by applying Risk Analysis techniques to identify the Risk associated with particular equipment failure mechanisms in a specific operating context. AS/NZS 4360:1999 is an established standard for the calculation of risk and can be useful in the assessment of risk based criticality. The risk can be calculated by applying a score to the likelihood of an event occurring and another score to the expected consequences associated with each occurrence. These scores are multiplied together to give a risk score which can be used as a measure of criticality. The risk (or criticality) ranking is used to identify the most important assets in the organisation. Depending upon the range of scores available (1...5 each for Likelihood and Consequences in this example) and whether the scale is ascending or descending with increasing importance, the Risk ranking can range from a score of 1 through to 25. In the examples in this document the scales range from 1...5 and increasing scores correspond to increasing importance. Therefore the Risk ranking can range from a low score of 1 through to a high score of 25.

4 DETERMINATION OF CRITICALITY (C)

Each asset has one or more primary functions in a process and can have one or more secondary functions, some of which may require more sophisticated operational or maintenance activities than the primary functions. In some circumstances, the criticality of the secondary functions can be more important than the primary function. Identifying the critical failure mechanisms (strictly speaking failure modes) and developing effective strategies to manage these is the role of the criticality assessment. Table 1 shows a simple assessment sheet used to identify the Criticality of some equipment.

An objective analysis will identify the critical items and ensure resources are not wasted on items that add little value to the process. These include low cost items that have built in redundancy or have little or no effect on production, safety etc. This allows the maintenance team to concentrate on the most important functions (primary & secondary) performed by the asset. It is very important when establishing the assessment project that adequate consideration is given to the practical aspects of the project especially how to ensure uniformity of response and consistency of approach. In this instance uniformity is taken to mean a common result from similar inputs by different teams at a point in time while consistency relates to getting the same response over time regardless of fatigue or other factors.

Very often the assessment methodology will change over time as experience is gained, fatigue sets in and resources become difficult to obtain. Any legitimate change to the methodology should be closely controlled using authorities and approvals and formally documented. Any equipment assessed under the earlier methodology must be reassessed to reflect a significant change in the methodology. Without this ability to review equipment previously assessed the overall criticality assessment would be undermined by the use of different assessment methodologies for different equipment.

The best assessments are made by those with appropriate experience, a systematic approach and using a well designed methodology. In addition, uniformity and consistency between teams can be achieved by use of standardised and agreed look-up tables for Likelihood and Consequences and by use of trained facilitators who can guide the teams in how to interpret the assessment methodology as well as share learning's from other teams. The facilitator also helps to 'drive' the assessment programs selecting assets for assessment, identifying suitable team participants, setting up meetings, chasing up necessary information such as manuals and drawings and ensuring that any follow up work is carried out. Review stages after the initial assessment are often used to authorise changes to the criticality ranking of equipment, provide support to the teams and ensure a high level of assessment is achieved at all times.

Table 1

Example of a very basic Criticality assessment sheet.

				PRODUCTION LOSS				SAFETY				ENVIRONMENT				EQUIPMENT DAMAGE			
EQUIPMENT ID	DESCRIPTION	FUNCTIONAL FAILURE MECHANISMS	MTBF (yrs.)	Likelihood	Consequences	Risk	Note	Likelihood	Consequences	Risk	Notes	Likelihood	Consequences	Risk	Notes	Likelihood	Consequences	Risk	Notes
BN01	Bin 1	Structural collapse				5				0								0	
BN01	Bin 1	Corrosion/Wear																	
BN01	Bin 1	Impact damage																	
BN01	Bin 1	Clamshell failure - including actuators																	
BN02	Bin 2	Structural collapse				5				0								0	
BN02	Bin 2	Corrosion/Wear																	

BN02	Bin 2	Impact damage																	
BN02	Bin 2	Clamshell failure - including actuators																	
BN03	Bin 3	Structural collapse				5				0								0	

It's important when considering multiple criterion that everyone understands that the 'Likelihood' being considered is not that of the failure mechanism occurring but rather the Likelihood of the failure having occurred, affecting the criterion of interest. This is an important distinction because the 'failure rate' of the failure mechanism being considered (i.e. the inverse of the MTBF) is common across all criteria while the Likelihood is criteria specific, at least in common cases found in industry.

For example, if we are considering Safety, Environment, Production loss and Secondary damage as our criterion of interest as shown in Table 1 and the failure mechanism being considered is bearing failure of an electric motor, then the bearing failure rate is constant (or approximately so) for the bearing in its operating context while the impact of the bearing failure on Production loss may be major while the same failure may have no impact on the Environment. Clearly from this and other easily demonstrated examples the Likelihood of interest in Criticality analysis is the Likelihood of the failure impacting on the Criteria rather than the Likelihood of the component failing by the failure mechanism of interest.

The 'Risk' associated with a particular failure mechanism and for a specific criteria is calculated by multiplying the Likelihood (L) of the failure impacting on the criteria and the Consequences (C) of failure for that criteria as shown in equation 1.

$$\text{Risk} = \text{Likelihood} \times \text{Consequences} \qquad (1)$$

Equation 1 represents a very simple example of the Risk equation and in some applications many more variables are included [2]. It is important not to make the assessment equation unnecessarily complex as the addition of each new variable increases the complexity of the assessment and obtaining appropriate data to 'feed' the equation can become very difficult. For example, data on the 'Coupling Coefficients' necessary to relate the different criterion is rarely available with any confidence and it is questionable if criteria coupling is logical or desirable in many instances. Similarly combining the MTBF with each criterion is problematic if we cannot allow any instance of a particular failure mechanism and hence will never (hopefully) have enough data to generate a MTBF.

A more subtle problem can be created by making the Risk equation overly complex in that the data used may be of poor quality but may be assumed to be accurate by those using the assessment output. In addition, as our knowledge of the relationships between variables and especially between criteria is often poor reliable data may not be obtainable at the time of the assessment and may not be constant over time.

Table 2

Example of a Likelihood prompt sheet used in a Semi-Quantitative assessment of the Criticality of equipment.

	PRODUCTION	HEALTH & SAFETY	ENVIRONMENTAL	SECONDARY DAMAGE
5	Loss of production is a common or repeating occurrence. Loss of production will result from every failure incident.	Constant. Happens regularly/repeatedly, is expected to happen.	Constant. 1	Loss of production is practically impossible.	Practically Impossible. Difficult to conceive – has never happened in spite of many years exposure	Practically Impossible. Difficult to conceive – has never happened in spite of many years exposure	Equipment damage is practically impossible.

Prompt sheets are vital to assist those carrying out the assessment to make consistent decisions regarding Likelihood and Consequence. The prompt sheets should be completed and agreed before the assessments get underway and training provided to the assessment team members in how to use and interpret these sheets. The facilitator in particular must be very clear on how to interpret these sheets and how they are to be implemented as many of the teams will have questions as to how to apply the prompt sheets when assessing one failure mechanism or other. Table 2 shows a basic Likelihood prompt sheet used in a Semi-Quantitative assessment of Criticality for a major quarrying company. The level of detail included in the prompt sheets will depend on the level of sophistication required and the intended application for the assessment output. In addition, the table should be designed with the available data in mind as there is no value in asking for input that is not available and may only serve to tempt those doing the assessment to 'guess' outside the range of their expertise in an attempt to complete the assessment.

Table 3 shows a basic Consequence prompt sheet used in a Semi-Quantitative assessment of Criticality for the same quarrying company as for Table 2.

Table 3

Example of a Criticality prompt sheet used in a Semi-Quantitative assessment of the Criticality of equipment.

	PRODUCTION	HEALTH & SAFETY	ENVIRONMENTAL	SECONDARY DAMAGE
5	Site wide shutdown, total loss of production for more than 24 hours. NB: downtime could be up to a week.	Major. Fatality.	Major. Extensive environmental damage, damage to company's reputation, major media interest.	Site wide shutdown, multiple unit failure, financial cost >$1M
4	Site wide shutdown, total loss of production for up to 24 hours, or reduced capacity for more than one day.	Serious. Permanently disabling injury.	Serious. Significant environmental damage, local media interest.	Multiple unit failure or shutdown, financial cost <$0.5M
3	Site wide shutdown, total loss of production for up to 8 hours, or reduced capacity for up to one day.	Moderate. Serious, medically treated injury.	Moderate. Moderate environmental damage, no media interest.	Unit shutdown or damage to equipment, some critical equipment failure, financial cost <$100K
2	Equipment failure or shutdown, equipment off-line for up to 4 hours, or reduced capacity for up to one shift. NB: refers to failure of a single machine that does not result in site wide shutdown.	Minor. First aid injury.	Minor. Minor environmental damage.	Some equipment damage, greater than normal repair time (e.g. 1 week), financial cost <$25K
1	Equipment failure that can be repaired on-line and no impact on production or can be repaired on a scheduled maintenance day.	Insignificant. No injury.	Insignificant. Negligible environmental damage.	Minor equipment damage, normal repair time expected, financial cost <$5K

Table 4

Matrix relating Likelihood and Consequences to form a Risk score.

		CONSEQUENCES				
		5	**4**	**3**	**2**	**1**
LIKELIHOOD		25	20	15	10	5
		20	16	12	8	4
		15	12	9	6	3
		10	8	6	4	2
		5	4	3	2	1

'A' - High Criticality

'B' - Medium Criticality

'C' - Low Criticality

5 THRESHOLDS

The raw scores generated by the Criticality assessment are often 'mapped' onto a simpler scale for convenience and it is this criticality score that is used for day-to-day applications. The threshold at which different maintenance or other responses are applied can be determined by nominating risk levels at which some specific activity is considered justified. This threshold risk level can arise from several combinations of the Likelihood and Consequence components. The Criticality derived from the calculated risk or the mapped score is used in the CMMS which is the score used for planning and scheduling decisions.

Table 4 shows the range of raw scores that result from combinations of Likelihood and Consequence scales with the shaded areas representing the thresholds agreed by the participants. The job of establishing the Thresholds should be left to competent staff having experience of the plant and responsibility for the outcomes if things should go wrong. This is the only way to get a serious assessment as well as acceptance of any decisions based on the criticalities.

Threshold levels can be difficult to determine objectively and can lead to many arguments as to the appropriateness of one level over another. For this reason it is helpful to settle any argument before commencing the assessments if possible however as the assessments are carried out using the raw scores the threshold levels can be recalculated later if necessary.

6 SUPPORT INFORMATION

A significant amount of support information is needed to carry out the assessments and as much as possible should be collected and collated before the assessments get underway. Support information required for the criticality assessment includes the following:

- Cost of downtime.
- Labour cost.
- Production schedule.
- Documentation.
- Drawings.

In many instances the information available is uncertain or variable or both, and the use of agreed, representative values is likely to be the most practical way to manage some of this data. For example, the cost of downtime can vary depending on the product being made, the amount of stock on hand and other factors. Similarly labour cost can vary depending on whether the work is carried out on ordinary time or overtime and whether the staff were on site at the time of the failure or were called in.

The availability of relevant documentation and drawings can impact on the analysis as those performing the analysis need to know the interconnection between plant items as well as whether sections of plant can be isolated for repairs or the whole plant has to be taken off-line to make repairs. It is not safe to assume that local staff knows this information and indeed criticality assessments carried out for a range of clients over several years has highlighted significant knowledge gaps among local staff. In particular, operations staff generally has a poor understanding of the maintenance requirements of equipment especially regarding statutory maintenance tasks or overhaul tasks when the link between these activities and daily operations is not immediately visible. Similarly, maintenance staff often fails to fully appreciate the impact certain faults or deficiencies have on plant operability and often do not give the priority to tasks they deserve because of their perception of the importance of these tasks.

The criticality assessment is often the first time that operations and maintenance staff have sat down in 'cross-functional teams' to discuss a range of equipment and its impact on operations. It is common during these assessment meetings to see a growing awareness of the subtleties of the equipment and how these details and subtleties can impact on others.

7 APPLICATIONS

The criticality assessment will be beneficial to the organisation if it impacts positively on decision making. In deciding how best to respond to various situations the criticality ranking is a useful guide in establishing typical responses for various end-user scenarios. These response guidelines can be used to promote uniformity of response by different people across sites and between shifts and provide guidance to those responsible for making decisions in often stressful situations.

When combined with Priority codes, Criticality codes allow automated work scheduling by the CMMS as well as highlighting jobs by their relative importance. Decisions regarding after hours call-in's, break-in decisions, expediting spares and services etc. should be made on the basis of consideration of the combination of Priority and Criticality associated with each job.

The application of the criticality rankings includes the following:

- Prioritization of routine work lists.
- Protecting the schedule.
- Backlog management.
- Prioritization of emergency repairs.
- Guide on effective call-in policies.
- Optimize spare parts holding.
- Review of documents, spares, maintenance plans, etc.
- Support 'Training Needs Analysis'.
- Shutdowns & Turnarounds.
- Development of budgets.

8 PROJECT PLANNING

The development of project plans needs to take account of the criticality of different equipment in the proposed operating system if maximum advantage is to be gained from the plant at the lowest cost. A clear and detailed understanding of equipment and system criticality is vital for decisions on reliability and the need for redundant equipment to achieve the design system reliability. Unfortunately, criticality information is often scarce at the project planning stage and in the absence of a formal assessment process only anecdotal rankings are possible. This is especially so for green field sites or when installing unfamiliar plant in existing sites. It is important to consider the criticality assessment before any major equipment or layout decisions are locked in if possible as it can be difficult and expensive to make changes to the project once underway – usually attracting 'variation' penalties.

9 PLANT DESIGN & REDUNDANCY

One of the most useful outputs from the criticality assessment is the ability to identify where the 'system reliability' is critical and therefore should be subject to additional reliability studies. For example, when the system reliability requirements are greater than can be achieved by one unit alone it may be necessary to install a stand-by unit to ensure the system reliability targets can be met. In most industrial applications the installation of a single stand-by unit is sufficient to meet the system reliability however, in critical industries such as aviation or nuclear power, triple redundancy may be needed. The decision to install additional capacity to protect system reliability will entail significant cost to the organisation and therefore must be based on sound judgement and auditable assessment procedures.

The positioning of installed equipment must also be considered carefully as the trade-off between the need to minimise the footprint of the plant while providing adequate space between the equipment for access and isolation (e.g. in a fire etc.). The criticality assessment needs to consider access and other issues as well as the likely failure mechanisms as the Life Cycle Cost of the plant can be adversely impacted by poor equipment layout and restricted access. It is not uncommon to see equipment sited such that one machine has to be removed to get access to another. More commonly, pipe and cable runs can significantly restrict crane access around machines and maintenance repair times can be extended by these restriction.

10 OPERATING STRATEGY

The manner in which the equipment is used during normal operations has a significant impact on the reliability that can be achieved from individual machines and therefore 'best practice' operating practices must be enforced to maximise the utilisation of equipment and achieve the 'Maximum Sustainable Capacity' (MSC) of the equipment (see Figure 1). Correctly specified equipment that is well operated and maintained has an 'Inherent Reliability' which sets the maximum reliability that can be reasonably expected from the equipment over time. Poor operating practice, inadequate maintenance, inferior parts and materials and poor application will all lead to a reduced level of reliability which will be reflected in the equipment performance over time. If the equipment 'Inherent Reliability' is inadequate for the system then redundancy will be needed if the system reliability is to be achieved.

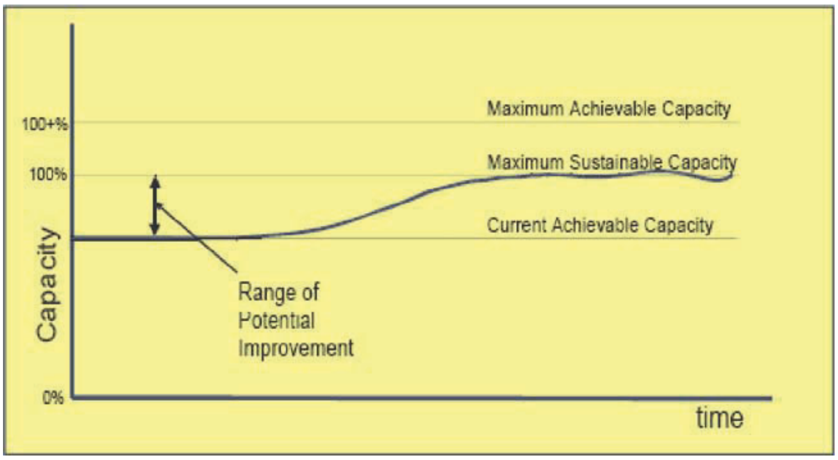

Figure 1 Showing relationship of MSC to MAC

The criticality assessment highlights weaknesses in equipment specification, operation and maintenance which can in turn lead to reduced reliability (compared to the inherent reliability for that item in its operating context).

Stand-by equipment (either active or passive) must be managed in such a way as to maximise the reliability of the system protected by the stand-by unit. One of the most important management considerations therefore is the 'condition' of the stand-by unit at the time it is required. Traditionally, operating practice in many plants has been to operate both the duty and stand-by units for approximately equal times by alternating the units in operation every week or so.

A little thought as to why the stand-by unit was installed should raise concerns about this practice. It is important to appreciate that the stand-by unit was installed to provide an alternative 'function path' should the operating unit fail in service.

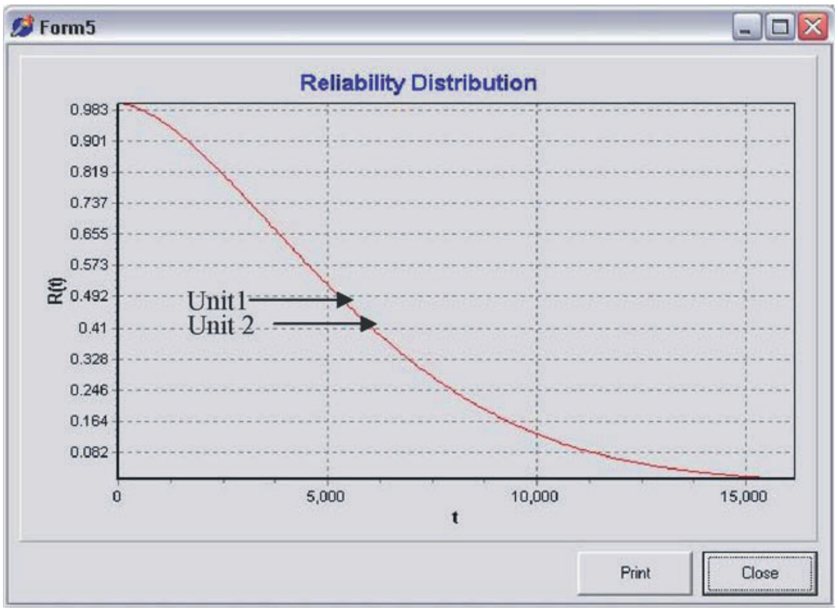

Figure 2 Showing the Duty and Stand-by units in approximately the same condition at the time the Duty unit failed. This is the expected result of operating both units for approximately equal times.

If we accept this logic it is clear that the best way to protect the system is to have the stand-by unit in the best possible condition at all times as this provides the maximum reliability for the unit when it is required (with the possible exception of degrading failure mechanisms unique to the stand-by condition).

Operating both units alternately for approximately equal times will degrade both units which means that when the duty unit fails the stand-by unit is also likely to be in the same condition (see Figure 2).

An alternative operating strategy is to designate one unit as the 'Duty' unit and the second (and possibly subsequent units) as stand-by units. To affect this strategy one unit is used for operations at all times except for when it is in a failed state, at which time the stand-by unit is operated. The stand-by unit under this strategy is in 'good' condition and better able to meet the system requirements while the duty unit is being repaired as indicated by Figure 3.

Repairs to the 'Duty' unit are carried out 'promptly' to return it to service as soon as practicable. It is at this point that the 'Priority' (i.e. how urgently do we need to attend to this task?') becomes important as it is clearly the case that high criticality equipment can have a range of tasks performed at different times some of which require immediate attention while others can be done when an opportunity presents itself. In this way the combination of Priority and Criticality give us an effective tool for decision making and managing a range of assets and systems some of which will be high criticality assets.

In practice, the criticality of the duty unit is usually lower than for the stand-by unit (assuming the 'switch over' time is acceptable) as the system is protected by the stand-by unit when the duty unit fails. This is not the case should the stand-by unit fail as it is only in service when the duty unit is unavailable and therefore failure of the stand-by unit results is system shutdown.

11 MAINTENANCE STRATEGIES

It should be clear from the foregoing discussion that it is the high criticality equipment in particular for which we will be trying to maximise the reliability and therefore every attempt should be made to achieve the 'Inherent reliability' at all times. This will require extensive training for operators and maintenance personnel as well as detailed consideration of the equipment specifications at design time. Poor operating practices can accelerate the degradation of equipment and result in a higher failure rate than necessary. No amount of maintenance will achieve the required reliability if the equipment is inadequate for the application or if it is poorly operated and maintained.

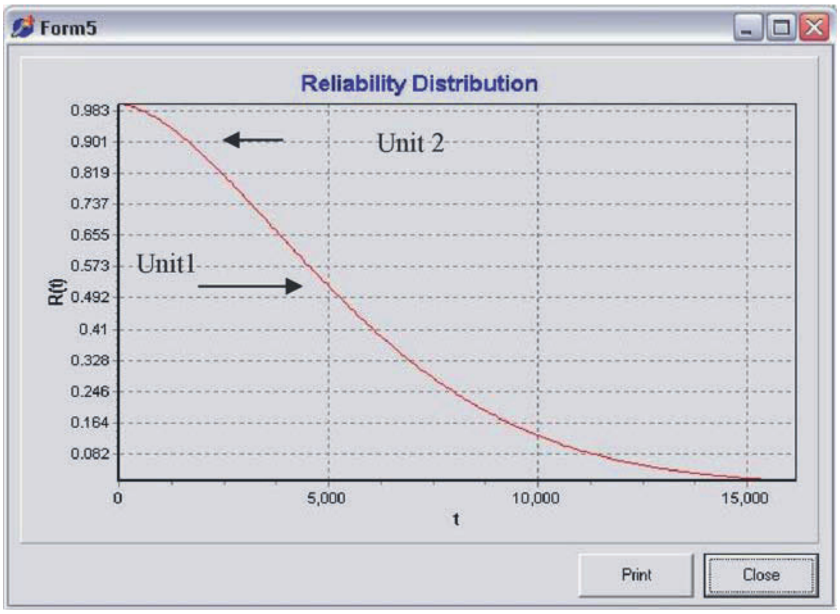

Figure 3 Showing the Duty and Stand-by units at the time of failure with the duty unit reliability reduced and the Stand-by unit still in good condition.

As a general principle every asset should have a maintenance strategy assigned to it, even if that strategy is to 'Run-to-Failure' as in this way at least, the strategy will be the result of deliberate intent rather than as the natural consequence of doing nothing.

Once the maintenance strategies are in place (at whatever level of detail suits the organisation) it is imperative that these strategies are put into effect according to the guidelines of the strategy. If a scheduled replacement is to be carried out at set intervals then these replacements must be done and done on time if the strategy is to be effective. Similarly, if an inspection based strategy is recommended (Condition Monitoring or Non Destructive Inspection or similar) then the scheduled inspections must be done and equally must be acted upon in the event of adverse findings. Failure to implement the agreed strategy will result in an increase in risk of in-service failure and exposure to the resulting consequences of that failure. The criticality assessment documents the consequences of each specific failure considered and as the maintenance strategy is (or should be) based on the findings of the criticality assessment the increased risk associated with failure to implement the maintenance strategy will be high for critical equipment.

It is too often the case that decisions to postpone or delete scheduled maintenance activities are made for narrow, short-term operational reasons (which might be valid in isolation) without a clear understanding or even discussion about the increased risk being assumed by the decision. The criticality ranking allows us to develop agreed policies on how to manage these decisions. Planning and scheduling of day-to-day maintenance activities is one area that regularly highlights this problem.

12 PLANNING AND SCHEDULING

In the words of Peter Drucker "Doing the right thing seems to be more important than doing things right". The relationship between Priority and Criticality can be used as a basis for decision making. By providing planners and supervisors with appropriately developed criticality and priority ratings the company's highest priority tasks will be addressed and addressed first, and decisions on job scheduling and resourcing will be more objective. The Planners can 'push back' against unreasonable requests for 'break-in' work which in the past may have been difficult to resist especially if the request came from a senior staff member. In addition, scheduling and resourcing decisions made by the planners are less likely to be influenced by the pressure applied by those wanting their job addressed first. It is important to establish systems that ensure that it is the company's priorities that are addressed rather than the priority of an individual or area as it is unlikely that addressing the priority of an individual or an area will always be consistent with the organisations priority as a whole.

The aim of Criticality (and Priority) as an Asset management tool is to:

- Use Priority and Criticality to schedule work.
- High Priority/High Criticality work should be done first.
- Provide a communication tool for the organisation.
- Synchronise Operations and Maintenance actions.
- Provide a guide for personnel responsible for managing maintenance work.
- Control set-up, sequencing and completion of maintenance jobs.
- Ensure high priority jobs get done and done first.
- Contribute to the maintenance audit trail from the raising of work through completion and documentation.
- Optimise the utilisation of maintenance labour, both in-house and external.
- Help manage/control costs.
- Help deliver the most cost effective maintenance service possible within the prevailing constraints.
- Help highlight areas where cost effective improvements could be made.
- Minimise downtime of critical equipment.
- Achieve 'Maximum Sustainable Capacity' of critical equipment.
- Assist in achieving zero Lost Time Injuries and zero Medical Treatment Injuries.
- Maximise the usefulness of spare parts held.

Once the maintenance schedule has been generated using a combination of Priority and Criticality it is important to protect the schedule from undesirable last minute changes. The task of protecting the schedule is complicated by the fact that competing aims are in play, namely:

- Resist changes to the schedule to ensure that planned jobs can go ahead as planned.
- Allow changes to the schedule where the change is in the best interests of the organization.

The key to finding the correct balance between these competing aims is to ensure that the jobs on the schedule are those with the highest combination of Priority and Criticality. Any late addition or changes to the schedule will therefore have to have a higher combination of Priority and Criticality than the lowest ranked job on the schedule before it can displace one or more jobs off of the schedule. This approach has the virtue of resisting unjustified changes while allowing those changes that are in the interest of the organization.

Without a clear set of guidelines by which the planners and supervisors can agree what is in the upcoming schedule, the decision will be made by whoever has the loudest voice or the most influence rather than in the best interest of the organization. Failure to provide 'tools' such as criticality rankings and priority rankings for use by operators, maintenance and supervisory staff leads to arguments as to which jobs should be done and in what order and quickly undoes any attempt to introduce planning and scheduling to the organization.

13 BACKLOG MANAGEMENT

Backlog management quickly gets highlighted whenever maintenance and operating practices are being reviewed and is a common point of conflict between the operations and maintenance groups. Much of the conflict arises because of a poor understanding of what jobs should be in the backlog and which shouldn't. It is common practice in many organizations to consider any job known about but not yet completed, to be included in the backlog. This approach results in a large backlog with some jobs remaining there for weeks, months and even years, in some cases only to be deleted later.

A better approach is to define backlog as being known jobs not completed on time or having very little chance of being completed on time. Some of these jobs cannot be completed on time while others may be completed with additional resources such as overtime, contractors etc. All known jobs which are not overdue and which have a high likelihood of being completed on time are not backlog jobs and can be defined as forward log if one wishes. The forward log therefore is made up of known jobs that need no additional efforts over and above normal practice to be completed.

It is sobering to realize that if the 'all jobs' definition of backlog is retained as the organization moves towards planned maintenance then the backlog will approach infinite size as the amount of jobs in the backlog would include all future scheduled jobs up to the end of the chosen planning horizon.

Using the recommended definition of backlog mentioned above (… known jobs not completed on time or having very little chance of being completed on time) a basic set of rules can be agreed by the operations, maintenance and management to ensure that the total job count or man-hours backlog remains low and contains only low criticality jobs. An example of rules agreed by one site is shown here.

- No High Criticality equipment in the backlog.
- Less than 10% of backlog to be Medium Criticality equipment.
- Rest of backlog is Low Criticality equipment.

These or similar rules can be established to avoid conflict and ensure that the important work is done and done first. If the amount of high priority work exceeds the available capacity it is unacceptable to reprioritize some of the work to lower levels just to keep within resource constraints and additional resources must be found or the risk associated with not completing the job on time managed some other way (e.g. may have to shut part of the plant in extreme cases).

14 SPARE PARTS MANAGEMENT

The reason for keeping an inventory of spare parts is to control or avoid the consequences of failure of the equipment. Spare parts have to be managed to maintain the optimum trade-off between the cost of purchasing/holding spare parts and the consequences of NOT having these spares available when required. When the cost of sourcing a spare part off-site only when required (considering all costs especially downtime and lost product) is significantly greater than the cost of holding the spare in-house, the spare is usually held on site. This superficially simple cost-benefit analysis can be very difficult to carry out in practice especially for those parts infrequently or irregularly used or if their impact cannot be easily quantified in dollar terms.

Over time spare parts holdings can increase to unacceptably high levels due to the generally conservative nature of maintenance personnel and the difficulty in removing redundant and overstocked spares from the store. It is common practice in many organisations to charge all spares to the maintenance budget when booked out of the store which in the case of redundant spares is a cost without a benefit to the maintenance manager and therefore the maintenance department is more likely to leave the spare in the store rather than absorb the cost of booking it out if there is no use for that spare.

Over stocked spares are usually easier to handle as the spares holdings can be run down over time and a lower maximum stock level set for future purchases. When control of the store is in the hands of the Administration department rather than the Engineering/Maintenance department there is little incentive for the maintenance staff to pursue spares reduction/optimisation.

Notwithstanding the difficulties mentioned above there are significant opportunities to reduce the spare parts holding of an organisation without increasing the overall risk to the business to unacceptable levels due to not holding adequate spares. ***This is not to say that reducing spares holdings while accepting a controlled increase in risk is not a viable business strategy***. The way to achieve this gain is to ensure that the parts held are biased towards the high risk assets and that sufficient numbers of these spares are available when needed. The optimisation of inventory is achieved by balancing the losses due to stock-outs or delays with the cost of holding the parts until needed. In addition, savings can be achieved by eliminating parts held for low to very low risk assets. In addition to the reduction in stock levels and the cost savings arising from that reduction the spares held are now known to be aligned to the high risk assets on the site and the levels held are known to be optimum or near optimum for the current operating context. The key to achieving the potential savings is in knowing where the asset related risks are in your business and tailoring the spare parts holdings to meet the needs of these high risk assets. The criticality assessment provides a basis for spare parts analysis by identifying ALL the assets in the area of interest, their components, parts and failure modes. In addition, the failure rate, cost of failure, downtime cost, labour cost, repair cost, safety & environmental implications etc. are generated for each failure mode.

15 DOCUMENT MANAGEMENT

Documents such as operating manuals, maintenance manuals, drawings etc. are a vital resource for the organisation and must be the subject of rational management strategies just as hardware or other assets might be. Documents can be difficult and expensive to obtain and in the case of drawings expensive to produce. Over time, drawings in particular will become out of date as changes are made to the plant requiring the relevant documentation to be updated. Frequently the resources are not available for this vital task and over time the documents become outdated and increasingly inaccurate. The safety implications of incorrect or inadequate data in particular means that documents associated with critical equipment must be managed well and kept up to date.

The criticality assessment and ranking can provide a guide for periodic review and updating of documentation associated with high critical assets as a minimum and a document management policy should be developed to manage these documents over time. Electrical drawings and pressure and steam system drawings if incorrect can lead to injury or fatality and only by ensuring that relevant documentation is regularly reviewed in line with its criticality can this danger be minimised.

16 BUDGET MANAGEMENT USING CRITICALITY

Across the board reductions in budgets have become almost routine in many organisations in pursuit of cost reductions and ever better efficiencies. Most common is the percentage based reduction over a previous budget (e.g. 10% reduction in the maintenance budget compared to the previous year) which is often repeated in subsequent years and by subsequent managers. In many instances these budget cuts are well reasoned and can be beneficial if well targeted and applied. In addition, tightening of resources can trigger some degree of innovation amongst staff however it is important not to get carried away with this logic as the extreme of too little resources will inevitable result in some loss of function whether intended or not.

Too often this policy is put into effect by the elimination of previously favoured programs especially those involving inspections or other proactive tasks as they are seen not to provide immediate effects (especially by operations staff) and may have some level of inconvenience associated with their implementation. In the short to medium term therefore the elimination of these programs can create the illusion of reducing costs and streamlining operations. It is however often the case that when these programs are eliminated that their impact cuts across all equipment effected by the program regardless of criticality.

Clearly a better approach would be to reduce activities on low criticality equipment and systems in a targeted way until the cumulative savings achieved in this way meet the required budget reduction. In this way the manager knows that the cuts have been applied to the lowest criticality equipment (or activities) and the likely increased risk traded off against the cost savings, are clearly identifiable and quantifiable.

17 CONCLUSIONS

Criticality and its close relative Priority are significant components in many operations and maintenance functions underpinning decisions regarding equipment operating strategies, maintenance strategy development, planning and scheduling of routine and ad-hoc jobs and backlog management. In addition, the criticality ranking assists in decision making regarding project design, redundancy, spare parts, training, document management etc. and therefore should be carefully developed and kept up to date over time.

If those charged with implementing the operating and maintenance functions of the organisation are not provided with a structured, solidly based criticality ranking of the equipment and systems in their care individuals will attempt to assign criticality (often confusing it with priority) in an attempt to get some deserving job completed. For this reason it is important that the organisation develops a clear indication of the criticality of its assets using a systematic approach which is sufficiently detailed, rigorous, auditable, and reviewable and can be updated over time. Of major importance it the need for widespread acceptance of the criticality by those who will have to work with it and therefore wherever possible, a wide range of people should be allowed to make contributions to the assessment consistent with the need to do so efficiently, effectively and cheaply.

19 DEFINITIONS

Criticality – **Static assessment of equipment or system importance**. Criticality is a fixed value that depends on the role of the equipment in the business and only changes when the operation changes.

Priority – **Dynamic assessment of activity importance**. Priority varies for each task to be carried out on equipment regardless of the criticality of that equipment.

MSC – 'Maximum Sustainable Capacity'. The equipment capacity that can be achieved in a sustained way over an indefinite period of time.

MAC – **'Maximum Achievable Capacity'**. The maximum capacity that can be achieved from the equipment over a short period and usually results in significant degradation of the equipment and therefore is not sustainable.

CAC – 'Current Achievable Capacity'. The currently achieved steady state capacity.

Backlog – 'A list of jobs requiring extraordinary efforts to complete'**.**

Asset – 'Hardware, software, procedure etc. used to provide a valued function'**.**

A REVIEW OF THE MIMOSA OSA-EAI DATABASE FOR CONDITION MONITORING SYSTEMS

Avin Mathew, Liqun Zhang, Sheng Zhang, and Lin Ma

Cooperative Research Centre for Integrated Engineering Asset Management, Queensland University of Technology, George Street, Brisbane, Queensland 4001, Australia.

Abstract: Condition monitoring systems are prevalent in industries that contain critical assets. Their use allows the detection of potential failures at an early stage in order to minimise downtime and maintenance costs of a system. Many condition monitoring systems are commercially available, however these systems are limited in their support of diagnostic and prognostic models developed by external parties. An attempt to develop an extensible condition monitoring software lead to the creation of an ISO 13374/OSA-CBM based system named BUDS, which focuses on vibration condition monitoring. Research into condition monitoring data management strategies led our team to implement a database to support the data-driven application. A database based on the MIMOSA OSA-EAI database specification was used to store asset and sensor location, measurement event, raw sensor and processed signal data. This paper investigates the use of the MIMOSA OSA-EAI database for condition monitoring systems, and presents several issues encountered during the development process.

Key Words: Condition Monitoring, Critical Assets, Downtime, Diagnostic, Prognostic, BUDS, MIMOSA, Sensor, Development.

1 INTRODUCTION

Condition monitoring systems have become more popular in recent years due to lower financial barriers to entry. Sensor technology is constantly improving in detecting more types of conditions and analysis models are becoming more mature. In an effort to expand the limits of traditional commercial condition monitoring systems, we developed a condition monitoring system, BUDS, which supports advanced diagnosis and prognosis models not available in commercial systems. Based on the Open Systems Architecture for Condition Based Maintenance (OSA-CBM), BUDS comprises of a single component of a larger asset management decision support system that also implements reliability and decision making modelling.

A major component of condition monitoring systems is data management. Although vast amounts of measurement and analysis data flow through condition monitoring systems, data management is not usually given high priority due to its less visible nature from a user perspective. Using a standards-based approach, BUDS implements a MIMOSA (Machinery Information Management Open Systems Alliance) OSA-EAI (Open System Architecture for Enterprise Application Integration) derived database. The MIMOSA OSA-EAI is a standard for data exchange of engineering asset management data. A detailed summary of the OSA-EAI can be found in Section 3.

In this paper we highlight the issues we faced in using the database specification from the MIMOSA OSA-EAI for BUDS. The issues presented are from a development viewpoint, and aim to assist the development of future condition monitoring systems based on the OSA-EAI.

2 BUDS

BUDS is based on the ISO 13374/OSA-CBM model of development. ISO 13374 is a two part standard that publishes general guidelines on the architecture of condition monitoring systems. It presents a modular approach to system design in order to allow for interoperability between various condition monitoring components and external systems. The standard was largely derived from the Open Systems Architecture for Condition Based Maintenance (OSA-CBM). Both standards comprise of a six block structure involving data acquisition, data manipulation, state detection, health assessment, prognostic assessment, and advisory generation. While the ISO 13374 standard provides guidelines on how to develop a condition monitoring system, the OSA-CBM provides the addition of tools for implementation.

There have been several implementations of the OSA-CBM. A vehicle health management system based on the OSA-CBM was developed by Boeing [2, 3]. Another OSA-CBM system was used in the diagnostic and prognostics for avionics health management [4]. Another implementation was used to monitor an electro-hydraulic test rig [5]. A team at Penn State University used the OSA-CBM for a generic monitoring application [6]. The data management strategies employed by each of the aforementioned projects are unclear.

BUDS is being developed as part of a larger asset management software suite that also supports reliability and decision making models. The condition monitoring component is essentially a module within the larger asset management system. Due to the extensible architecture of the system, different signal processing models can be exchanged depending on the monitoring situation. An integrated database supports the data requirements of the system. The MIMOSA OSA-EAI was selected as a design for the database for several reasons:

- The OSA-CBM is based on sections of the OSA-EAI specification, providing for easier integration;
- The specification has been designed and validated by asset management experts;
- Following a standard specification will provide greater interoperability with other systems.

The merits between a database and a file system for condition monitoring systems have been debated before [7]. A database is not a panacea, and the justification of the data management strategy employed must be based on the functionality of the condition monitoring system. The data used by BUDS is largely relational. Asset registry information, such as asset types and model numbers, need to be linked to current and historical locations of the asset, measurement points on the asset, sensors installed at the measurement points, readings taken from sensors, and calculations performed on those readings. The housing of such relational information is best performed through use of a relational database. Apart from the numerous advantages in storing information in a database, additional advantages can come through possibilities for interoperability of programs [8]. As database programming interfaces are open and well documented, a potential central data repository can be created more easily [9]. Given the provision that the programs follow the same database specification – in this case, the MIMOSA CRIS – multiple programs can access information within the same database. This leads to a reduction of redundant data and may streamline data management processes within an organisation.

3 MIMOSA OSA-EAI

With the numerous asset management systems offered by different vendors, the processes of integration can be problematical as many systems have their own unique data exchange interfaces. This leaves businesses facing a dilemma, as different integration techniques bring their own advantages and disadvantages. Purchasing systems from a single vendor leads towards system compatibility, however suppliers may not provide a total asset management solution, and the reliance on one vendor can prove risky. Businesses may purchase a custom bridge that integrates different systems, which may prove more cost effective than internally building one, but provides less customisation ability and requires updates for new system versions. Another option is to use an industry-standard bridge, which allows businesses to mix different systems with reduced integration costs. However, there may be performance loss compared to a custom solution and vendors must be willing to support the standard.

The absence of a standard for asset management data exchange was a driving factor in the formation of MIMOSA and the subsequent development of the OSA-EAI. The OSA-EAI provides open data exchange standards in several key asset management areas: asset register management; work management; diagnostic and prognostic assessment; vibration and sound data; oil, fluid and gas data; thermographic data; and reliability information. These seven areas are defined by a relational model named Common Relational Information Schema (CRIS). The CRIS defines asset management entities, their attributes and associated types, and also relationships between entities.

As seen in Figure 1, a reference data library sits on top of the CRIS. The library contains reference data compiled by MIMOSA which can be stored by the CRIS and are intended to facilitate communication between MIMOSA-compliant systems. The reference data primarily consist of ‘type’ information such as asset, segment, and event types. However, the largest component of the reference library is manufacturer details.

The OSA-EAI package contains SQL (Structured Query Language) scripts for creating a database based on the CRIS and inserting data from the reference library. A program does not need to implement the database component to be MIMOSA-compliant – only the XML schema must be implemented. However, a MIMOSA database implementation makes future development significantly easier in order to comply with the MIMOSA standards.

One key advantage of using the OSA-EAI is through software reuse. Software reuse is a technique that aims to develop components that can be implemented in multiple systems with slight or no modification. Reusable components increase the likelihood that prior testing has been undertaken, and that common bugs have been detected. Another significant advantage in reuse is the potential reduction in implementation time for not only the development stage, but also those of design and testing. As MIMOSA have undertaken a comprehensive analysis of the data elements involved in engineering systems, harnessing their effort avoids duplicating existing research.

Another key advantage of using the OSA-EAI is that of data interoperability. Our experience has found many condition monitoring systems storing information in proprietary file formats; making it difficult to use the data with external programs, such as analysis tools. Unless the software supports an export facility, organisations are effectively locked into particular tools. An open specification for data management would assist in interoperability between engineering asset management systems.

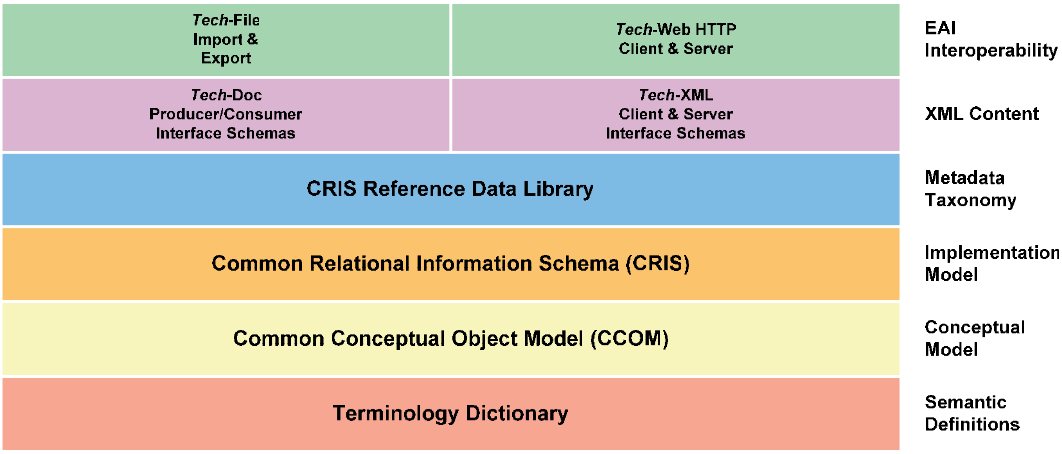

Figure 1: MIMOSA OSA-EAI layers

The suitability of the OSA-EAI for condition monitoring programs stems from its heritage as a standard for vibration data exchange. The current version of the OSA-EAI is markedly different from its predecessors, and has been expanded to support sound monitoring; fluid, air and solid sampling; and thermographic and image monitoring.

Documented implementations of the OSA-EAI specification are rare. There are currently two systems that are certified as meeting the MIMOSA standard, Emerson Process Management RBMware 4.2, and Rockwell Emonitor Odyssey 1.2. Both of these programs implement the OSA-EAI version 1.0. Various other providers including DMSI, Ivara Corporation, Ludeca, SKF, and Vibration Consultants have some compatibility with the OSA-EAI, but are not compliant. Although most projects that use the OSA-EAI inevitably implement the XML communications layers and forego the database element, one exception is a condition monitoring system developed by a Chinese university [1]. The system used an OSA-EAI database, however, the scope of the usage was very narrow. Only three tables were used in their implementation: those of `segment`, `site`, and the `unit_type` tables.

4 MIMOSA OSA-EAI DATABASE ISSUES

During the development of BUDS, several problems were identified in using the OSA-EAI database. Most issues could be resolved with changes to the data model, and these are outlined in Section 4.1. However certain issues were too large to be resolved, such as poor documentation, and these are detailed in Section 4.2.

4.1 Resolvable Issues

Resolvable issues are those where direct management action could be undertaken by our team. These included the customisation of the data model through additions, deletions, and renaming; the modification of reference data; and dealing with design ambiguities.

4.1.1 Data model simplification

The CRIS tries to provide a generic relational model for a wide spectrum of asset management firms and systems. Because of the abstract model on which it is based, many supported features are not needed in a pure condition monitoring system.

Naturally, work management, ordered list, network and function tables will not be used. To tailor the CRIS to meet our needs, a two stage simplification process was conducted.

The first simplification step was to identify unwanted tables in the database. This involved firstly identifying the functions of the system and data required for the database, the results of which filtered the remaining tables. To assist with this process, a tool was developed that would determine the minimum set of tables required to support a particular input table. By examining the non-null foreign key relations, a depth first search is performed to determine the required tables. For example, Figure 2 shows the minimum number of tables required to support a measurement event record. The rounded boxes represent the tables, while the square boxes on the arrows represent the non-null foreign keys.

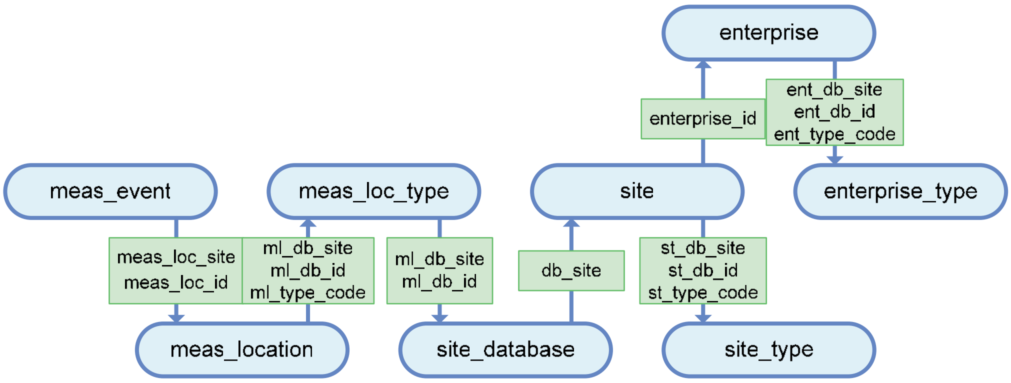

Figure 2. Minimum set of entities to support `meas_event`

The second simplification step was to identify unwanted columns in the data model. The CRIS employs a complex tracking system that distinguishes which database information is derived through the `site_database` table. This leads to many situations where three fields are required to represent a foreign key code. For example, as seen in List 1, the asset table requires three fields (`as_db_site`, `as_db_id`, and `as_type_code`) to define an asset type, three fields (`mf_db_site`, `mf_db_id`, and `mf_duns_code`) to define the manufacturer's DUNS code, and three fields (`asr_db_site`, `asr_db_id`, and `asr_type_code`) to define the asset readiness state.

`<table name="asset">`	
`<column name="asset_id" type="unsignedInt"/>`	
`<column name="as_db_site" type="string"/>`	
`<column name="as_db_id" type="unsignedInt"/>`	Asset type
`<column name="as_type_code" type="unsignedInt"/>`	
`<column name="mf_db_site" type="string" minOccurs="0"/>`	
`<column name="mf_db_id" type="unsignedInt" minOccurs="0"/>`	Manufacturer's DUNS code
`<column name="mf_duns_code" type="unsignedInt" minOccurs="0"/>`	
`<column name="asr_db_site" type="string" minOccurs="0"/>`	
`<column name="asr_db_id" type="unsignedInt" minOccurs="0"/>`	Asset readiness state
`<column name="asr_type_code" type="unsignedInt" minOccurs="0"/>`	
.	
.	
.	

List 1. MIMOSA OSA-EAI `asset` table definition

BUDS is designed to run on a single database architecture. Any intersection of data from multiple BUDS instances should be equivalent, and hence, the advantages of supporting `site_database` information is negated. Simplification involved converting such triple column keys into single columns by removing the `db_site` and `db_id` columns. Consequently, the primary keys in the linked tables were reduced from three to one column. This reduction dramatically reduced the system development overhead for managing tables.

4.1.2 Data model additions

While the OSA-EAI provides a comprehensive data model, several additions were required during the development of the condition monitoring system. These additions were made to support particular functions in the condition monitoring system.

The condition monitoring system provides an automated expert system for the diagnosis of faults. It stores FMEA information such as symptoms, causes, and remedies. To provide tight integration between the additions and the standard MIMOSA data model, symptoms are linked to asset types. To assist with automated analysis, symptoms are recorded with specific types, such as physical symptoms, vibration time domain symptoms, or vibration frequency domain symptoms.

To assist in the administration of asset registry information, another table was added that related numeric data to asset types. As mentioned in Section 5.3, the numeric data tables provided a flexible structure to add numeric data to other tables. A filter in the condition monitoring system limits the displayed numeric data types to only those relevant for a particular asset type. For example, rated speed is suitable characteristic for a motor asset type, however, it is nonsensical for a power transformer asset type.

Because analysis is rarely undertaken on a raw signal, the data must first be processed to calculate relevant features. These features can then be used in diagnosis or prognosis analysis. One of the functions in BUDS is to process raw signals and extract time domain (e.g. kurtosis) and frequency domain (e.g. band frequencies) features. There are two motivating factors on storing these features. Firstly, the features are computationally expensive to calculate, so retrieving a previously stored value would increase system performance. Secondly, the features can act as a form of data compression (albeit lossy) as once the features are calculated from the signal, the original raw signal can be deleted.

Figure 3 illustrates the three typical data structure models used in database design. Methods 1 and 2 hard code features, while Method 3, as followed by MIMOSA, provides extensibility at the cost of performance. As opposed to the flexible structure that MIMOSA generally adopts, BUDS stores the features using Method 1. With vibration data, 20 features are calculated from a time waveform record. Storing these features using Method 3, means 20 rows per time waveform record, as opposed to one row using Method 1. For multi-asset/multi-site monitoring, our calculations showed that the feature table would be receiving a million rows within months of operation, hence the selection of Method 1. Method 2 was not selected as it became unwieldy when dealing with a large number of features.

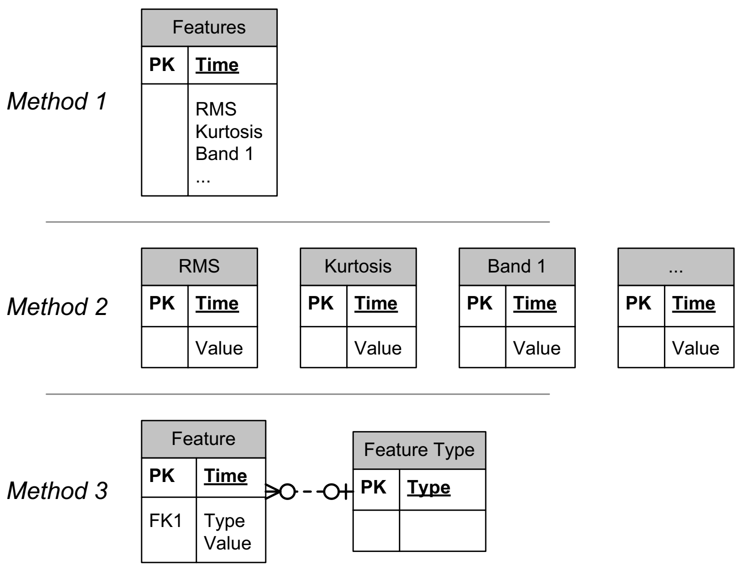

Figure 3: Foreign key ambiguity

4.1.3 Miscellaneous Issues

Hierarchies in type tables — Some type tables in the OSA-EAI support hierarchical data. For example, the `asset_type` table has an associated `asset_type_child` table which records parent and children pairs between different asset types. However, an issue of data redundancy occurs in the reference data supplied by MIMOSA. The duplication of the hierarchical structure can be seen in Listing 2. The `asset_type_child` table stores numerical parent and child identifiers, while the `name` column of `asset_type` stores the hierarchy by separating items by commas.

Table 1 Hierarchical `asset_type` and `asset_type_child` reference data

as_type_code	name
374	Bearing
367	Bearing, Journal
363	Bearing, Journal, Elliptical
365	Bearing, Journal, Plain
366	Bearing, Journal, Pressure Dam

as_type_code	child_as_type_code
374	367
367	363
367	365
367	366

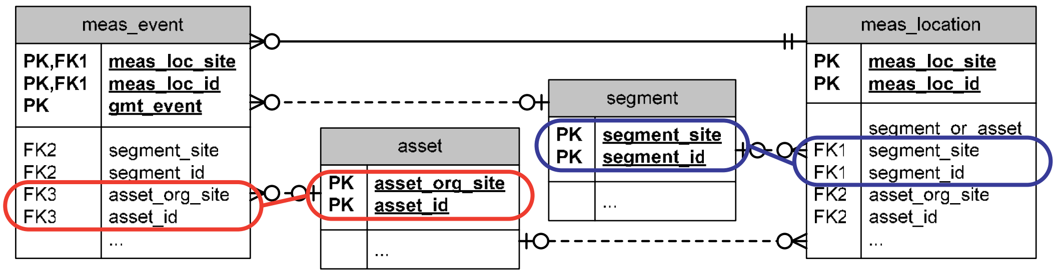

Figure 4: Foreign key ambiguity

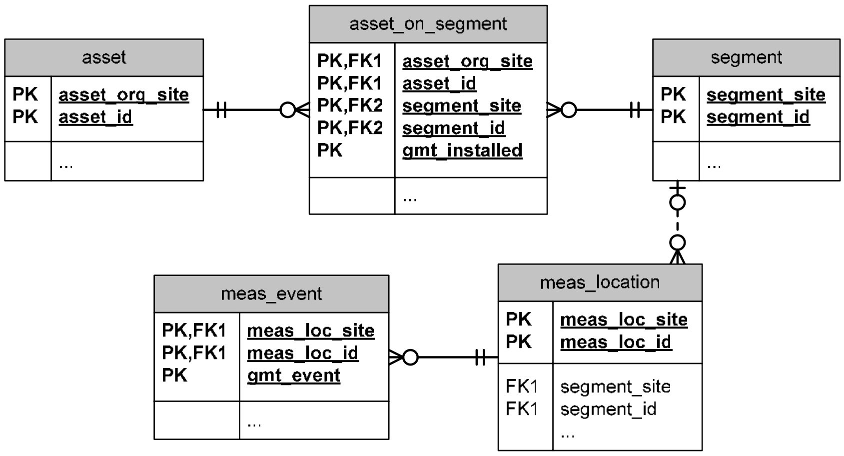

Figure 5: Normalised data model

From both a system development and data modelling perspective, the MIMOSA implementation is not optimal. The commas in `name` make the development of hierarchical views in the condition monitoring system more difficult, because content and presentation are combined. The `name` column cannot be used directly, as it presents a confusing display for users. It must be first processed to remove the parent component – that is, only the element after the last common remains. Normalised data models should not contain duplication of information and the situation should be remedied by removing the parent hierarchy in the `name` column of the `asset_type` table.

Country specific columns — The `manufacturer` table contains two columns `us_ph_number` and `us_fax_number` which store United States phone and fax numbers respectively. Distinguishing between US and international numbers is an unusual inconsistency in the generic nature of the OSA-EAI. While manufacturer contact information is not critical for condition monitoring, the offending columns were removed.

Table and column names — The naming of certain tables and columns is somewhat inconsistent. Abbreviations of a term are used, while in other instances, the full term is used, and in some cases, different abbreviations area used. For example, `meas_event` is abbreviated to `mevent` in the `mevent_chr_data` table, presumably to reduce the length of the name. Consistent naming makes system development easier and hence we adopted a naming scheme that only used one version (either the full name or abbreviated) for table and column names. Thus the `mevent_chr_data` was renamed to `meas_event_chr_data`.

Foreign key ambiguity/Denormalisation — One issue that arises with the `meas_event` and `meas_location` tables is relating measurement events and locations to assets and segments. As Figure 4 shows, both the `meas_event` and `meas_location` tables can be associated with either the `asset` or `segment` tables. The OSA-EAI only provides the constraint on `meas_location` that either the asset or segment but not both should be populated which stands to reason that `meas_event` must undergo the same constraint, lest the data model be denormalised. As measurement locations and segments are very similar conceptual entities, the approach that we viewed as most logical is outlined by the coloured boxes in Figure 4 (`meas_event` with `asset`, and `meas_location` with `segment`).

However, the discussion becomes moot when the `asset_on_segment` table is considered. This table details asset utilisation on a segment, and as it also joins the `asset` and `segment` tables, it indicates a denormalised data model. Normalisation is a goal for proper database design, and a normalised model which implements the decision about joining `meas_location` and `segment` is presented in Figure 5. From the figure, the reasoning behind the inclusion of the extra columns becomes apparent. To find a particular asset on which a measurement event was taken now requires a query that contains four joins, while previously it required just one. While the latter approach is more correct from a data modelling perspective, our database implementation used the former, since the issues associated with a denormalised model would be insignificant.

Linked data limits — To provide flexibility for cross-domain implementations, many core tables are linked to data tables which can be used to dynamically add virtual columns to the core tables. Attributes can either consist of character data, or numeric data. The data tables typically consist of the attribute type, a value for the attribute, and also the unit type of the attribute. While such a model provides flexibility, it results in a slightly longer development time, as instead of hard coding particular columns, a generic approach is required to handle 'virtual' columns.

The OSA-EAI has such data tables for the `asset`, `segment`, and `meas_event` tables. The OSA-EAI places limits on the number of data that can be attached to records in the former tables. Table 2 indicates the restrictions placed on the asset, segment, and measurement event tables. For example, an asset cannot be linked to multiple voltage characteristics and measurement events cannot be linked to two pressure values whose units are Pascals. As there seems to be no justification for this restriction, to overcome this problem, an extra `ordering_seq` (named to follow the OSA-EAI conventions) primary key field that acts as a counter was added to the linking tables (`as_chr_data`, `as_num_data`, `sg_chr_data`, `sg_num_data`, `mevent_blob_data`, `mevent_chr_data`, and `mevent_num_data`).

Table 2 Restrictions on linked data tables

	Type of linked data	Restriction
`asset` / `segment`	Numeric / Character	Unique numeric / character type
	Binary	None
`meas_event`	Numeric / Character	Unique unit type
	Binary	Unique binary type

4.2 Integral Issues

This section details those issues where it was impractical or valueless to modify the specification due to the sheer size or integral nature of the issue. They are included in this discussion to highlight certain problems that may affect future implementations of the OSA-EAI. Two issues are discussed: that of insufficient documentation on the specification, and the database design choices that must followed to retain a consistent data model.

4.2.1 Documentation

The largest issue our team had with the MIMOSA OSA-EAI was the lack of comprehensive documentation for the CRIS. The documentation for the CRIS is currently supplied through a single Microsoft Word document. The format of the documentation is such that each table is allocated its own page containing the name of the table, a description of the table, columns of the table, a description of the column, and the type of the column. Primary key and foreign key information are also included. For main tables, such as site, asset, and measurement event, descriptions adequately describe the function of the table. However, there remain many smaller tables where descriptions are not evident or even non-existent.

Many descriptions for attributes are also non-existent or purposefully omitted. For example, the critical `meas_event` table has no descriptions for ID, site and code columns. While column codes can eventually be recognised through repetitive familiarisation, even simple descriptions would assist in learning for beginners.

Apart from providing more comprehensive textual descriptions for entities and attributes, a suggestion for the CRIS is to restructure the documentation to improve navigation. It is currently difficult to traverse through the Microsoft Word document, particularly with the current formatting where primary and foreign key information is kept separate. Instead of a separate section for keys, columns related to primary and foreign keys should be marked as such in place, and have links to associated table pages. Although the Portable Document Format is a better option than the Microsoft Word format in terms of document portability standards, moving to a more linked structure, similar to web-based documentation, would enhance learning and ease of use.

Additional documentation to select problems can be found on message forums available through Yahoo! Groups. It forms an interactive knowledge base by providing a method of contacting developers and other MIMOSA users for help, where all messages and replies are publicly accessible.

4.2.2 Surrogate keys

From a data modelling perspective, parts of the OSA-EAI is built on surrogate keys rather than natural keys. That is, the primary key for an entity is a numeric value that has no real-world relation to the record it identifies. The advantage of surrogate keys is that changes to primary key values can be performed easier, as the surrogate key remains unchanged, while the data attached to it is changed. Such keys may also improve the performance over situations where the primary key may consist of a multi-column natural key. The disadvantage is that queries generally require more joins, although joins are easier with single rather than multi-columned keys. From a condition monitoring system development point of view, apart from the increased complexity of queries, management of data is made easier using a surrogate key approach.

4.2.3 Excessive normalisation

One of the criticisms voiced by industry about the OSA-EAI is the excessive normalisation that takes place in the data model. While normalised models are recommended for transactional database systems for recording and managing data, they are not as suitable for analysis systems. As condition monitoring systems serve both as a recording and analysis tool, a compromise must be made. As discussed prior, the OSA-EAI attempts to produce a generic model for asset management data, and consequently, complexity is increased. Linking tables for adding characteristic data to entities are included to provide extensibility, but the downside is the increased number of joins for SQL queries. In addition, the OSA-EAI is laden with nearly every attribute being referenced as a foreign key to another table. In the administration of table keys, the surrogate key approach keeps key naming consistent.

5 CONCLUSION

The MIMOSA OSA-EAI is a thorough and well constructed specification for asset management data. The CRIS provides a usable database implementation which can be populated by a comprehensive reference data set. With a few adjustments, the OSA-EAI is suitable for a condition monitoring database, covering the major aspects of condition monitoring, including asset and sensor registry management, measurement event management, and storing raw and processed signals. The primary issues encountered for condition monitoring system development were the lack of documentation and the complexity of the data model. Peculiarities also arose in the reference data and certain sections of the data model. To support advanced trending and diagnostic functionality, additional tables were required. Although the MIMOSA OSA-EAI continues to be a work in progress, it provides a bright future for engineering asset management systems.

Abstract: Condition prognosis is an essential element for predicting the health of physical assets. Prognosis enables a projection of asset condition progression from the past and current into the future, thus providing a significant input into the asset related decision making process. Of different prognosis technologies, signal or feature based methods make predictive decisions according to progressive condition information and have been one of the focuses of recent research in the area. The success of these methods largely relies on effective feature extraction and feature manipulation. This paper proposes the use of eigenvector analysis for machinery condition trending and prognosis which incorporates multiple variables. An eigenvector analysis method, Principal Component Analysis (PCA), is selected to handle the features extracted from both time and frequency domains of vibration signals. The derived composite features facilitate the visualization of condition progression from different dimensional views, hence assisting condition prognosis. Control limits of the composite features are also designed for triggering condition alarms. The proposed method is verified using data from pump condition monitoring during flow fluctuations.

Key Words: Condition prognosis, Physical assets, Condition progression, Predictive decisions, Eigenvector, PCA, Pump, Flow.

1 INTRODUCTION

The research focus in condition monitoring has been shifting from fault diagnosis to prognosis in recent years. As fault diagnosis undertakes the investigation of past asset condition, prognosis targets the prediction of future asset condition. The ISO defines prognosis as "an estimation of time to failure and risk for one or more existing or future failure modes" [1]. Such an estimation derived by prognosis techniques is of significance for asset management. It assists in a range of asset related decision making, such as determining maintenance schedules, asset renewal, replacement, and disposal. Pursuing a capability in asset health prognosis has become an important agenda for many enterprises.

Conducting successful prognosis, however, is more difficult than conducting fault diagnosis. Prognosis generally requires a sound understanding of asset condition history. A much broader range of asset health related data, especially those related to the failures, shall be collected. The asset health progression can then be possibly extracted from the congregated data, which has proved to be very challengeable. Technically, prognosis can then be carried out by using predictive techniques to project this condition progression into future [2]. As a result of such challenges, prognosis is "normally intuitive and based on experiences", and relies highly on fault diagnosis, and "it is usually effective for faults and failure modes with known, age-related, or progressive deterioration characteristics, the simplest of which is linear. Prognostics are most difficult for random failure modes"[1].

A number of prognosis models have been developed in the past. These models can be roughly allocated into four categories, physical models, signal based models, reliability based models, and hybrid models [3][4]. The general ideas behind these models are somehow related - they more or less apply regression or extrapolation techniques to project history and current conditions into the future.

The literature contains several publications in the area particularly those that use signal based models for condition prognosis. Mba [5] conducted studies in the prognosis of gears and bearings. Pitting and spot defects were selected as the failure modes respectively. Vibration and Acoustic Emission (AE) were used as the basic technology for developing the prognosis algorithm. Wang etc. [6] studied the prognosis for gears with wear, chipped and crack failures using a Neuro-fuzzy method. Jantunen [7] studied the prognosis for bearings using accelerated experiments. The polynomial regression technique was applied to derive condition prediction. Byington and Roemer et al. [3][8] studied the gas turbine fuel nozzle. Clogging in the nozzle was selected as a failure mode.

Some work has been reported on physical model based prognosis techniques. Both Li [9] and Byington etc. [3] proposed a physical model for the simulation of crack growth in gears. Reliability based models are reasonably well advanced for prediction in maintenance. For prognosis, some efforts have been expended in the manipulation of condition data and reliability information to derive more accurate asset health prediction. Two models have been reported. One is the Proportional Hazard Model (PHM) which incorporates asset environment variables into the reliability model. This model has been comprehensively studied by Jardine, Vlok etc [10][11][12]. The Proportional Covariates Model (PCM) which combines response variables of asset condition into the reliability model is an additional approach. This model was proposed by Sun et al [13]. Apart from these models, Hess et al [4] suggested using hybrid models which combine different prognosis methods to reach a potentially more effective solution for prognosis.

Most of the works on prognosis have been conducted at a component level. Performing prognosis at a system level is relatively more complex. Some traditional methods, such as Reliability Block Diagrams (RBD) and Fault Tree Analysis (FTA), enable reliability analysis at the system levels and may be expanded for prognosis. Also, hybrid models can be investigated for system level reliability analysis and can eventually achieve a prognosis estimation.

This paper presents a signal based model for machinery condition prognosis using vibration signals from a pump during a flow fluctuation process. The vibration signal contains rich information from both time and frequency domains. This provides one with the opportunity for feature extraction using multivariate analysis. An eigenvector analysis method, Principal Component Analysis (PCA), has been used in the past [14][15]. It will be applied to trace the flow fluctuation process indicated by vibration features. This method is suitable to depict any condition progression regardless the failure mode.

The rest of the paper is organized as follows. In Section 2, the eigenvector analysis and PCA theory are briefly described. Section 3 presents multiple features extracted from vibration signals. In Section 4, the experiment on pump condition monitoring is described and vibration data is used to validate the proposed method. The results of the analysis are also presented in this section. The conclusion is drawn in Section 5.

2 EIGENVECTOR ANALYSIS AND PCA

Among all multivariate analysis methods, eigenvector analysis has attracted substantial interest. Of which the PCA is widely accepted for feature selection or feature compression. PCA transforms data from a variable space to a principal component space. The principal components containing large amount of data variability can be selected for condition monitoring purpose.

PCA approximates a general matrix by a sum of a few matrices ranking one. Let A be a real observation matrix of size $m \times n$ (n variables and each variable with m samples), then the economic-sized singular value decomposition on A is [16]

$$A = U \Sigma V^T \tag{1}$$

A can be rewritten as the sum of orthogonal component matrices

$$A = \sum_{i=1}^{p} E_i \text{, with } p = \min(m,n) \text{, } E_i = \sigma_i u_i v_i^T \tag{2}$$

where, σ_i are the singular values of E_i, μ_i and v_i are nonzero singular vectors from the ith column of U, and the transpose of the ith column of V, respectively. The norm of each component matrix E_i is its corresponding singular value σ_i. Therefore the contribution that E_i makes to reproduce A is determined by the size of σ_i. A can then be approximated by E which is the sum of r component matrices.

$$E = \sum_{i=1}^{r} E_i \tag{3}$$

The resulting E is called the loading matrix which has the size of $r \times p$ and rank of r. The importance of ith component, I_i, can be determined by comparing the ratio of its singular value and the sum of singular values.

$$I_i = \frac{\sigma_i}{\sum_{i=1}^{r} \sigma_i} \tag{4}$$

The correlation matrix is commonly used for A in principal component analysis. For example, given an observation matrix being standardized by subtracting the means of the columns and dividing by their standard deviations, A is the cross-product of the standardized observation matrix.

The transformation matrix E, which is derived from the observation matrix A, describes the mapping between the variable space and the principal component space. Hence, given X as a signal matrix with size of $p \times n$ (each row as a variable, and each column as a sample), the transformed matrix Z is

$$Z = EX \tag{5}$$

where, Z is of size $r \times n$, with each row a Principal Component (PC), and each column a sample.

The resulting principal components can then be selected as condition indicators. The top principal components are commonly selected since they contain a large portion of variations in the raw variables. However, there are no firm guidelines about how many principal components needs to be retained in order to produce an effective monitoring procedure. Since the principal components are the linear transformation of raw variables, they do not express physical explanation directly. This renders a problem for setting up alarm limits for the components. The alarm limit can be generally derived from the PCA analysis of accumulated observation data. The major components can also be plotted vs. each other. The resultant plot or trajectory indicates how the condition is progressive in the principal component space. The limit for the trajectory can be designed using multivariable control chart methods, where the principal components are fitted by a multivariate empirical reference distribution to establish a control region for the condition process [17].

3 MULTIPLE FEATURES FOR CONDITION MONITORING

Various data are generally available in condition monitoring, such as vibration, oil debris, thermograph, temperature, and pressure. Vibration is probably the most widely used signal in machine health assessment. Multivariate analysis e.g. PCA can be applied to the condition monitoring data or the vibration signal only for feature extraction and health assessment.

Observed vibration signals are the result of excitation from relevant machine components. Different features can be extracted from vibration signals to identify the machine health condition. These features are usually derived from either the time or frequency domains. Joint time-frequency domain signals, such as those developed using wavelet techniques, can be considered as time waveforms confined in specific frequency bands. A list of vibration features has been proposed and studied in [18], which includes P2P, RMS, Kurtosis, Crest factor, <1RPM, 1RPM, 2RPM, sRPM, >10RPM, OA, Band1, Band2, Band3, Band4, Band5 and Band6.

The first four features are vibration measurements from the time domain. They are largely the result of time waveform moments and their derivations by using statistical analysis. RMS, the first order of signal moments, reflects the signal energy and is an important indictor of vibration severity. Kurtosis, the fourth order of signal moments, reflects the peak characteristic. Crest factor is defined as the ratio between the peak value and RMS. Both kurtosis and crest factor are effective in detecting periodic impacts caused by the faults such as, rolling element bearing wear, gear tooth wear and pump cavitations, for which the spectrum analysis may fail to differentiate in the presence of random noise.

The rest features in the list are from the frequency domain. The feature frequencies, i.e. 1RPM, 2RPM and sRPM (the sum of harmonic and half harmonic between [0-10] RPM), are rotational speed dependent and can indicate the symptom of a specific component or fault. OA (Overall Spectrum) is an overall measurement of the signal in the frequency domain. The six band features are the measurement of signal components in specific frequency ranges. A reference definition of the band features is given by the Technical Associates of Charlotte [19]. Each of the six bands contains specific information sources. Band4, for instance, roughly covers the fundamental bearing defect frequency. While Band5 and Band6 cover the low and high harmonics of bearing frequencies, respectively. Note that the characteristic frequencies of specific parts, such as rolling element bearings, gearboxes, vanes and impellers, are also important condition indicators. For example, the characteristic frequencies of rolling element bearings are effective in identifying failures cased by faulty inner race, outer race, ball or cage. These features are generally machine structure and rotating speed dependent. One may care to add more features from time and frequency domains, such as the Spectrum Peak Ratio (SPR) [20].

Reference severity charts for monitoring the features have been proposed by the ISO and other practitioners. For example, the ISO 10816-3 (original the ISO 2374) gives a measurement of overall velocity in terms of RMS. Charlotte provides a chart for measuring overall velocity in terms of Peak to Peak (P2P) value and also suggests reference limits for the band spectrums. If no reference is available; the feature limit can be statistically derived from baseline data – a practical approach in most applications. A rule of thumb to determine the severity limit is double of the baseline for most vibration features.

The vibration features can be utilized individually in both diagnosis and prognosis. However, they are more often utilized in an integrated manner. There are two approaches to manipulate multiple features. One approach employs individual features for diagnosis or prognosis first. The conclusions from each individual feature are then fused by a decision fusion model to reach a final conclusion. This approach has been used in [21] for diagnosis. Another approach is to manipulate the features as a whole. The most relevant features or their derivations can be determined by a suitable model. In this approach, the feature and decision fusions are reflected in the chosen model. This approach has been investigated using the above listed vibration features for rolling element bearing diagnosis [22], where Bayesian neural networks were applied.

This paper investigates feature manipulation for prognosis. The application of PCA for feature extraction in this work falls under the second approach, which conducts the feature fusion in the PCA model.

4 EXPERIMENTS AND RESULT

Double-suction pumps are a special class of centrifugal pumps used in the process and water industries for high volume, medium head applications. Process plant experience has shown that partial flow operation can result in severe axial vibration and subsequent component failure. Therefore, it is valuable to gain an insight into the effect of partial flow on the axial vibration response of double-suction pumps.

This paper adopts the results from [23] to demonstrate the PCA application in prognosis. Vibration signals were collected from a double-suction pump (pump set A) shown in Fig. 1. The pump has two casing suction passages joined to a common suction nozzle and flange. The flow enters to the pump and is split into two annular suction chambers that turn and diffuse before entering the impeller through the opposing entrances. The flow fields from the two suction eyes are joined mid-way through the impeller vane passage and discharge into a common volute. The impeller is mounted on a shaft which passes through two suction chambers and is supported by two bearings. The bearings support the hydraulic loads imposed on the impeller, the mass of the impeller and shaft, and the loads from the drive components. They keep the lateral deflection of the shaft within acceptable limits for the impeller and shaft seal. The detailed specifications of the pump are given in [23].

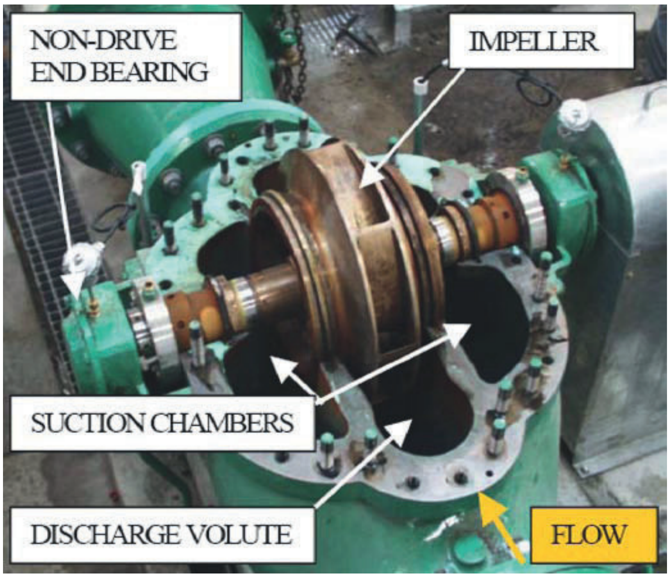

Fig. 1 The double-suction pump

When the impeller is centred in the casing and operated under design conditions, axial vibration levels are very low. Peaks at vane pass frequency are detectable anywhere on the pump casing and bearing surface and this is the major contributor to the pump's overall vibration. Radial vibration data measured on the bearing housing(s) in the horizontal and vertical directions contains vane pass frequency and often harmonic rotational components. During partial flow operation a complex, unsteady, asymmetric flow pattern at each suction eye results in loss of the hydraulic balance and axial motion of the impeller which can be detected as an axial vibration on the bearing housing of the pump.

The axial vibration of the pump was measured at 15 discrete operating points over a range of flows [0.40, 1.20] *Q*/*QBEP* (ratio relating measured flow rate to the flow rate at best efficiency point) by adjusting the position of a valve on the discharge line of the pump. The 15 operation points are listed in Table 1.

Table 1. Operation points of the pump

Test ID	1	2	3	4	5	6	7	8	9	10	11	12	13
Q/*QBEP*	0.42	0.56	0.59	0.67	0.8	0.84	0.99	1	1.01	1.11	1.14	1.2	1.2

At each operating point, 150 seconds of vibration data were digitally tape recorded using B&K 4396 Deltatron accelerometers stud mounted on the non-drive end bearing in the axial location. The data was sampled at a 2k*Hz* sampling rate when the pump was running at 1459RPM. Meanwhile, the performance data providing flow, pressure and pump efficiency was measured using a Yatesmeter [24].

The 15 operation points describe a progressive condition during flow fluctuation. The vibration signals of the condition can be processed by PCA and future vibration due to flow changes can then be predicted. The sixteen features as listed before were used individually to describe the vibration changing along the flow fluctuation. Fig. 2 demonstrates the trend depicted by each feature. As can be seen, some features show a clear trend e.g. P2P and RMS, while others do not e.g. Kurtosis and Crest Factor. There is a need to extract composite features to represent the trend from these multiple features.

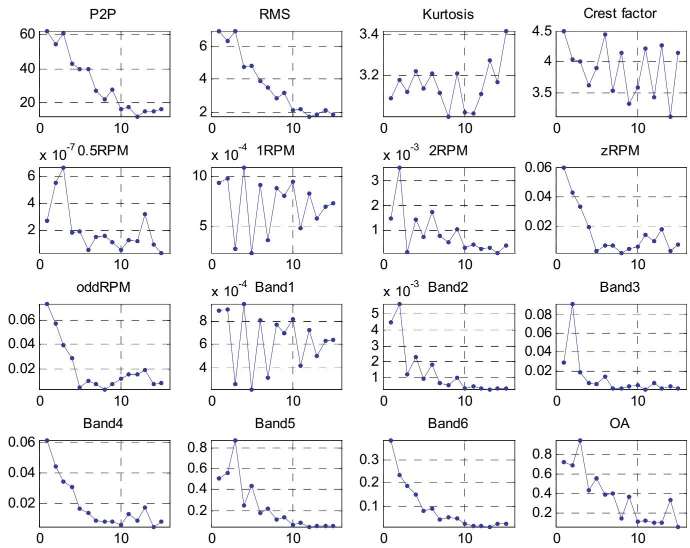

Fig. 2 Individual feature trending

The PCA model is applied to multiple feature manipulation. In theory, 16 principal components can be drawn from the feature sets. Fig. 3 illustrates the top four principal components – they represent the top ranking components which contain a large portion of variations in the raw variables. The result shows that the first principal component is very dominant compared with the rest since it contains 93% of the data variation (from Eq.(4)). Generally, the approach would be successful if sufficient components are included as a reasonable proportion of the total process variation. However, as mentioned before, there is no rule on how many PCs should be included. The components can be shown jointly to provide a process trajectory. Fig. 4 and Fig. 5 give the results in a 2-D and 3-D view respectively.

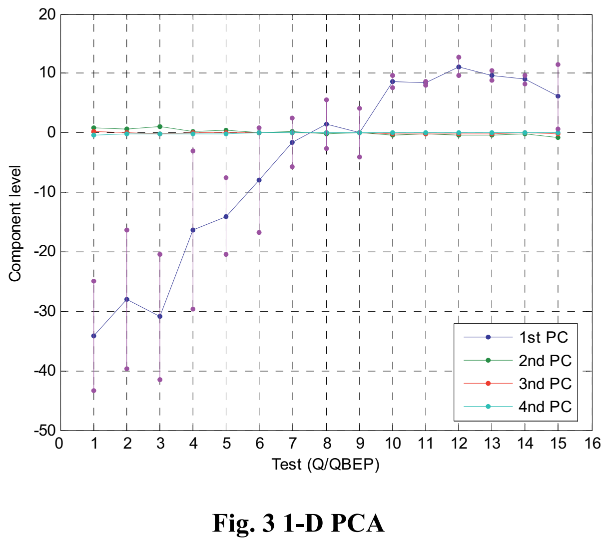

Fig. 3 1-D PCA

The three PCA diagrams present a clear trend of vibration changes during the flow fluctuation. This trend gives the opportunity for prognosis to predict future vibration condition due to flow fluctuation. Also, if the operation points near the Best Efficiency Point (BEP) of the pump are taken as normal conditions, e.g. operation points 7, 8 and 9, then the alarm limit can be plotted by a specified percent of confidence. In this study, the 2-D and 3-D principal components were assumed to follow a joint multivariate Gaussian distribution respectively. A 95% confidence for the normal condition consisting of the points 7, 8 and 9 was designed. This confidence level corresponds approximate 2.5 times of standard deviation of the multivariate in the Gaussian distribution [17]. Abnormal operation points can then be displayed which are beyond the normal confidence range as illustrated in Fig. 4 and 5. The change of vibration condition due to flow variation can then be traced easily from the diagrams.

In all the three diagrams, each operation point can also be described using a confidence boundary. Again, a 95% confidence level was used to describe the operation point in all the three cases.

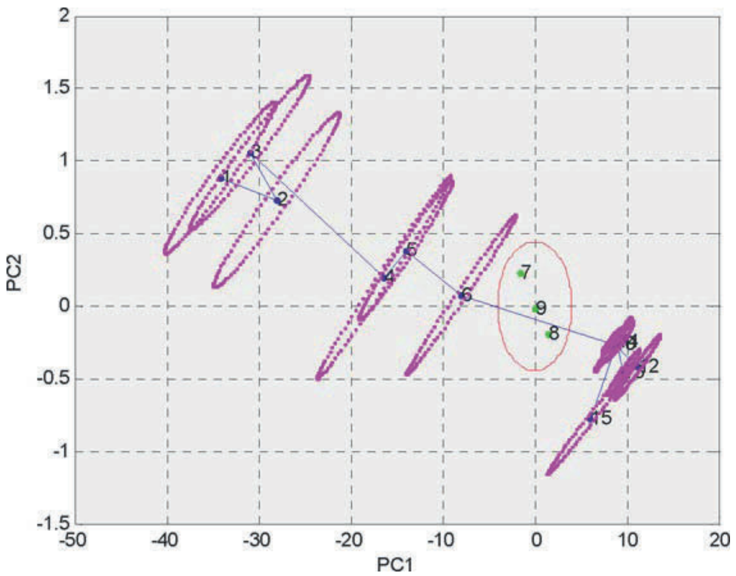

Fig. 4 2-D PCA

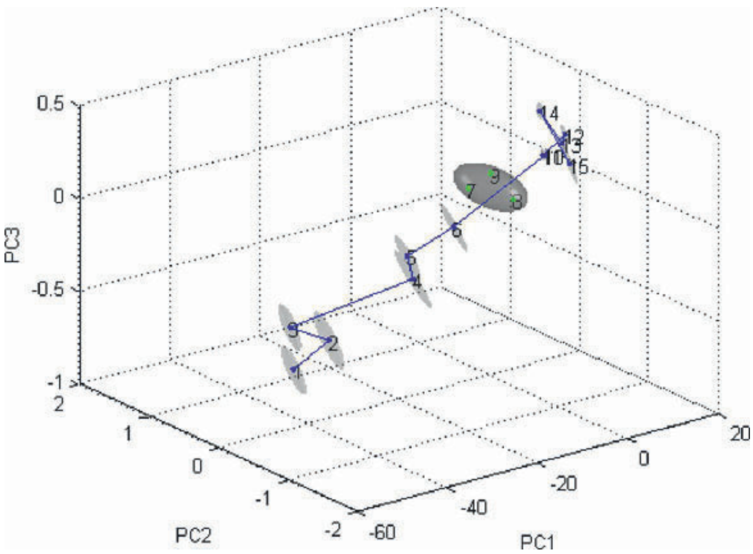

Fig. 5 3-D PCA

5 CONCLUSION

A multivariate analysis method, principal component analysis, was investigated in this work for condition prognosis purpose. It was applied to extract composite indicators (principal components) from different vibration features which are generally used for indication of condition variations. The different dimensional views, 1-D, 2-D and 3-D of principle components, facilitate the visualization of condition progression, thus ease the tracing of condition changes and assist prognosis. The vibration response from a double-suction pump during flow fluctuation was selected for the verification of the method in prognosis applications.

STRATEGIC ASSET MANAGEMENT
– GETTING THE PEOPLE AND SYSTEM ISSUES RIGHT

Albicini, V[a], Marmaras, F[b] and Hanrahan, M[a]

[a] *Knox City Council, Burwood Hwy, Wantirna South, Victoria 3152, Australia.*

[b] *Integr8 Pty Ltd, Suite 303,145 Russell Street, Melbourne, Victoria 3000 , Australia.*

Abstract: This paper details the recent experience of a Victorian Local Government authority, Knox City Council, as it attempts to implement strategic asset management principles across the organisation. It outlines challenges faced when shifting from a culture that supports a reactive response system to one that encourages a proactive, whole of network approach that uses risk to prioritise workloads. Knox encountered two main challenges in delivering on Council's strategic asset management objectives – getting the people issues right and getting the system issues right. Whilst Council recognises that it still faces considerable challenges on both fronts, it has come to realise that people and system issues are interdependent and cannot be analysed or improved in isolation.

Key Words: Strategic Asset Management, Change Management, Asset Management Systems

1 OPERATING ENVIRONMENT

Knox City Council is an outer eastern Municipal Council in Melbourne. The Operations Centre at Knox Council is responsible for completion of maintenance and renewal works on engineering infrastructure across four work areas – Parks (active and passive reserves, vegetation, playgrounds), Works (roads, paths, drainage), Buildings (community facilities, child care centres, pavilions) and Fleet (motor vehicles, plant). This paper focuses on the changes necessary to improve operational output in both the Works and Parks areas through application of strategic asset management principles. To achieve performance improvements, it was necessary that changed work practices be implemented at a procedural level (the system used to record and manage work activities) as well as at a people level.

Figure 1. City of Knox

Traditionally, Operations Centre staff have operated on a reactive basis, with performance measurement systems that encouraged a response to the squeakiest wheel rather than an objective assessment of need. A customer request system which channels requests from the community or Council officers to the Operations Centre was the key driver of maintenance action within the municipality. Timeframes for asset repair typically reflected resource and funding availability, with little documentation available to quantify works undertaken, plant and labour requirements and justification for carrying out works. Typically, the decision to undertake maintenance works was solely at the discretion of the field officer, administrator or their supervisor. Review, auditing and quality assurance were undertaken but not to any great degree.

Table 1 contrasts the people and systems at Knox today with the situation before the journey toward strategic maintenance service delivery was initiated.

One of the more significant challenges involved changing the people culture within Knox, with Operations Centre staff often seeing themselves solely as a maintenance crew, finding little correlation between their own works and the performance of the asset as a whole. This was in part a result of deficiencies in the asset management system and appropriate reporting mechanisms that could reliably inform staff about asset performance. This itself was likely a bi-product of the 'as needed' relationship which had developed between Council's Engineering, Asset Management and Operations Centre departments, providing minimal opportunity for effective interaction between work units.

Table 1: People and systems before the journey commenced and now

PEOPLE - Maintenance crews and supervisors	
Before the Change	**Now**
– administrators drove the service instructing field staff to address customer requests – isolated from other departments responsible for asset management (planning, design, construction, renewal, disposal) – inconsistent responses to customer requests – delivery times for repair not objective – status quo not challenged – officers saw themselves as doers not thinkers – reluctant to become involved in strategy development – confident in ability to repair assets but lacking skills in data recording and analysis	– recognise and communicate to others the benefits of a structured proactive approach to asset management – supervisors drive the service instructing field staff on better ways of delivering the service – consistent responses to customer requests based on a robust risk assessment process to justify action or in-action – earning respect from other departments because they are able to quantify and justify what they do – more confident to challenge traditional work practices – eager to support expansion of system into other interrelated departments – confident in ability to repair assets improving data recording and analytical skills
SYSTEMS - Computer applications and work prioritisation processes	
Before the Change	**Now**
– asset management system did not record any maintenance data against assets – independent customer response and finance systems – no maintenance management system – no documented maintenance intervention levels to dictate whether an asset requires repair – customer response system used to initiate maintenance activities. Decision to repair asset at discretion of crews, administrators and supervisors – limited inconsistent recording of maintenance actions undertaken by field staff – adhoc asset inspections used to supplement workloads during quiet times – no clear auditable process for prioritisation of workloads - multiple spreadsheets managed by multiple supervisors with inconsistent, overlapping, incomplete information – no centralised codified system – difficult to locate and interrogate data – performance auditing difficult due to lack of documented work processes and responsibilities and data collection in disparate systems	– maintenance data recorded against individual assets enabling sites with repeat issues to be easily identified and future prediction of asset deterioration rates – new maintenance management system integrated with existing asset management system, customer response and finance systems – documented maintenance intervention levels dictate whether an asset requires repair and timeframe for completion of repair based on risk – maintenance service levels built into the new maintenance management system to drive changes in work practices and measure performance – issues raised by customers assessed to determine whether they exceed intervention levels. Timing for completion of repair, if required, based on public safety risk assessment at the time of initial inspection – regular asset hazard inspection program introduced. Assets with defects that exceed maintenance intervention levels recorded, public safety risk assessed at each location. Work prioritised and delivered accordingly – adhoc asset inspections enable crews to report high public safety risk issues identified on site – centralised codified system - data can be analysed to determine workloads, causes of asset failure, performance in delivery of target repair timeframes , reasons for delays etc. – auditable work processes based on public safety risk

At a senior management level, strategic asset management had been identified as a core function of Council's future operations, however responsibility for the development of strategic plans at this early stage rested solely with a newly created Asset Management department. Implementing the strategic objectives and the required cultural and procedural changes in a manner which was meaningful and applicable to staff rested with the Operations Centre Manager with support from the Asset Management team. It was recognised that a system alone would not be able to deliver the desired results, but also noted that a change process without a key driver (system) would be extremely difficult. The considerable task of system development coupled with people management was subsequently initiated.

It is important to note that enacting change in staff practices within a public sector environment has its own challenges. Organisational inertia is compounded by public and political scrutiny and the financial and operational constraints that these may bring. Major changes to the structure of the organisation and staff position descriptions are difficult. Skills and capabilities of staff may not be completely understood or utilised effectively in an environment where monitoring and reporting has not previously been well utilised. Effective senior management is therefore essential to not only develop the vision for the team, but also be prepared to take all steps necessary to deliver this vision in the face of any barriers which may present themselves.

2 DRIVERS FOR CHANGE

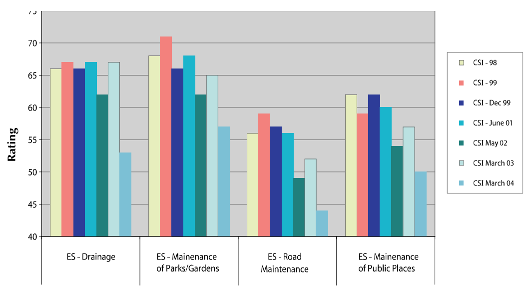
2.1 Customer Dissatisfaction

The original Knox shire extended over 110 square kilometres and included the suburbs of Bayswater, Boronia, Ferntree Gully, Knoxfield, Wantirna, Wantirna South, Rowville, Scoresby and The Basin. At the time of its inauguration on 16 November, 1963, the Shire of Knox had a population of just 24,000. During the 1970's and 1980's the population density of the City grew with an influx of businesses and rapid expansion in the residential sector. Today 147,000 people live in Knox.

Figure 2. Council Assets

Roads	***703 km***
Kerb & Channel	**1 300 km**
Footpaths	**1 166 km**
Bike Paths	**70 km**
Drainage	**1 107 km**
Playgrounds	**203**
Buildings	**262**
Parks/ Gardens	**650 ha**

By the early 90's as growth of the municipality had begun to slow it was becoming obvious to Council's Senior Management team that Council faced a huge potential future liability if its assets were not managed for the long term. Council was left responsible for maintaining an ageing stock of infrastructure assets to a standard deemed acceptable by its customers – the same customers who possess ever-increasing expectations for improved services and an ever-reducing willingness to pay. Surveys undertaken by Council of residents and businesses indicated that the community was often unhappy with the way key assets such as footpaths, roads, drains and parks were being managed.



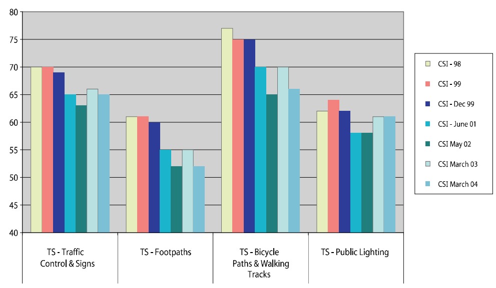


Figure 3. Auspoll – Customer Satisfaction Survey Results

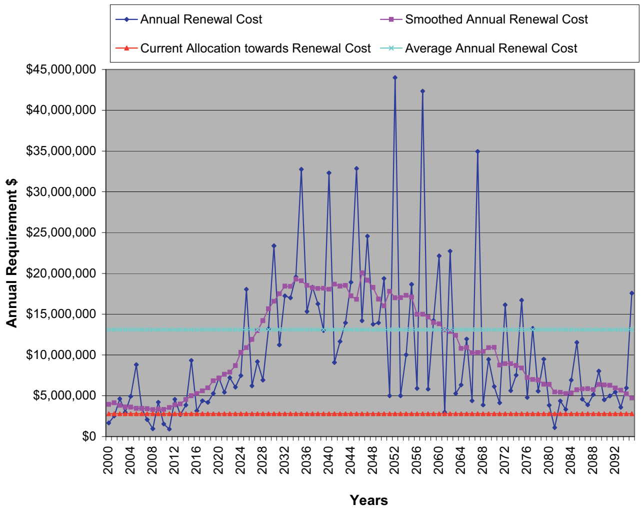
2.2 Staff Recognition of Inefficiencies in Service Delivery

Internally, there were also some concerns, with staff satisfaction surveys suggesting a need to review internal processes to improve communication among departments, remove duplication of effort in some areas, and provide greater opportunity for professional development. In addition to this, the Operations Centre underwent a major review of its service delivery areas in mid 2004. This review assessed requirements and capabilities of all Operations Centre staff, structure issues and service delivery improvement opportunities. The summary findings of this review were seen to be a key driver for the change needed at Knox, with staff participation in this review raising awareness of key issues and setting the environment for future change.

2.3 Financial Sustainability

Council initially responded to some of the above concerns with the development of a Strategic Asset Management Plan. This strategic document researched and assessed Council's assets in an attempt to broadly quantify the age, condition and performance of Council's asset stock and subsequently predict the extent of future liabilities under varying funding scenarios and demand/growth projections. The data was to provide a basis for informed decision making which would assist with long term financial planning in Council. The Plan took into account the need for clear decision making processes associated with service provision, risk management, future asset growth and rationalisation opportunities. The framework for delivery of the plan was linked directly with Council's commitment to sound asset management, which had been articulated in Council's long term vision and Corporate and Community Plan.



Asset Category	Current Replacement Cost ($,000)	Valuation (30/6/05) ($,000)
Footpaths	87,857	41,059

Figure 4. Financial liability – ageing assets following a peak growth period

This strategic document was used to communicate and influence elected officials on the importance of embedding strategic asset management principles into day to day decision making. However, like many strategies, staff at Knox were best placed to apply these principles through their own work practices. The magnitude of funding required to bring all assets to an acceptable service level in the eyes of the community using only limited funds would require risk-based prioritisation of maintenance and asset rehabilitation expenditure. In order to justify and enforce such decision making, improved systems would be necessary to adequately record and quantify the performance of Council's assets.

2.4 Legislative Change – The Road Management Act, 2004

The momentum for change did not gather pace until a sense of urgency was created by the High Court decision (Brodie vs Singleton Shire Council and Ghantous vs Hawksbury City Council) which made it possible for a road authority, such as Knox Council, to be found negligent for failure to act to inspect or repair a road asset. This decision ultimately resulted in the development of the Road Management Act, 2004 in Victoria, legislation which provided senior management with a motive and opportunity to drive change in the maintenance delivery methods of Council.

The legislated deadline for compliance being a period of only 12 months meant that at a minimum, Council's asset inspection regime and maintenance service levels had to be developed and documented with staff educated and geared to deliver and record the delivery of these. This tight timeframe for delivery of significant change meant there was little time for detailed forward planning. The team launched headlong into implementation of a more strategic approach to asset maintenance.

3 THE JOURNEY

The asset management team set themselves the task of delivering three key outcomes:

1. Develop and document maintenance service levels applicable to Council's drainage, park, road and road related assets;
2. Change service delivery principles from a reactive approach that serviced the most vociferous customers at the expense of others to an objective public safety risk based approach that considered each asset repair request within the context of the condition and criticality of the whole network of assets;

3. Upgrade of the existing asset management system to incorporate a maintenance management system that would support the changed service delivery principles, record and report on compliance with documented maintenance service levels and provide data for analysis to improve asset management into the future.

Delivering on the objectives required shifting the mindset of a team of some sixty maintenance staff, administrators and supervisors from a culture that supported a reactive response system to one that encourages a proactive, whole-of-network approach that uses risk to prioritise maintenance workloads. All tasks were to be completed within the surrounding legislative context with recognition of the need to maintain existing service to the Community at all times through the process. The key tasks undertaken are outlined in the table below

Table 2: The Journey – Key Tasks

Project Planning

- Education in principles of strategic asset management - limited to the Asset Management Team
- Informal planning of the change project aimed at overcoming hurdles as they were encountered.

Capture & challenge local knowledge to develop and document maintenance service levels

- Numerous formal meetings with officers responsible for asset repair to gather existing documentation, determine what they do and how work processes could be improved
- Maintenance service levels documented - including risk assessment to determine appropriate repair timeframes

Introduce changed maintenance service delivery principles

- Process developed for use by field staff to assess the risk associated with defects identified on site
- Field staff training :
  - assessing and recording public safety risk,
  - detailing the expected scope of work required to repair a hazard (including plant, labour and material requirements)
  - recording details of work undertaken
- Monthly meetings to discuss issues encountered by staff as they attempt to deliver documented service levels
- Performance auditing with measurable improvement requirements to drive change in work practices including data collection

Develop and introduce a new maintenance management system

- System developer engaged to create a maintenance management system (MMS) as an add-on to Council's asset management system.
- System development - not staged or tested
- System implementation –not staged, system required ongoing modification to iron out glitches, keep system functional and develop reporting tools that met Council's needs
- System training - informal "on the job" training for all users individually as system was rolled out.
- Monthly meetings with user groups to identify and prioritise system issues and identify improvements to be included in subsequent system upgrades

4 KEY LEARNINGS

In total, Knox have taken nearly two years on this journey toward proactive strategic asset management. Looking back, it is reasonable to surmise that the practicalities of delivering both system changes and people changes were significantly underestimated both in respect of time and effort to achieve the desired outcomes. Nonetheless, the journey provided us with valuable insights into staff management issues and the impact these may have from an operational perspective both now and into the future. In practice, senior management are now far better positioned to implement any future change within Council.

4.1 Espouse Strategic Asset Management principles to affected staff

Senior management created an asset management team and empowered them to challenge the status quo within the Operations Centre. This team were encouraged to build their knowledge by attendance at conferences and active participation in numerous asset management reference groups. This in itself created a divide between them and the Operations Centre staff, who had little initial awareness of the principles of asset management. As a result, initial discussions between the two teams left Operations Centre staff somewhat reluctant to reveal key data out of fear that such information may be used against them. Operation Centre staff had a great deal of pride in the way they had delivered the service on the ground and found the idea of being told by outsiders how to run their service objectionable.

A key challenge in the development of the maintenance management system was to ensure that staff saw any new application as being a permanent part of doing business and not simply a passing fad or strategic direction which had little application. General scoping of system requirements therefore involved Operations Centre staff. At this early stage however, the staff were not sufficiently educated in the principles of asset management to provide appropriate guidance for the consultant engaged to develop the system.

Early introduction of more staff to the principles of asset management by encouraging attendance at relevant conferences and participation in reference groups may have reduced the knowledge disparity between the two groups, provided the system developer with more coherent objectives, and created more widespread excitement toward the prospect of changing the way Council manages its assets. Even though many staff may perceive attendance at these sessions to be a waste of time better spent on productive activities they tend to provide an opportunity for staff to learn from others and challenge traditional ways of working in an unthreatening environment.

4.2 Plan and communicate the change management project

The twelve month timeframe for delivery of the three key project objectives meant that virtually no time was spent in the project planning stage. Planning including a stakeholder threat & opportunity analysis would have armed the team with a better understanding of the people issues likely to be encountered and provided an opportunity to develop systems and strategies to address them. In future, the team should have more private talks with as many people as possible, as early as possible to identify where support and challenges are likely to come from. Stakeholder analysis should identify whose cooperation is essential and key allies that can be relied upon to provide insight into others and later help drive the change effort by priming others to at least listen then follow their example. Allies don't have to be those in formal positions of authority but must be respected and trusted by other staff. The analysis of all affected individuals should consider the following:

- What motivates them, excites them and annoys them
- their concerns/ interests / issues
- how has change been avoided by them in the past
- expected type/ amount of resistance
- expected reasons for resistance
- their tolerance for ambiguity
- their likely allies (common goals)
- their likely enemies

This enables the team to group individuals with similar personalities, issues and tolerances to change together and then for each group, determine appropriate communication methods, specific tactics (structural, system, training, incentives etc) to counter predictable resistance.

It is important to note that affected individuals exist outside the affected department, and can be identified by looking at all work processes that involve interaction with other departments. Unfortunately, interdepartmental relationships were largely overlooked by the team. Customer service operators, charged with the responsibility of explaining likely maintenance repair works and timeframes for service delivery to customers found themselves providing customers with outdated information. Design engineers who had previously been able to direct the activities of maintenance crews, found themselves frustrated by crews that now operated according to a new set of guidelines based on a risk assessment to prioritise their workloads. This lack of communication was addressed by the team as a matter of urgency but could have been avoided by recognising and communicating changes to these indirectly affected parties. The above planning process would have revealed the importance of communicating maintenance service level changes.

4.3 Build trust to capture and challenge local knowledge

Maintenance service levels were established and now act as service delivery targets. They define performance expectations and were formulated based on local knowledge through an assessment of legislative requirements, organisational objectives, customer expectations and financial constraints. Staff at the Knox Operations Centre had a proud history of delivering continued service when delivering maintenance outcomes. Indeed, many staff at supervisory level had in excess of twenty years experience at Knox - resulting in detailed knowledge of asset performance and local area issues. Unfortunately, most of this knowledge rested within the minds and memories of staff, who were able to articulate when and where work was completed but without documentation to prove this.

When originally asked to quantify how they undertook their works in an effort to establish preliminary service levels, staff felt threatened and challenged by senior management. This may have related to a sense that they were failing to deliver an appropriate service or perhaps a more real and greater fear that, in documenting service levels, individual officers would personally be more exposed should they fail to meet such delivery timeframes or provide indicators of proof that the works had been completed. Previously, officers had received the benefit of a customer response systems which would allow timelines to be extended should a deadline not be met, resulting in a remarkably effective service delivery outcome.

D-066 - Damaged Pit Lid/ Structure
For all Drainage Pits within Road Reserve and along Shared paths:
Intervention Level

D-066A.	Pit lids, grates, and /or pit surrounds that are damaged or deteriorated to the extent that they pose a potential hazard to road users/pedestrians
D-066B.	Vertical displacement >15mm only if the pit is within a designated pedestrian walkway
D-066C.	Cracks >5mm considered likely to cause the pit lid and/ or surround to collapse prior to the next routine hazard inspection
D-066D.	Broken or missing pit covers
D-066E.	Broken frames that no longer support the pit lid
D-066F.	Missing/damaged / deteriorated step irons and/or mesh panels.

ACTIVITY TITLE:	Drainage Pit Lid/ Structure Repair (excluding lintels)
DESCRIPTION:	Repair or replacement of pit lids & structural components i.e. pit lids, grates, frames, step irons, surrounds, & mesh panels (installed to divert litter). (This activity includes drainage pits within the road reserve and along the footpaths/ shared path network).
POTENTIAL RISKS IF ACTIVITY IS NOT UNDERTAKEN:	Personal injury from falling into pits with missing lids/ grates/unstable frames Personal injury/ vehicle damage resulting from pit surface components not flush with road/ path surface Personal injury to workers due to broken/ missing step irons

REACTIVE MAINTENANCE	D-REA-066 - Drainage Pit Lid/Structure Repair (excluding lintels)
CURRENT SERVICE LEVEL:	Provide temporary and/or permanent repair when: a) Pit covers are broken or missing b) Cracks >5mm are considered likely to cause the pit lid or surrounds to collapse c) Vertical displacements >15mm within designated pedestrian walkways only d) Pit lids, grates, and/or pit surrounds are damaged or deteriorated posing a potential hazard to road users/pedestrians.
TARGET TIME FOR INITIAL RESPONSE: (Site Inspection/Public Safety Risk Assessment)	3 days
TARGET TIME FOR RECTIFICATION WORKS:	96 days

Figure 5 Sample maintenance service level

Given the short timeframe available to determine and document maintenance service levels there was little time available for the team to develop a trusting relationship with the knowledge holders before bombarding them with questions on what they do, why, how long it takes, and what could be done to become more efficient. Aware of this, the team made a conscious effort to build trust by acting in a consistent manner in all interactions with the knowledge holders. Delivering on responses to issues raised within agreed timeframes, not claiming to have all the answers, being forthright about their own mistakes and those of others, admitting their own feelings of uncertainty and asking directly about the feelings of others.

One of the most important recognitions for the team when developing service levels were that effective communication enabled greater clarity as to when maintenance work would be carried out by staff. Site visits, common language and sample photographs built trust and enabled adequate documentation of the service levels to be carried out. Immediate documentation of all thoughts and ideas was essential prior to the collation and review of the available data. Importantly, although a large quantity of material required review, documentation enabled all stakeholders to develop a common understanding and focus on reaching agreement on service levels to be delivered.

4.4 Assisting people to change – skill development and confidence building

The introduction of maintenance service levels that specified a timeframe for defects to be inspected, made safe and rectified based on a public safety risk assessment at the time of inspection meant that field staff needed to be able to understand the service levels and assess the risk that the defect would likely impose on public safety if no maintenance were undertaken. In addition field staff were for the first time required to record specific details of their assessment and the work undertaken so that this data could later be analysed to measure performance against service delivery targets and highlight potential process improvements.

The team recognised the fact that despite the legislative pressures for total compliance with documented service levels staff couldn't be expected to learn the required skills overnight. Intensive training, support and both positive and negative reinforcement were required. Those displaying clear resistance to change were actively exposed to the process and the logic behind the change and made accountable for delivering outcomes.

Knox City Council Works Order: 511287 *Date Received:* 25/01/2006 *CRS No:* 248850

Issue Location: 108 Rickards Avenue North KNOXFIELD 3180 *Extra Loc:* *Mel Ref:*

Figure 6 Form used to assess issues

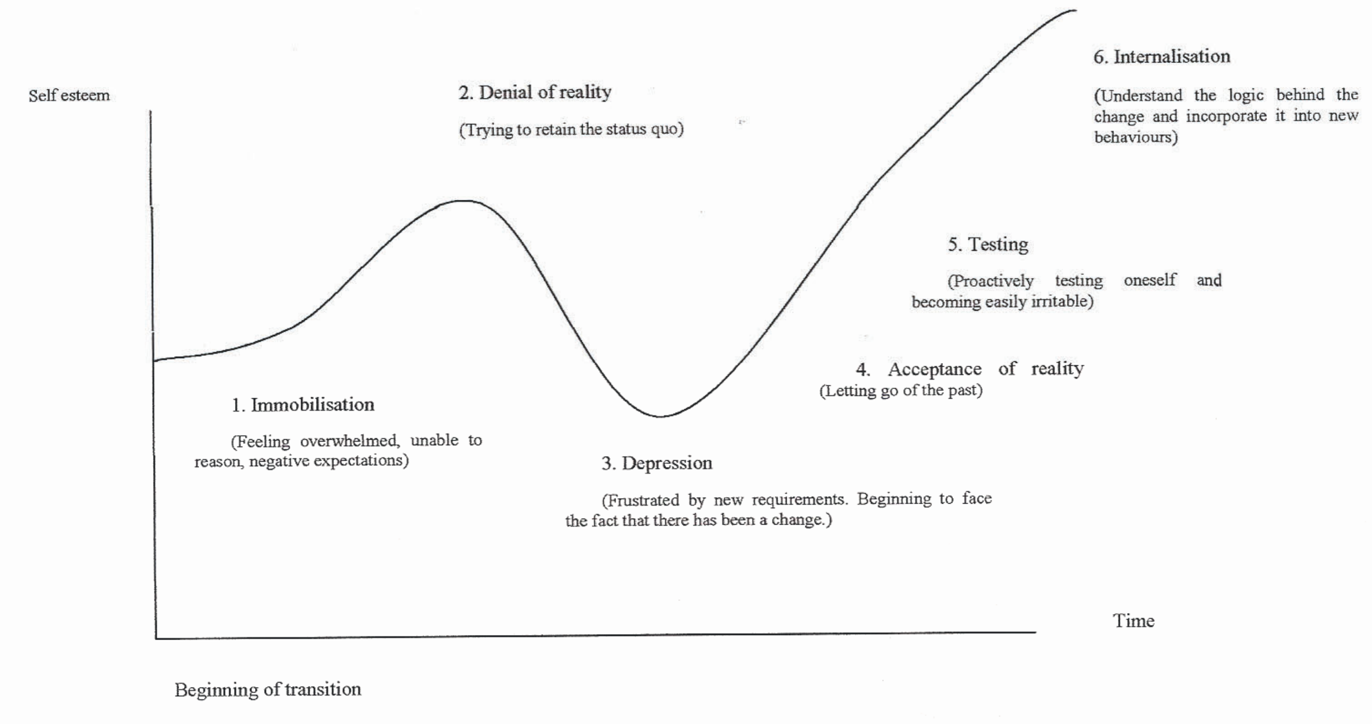

Figure 7. The emotional roller coaster of a changing work environment

A flowchart of the risk assessment process was documented as simplistically as possible and issued to crews for use on site. Supervisors were trained first, then assisted with workshops for field staff. Each training exercise was a hands-on application of the process rather than hypothetical or conceptual. The sessions involved real examples to give substance to the theory documented and provided to staff in both written form and flowcharts Training workshops acknowledged that the system may not be perfect and encouraged constructive criticism. These workshops provided information, skills and tools which were supplemented by a full time resource dedicated to working with groups and individuals to guide them in the new way of approaching issues as they tried to negotiate their day-to-day activities with a new set of rules. This support included open discussion to reinforce the fact that there was no hidden agenda, repetition of the change message to avoid staff slipping back to old familiar comfortable ways, allowing individuals to make mistakes and learn from them.

The collection and challenge of existing information and processes, together with the introduction of new work management and data collection processes and computer applications meant that at anyone time Council officers found themselves in one or more of the emotional states described in Figure 7. Successful change required the change management team to understand these emotional states and help officers move through the phases toward internalisation of the change.

Future change management should continue to include efforts to equip individuals with the skills to manage change. Informal coaching of staff would be enhanced by formal personal development programs aimed at equipping staff with an understanding of how and why people resist change, how to self evaluate, and develop coping mechanisms to deal with the emotional roller coaster that accompanies a changed work environment.

4.5 Plan system development and implementation

Given that delivery of the documented service levels could only be ensured if staff followed quite specific work processes it was recognized that a custom built system would be required. It was also considered essential that the maintenance management system be linked to Council's existing asset management system so that the data could be used in predictive lifecycle analyses. A custom built system was preferred because it could be designed to support the way we wished to operate. The key desired features included:

- systematic collection of maintenance histories against the affected asset
- ease of use and reporting
- integration with other corporate databases and applications (Latitude GIS and AXS One, GEAC Pathways)
- flexibility to change to reflect new reporting and business process needs
- ability to be expanded for use on portable handheld computer devices
- data validation to force users to use the system correctly

It was decided that the maintenance management system would be developed as an add-on to Council's existing asset management system by the original system developer with whom Council has a long relationship. Unfortunately it took longer than expected to develop a stable system relatively free of glitches. The delays were the result of a multitude of factors primarily:

- incomplete scoping of Council's needs at the outset
- work processes were evolving in parallel with system development as the team developed its understanding of how data should be collected so that compliance with service levels could be measured
- an unrealistic expected application delivery time
- system provider engaged to develop the system were moving their business focus away from provision of specialised system modules

Council's relationship with the system provider established over many years although tense enabled modification to the scope without a blow-out in costs.

Key system features are now inclusive of data validation capabilities, a system for recording worksite traffic management, a module for scheduling rectification tasks based on location, due date, risk and work activity, multiple reports including causes of asset failure and locations receiving duplicate requests. Performance reports are also able to be prepared to measure maintenance crews' timeframes for initial response to customer requests, temporary works to make the sites safe and rectification works and to measure the volume of work generated. Operations Centre staff and the asset management team met regularly during system development and continue to meet every three weeks to see how things are going. Issues continue to come up and are either resolved, a work around provided, or the need for a major system rethink noted for consideration when the system is next upgraded.

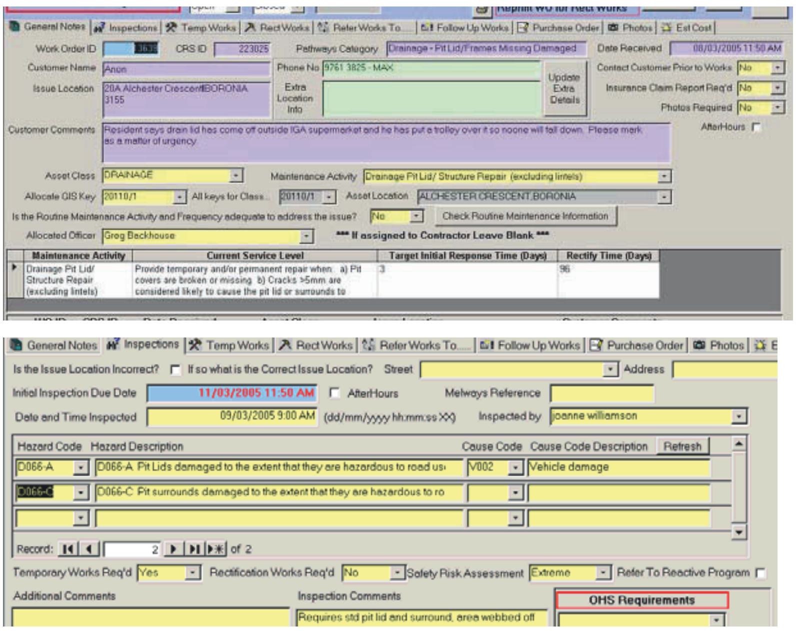

Figure 8 Sample data collection forms

Tight time constraints imposed by legislation, meant the team had no time to dedicate to the search of a system developer and little time to prepare a detailed scope as work processes were continually evolving. In hindsight however, as most people need little encouragement to avoid the confronting the challenge of actually trying to change the way they work the reliability of the system was critical to success and its development and implementation warranted a more thorough approach. Staff feedback on their experience of the change process, twelve months after the system was rolled-out has made it clear just how closely staff link their perceptions about the change experience with the computer system. From their perspective the two are inextricably linked. System instability, as both the system and paperwork requirements underwent numerous modifications, during the first few months was unsettling for staff but also gave them an opportunity to influence and improve system functionality.

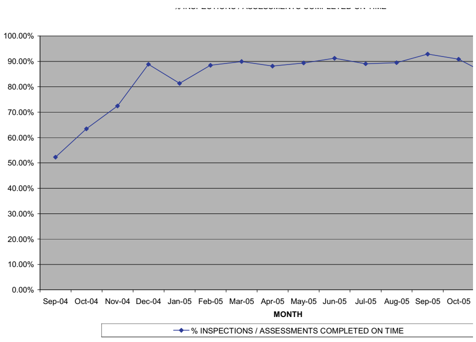
4.6 Data validation to enforce system compliance

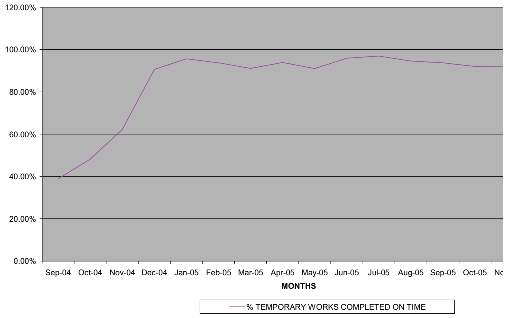
The collection of comprehensive maintenance data was essential to the asset management team as this information is critical for predictions of asset deterioration rates, repair costs, identification of locations where assets are failing abnormally etc. Operations Centre management and supervisors also required good data for budget and resource planning, efficient programming of works, measurement of compliance with the documented service levels, and compliance with the traceability requirements of Council's insurers. To make future data analysis possible, considerable effort went into developing codes for assets, activities, defects, failure causes etc. This was intended to simplify data collection on site without losing valuable information. However, field staff had a long history of recording simply the date they attended the site and a statement like "job done" on the printout of a customer request so collection of data as expected was overwhelming to many and others simply couldn't see the point.

When the system was first rolled out to staff, it did not incorporate any data validation. Analysis of data collected in the early days therefore revealed a clear case of 'garbage in equals garbage out'. Errors included blank fields, no risk assessment, inspection times later that the date the issue was repaired, no record of who undertook the inspection or repair, no record of how long the repair took, what plant or materials were used– none of which was surprising given that staff had never before been required to record their assessment of a site or the work they had done in such a structured manner. The introduction of data validation meant that they could not close off a request unless key data fields were completed with valid information. This made data analysis possible.

4.7 Performance reporting and auditing to drive improvement

Compliance with the strategic documents required a change in the way staff operated however the move toward risk based prioritisation of maintenance activities did not commence in earnest until the system could produce performance reports. This is evidenced in the graphs in Figure 9. The system was introduced in August 2004, performance reports became available toward the end of December 2004. These reports made key staff change their own ways and encourage others to follow. They realised that they would not be able to achieve performance targets if they continued with the old way of working - sticking to the old ways began to look unattractive. Performance reports therefore made it easier for managers to drive process improvements.





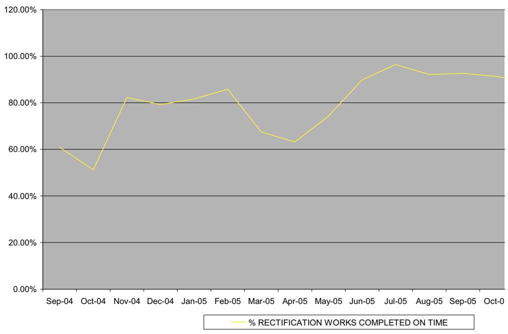


Figure 9 Compliance with service level timeframes

Improvement was seen almost immediately in terms of inspecting and assessing issues and making them safe however delivery of defect rectification target times was more difficult for staff to manage. This required systematic prioritisation of works. The large dip in performance in April resulted from poor management of footpath repair works generated by Council's new asset inspection program. The volume of footpaths requiring repair is still much greater than it had been before the introduction of inspections but now the staff interrogate the data to find up coming work and program it for repair.

Performance reporting was supplemented by performance audits undertaken under the direction of the Manager Operations. These audits considered all phases of the new work processes from completing and filing the necessary paper work, to site activities, risk assessments and data entry. Audits are undertaken regularly and non-conformance reports are prepared requiring officers to take corrective actions within a specified timeframe.

5 QUANTIFYING THE BENEFITS

Since the introduction of maintenance service levels and the supporting system in August 2004, the most obvious benefit has been a reduction in the number of requests made by customers for repair to a Council asset. This suggests that that the introduction of a proactive regular asset inspection program has enabled Council to identify and repair assets before the Community become sufficiently irritated by the issue to contact Council

Increased staff productivity is also evident in this graph as more issues are now able to be repaired without any significant increase in resources or funding, a direct benefit of programming the work efficiently. Data collected at the issue inspection phase includes scoping of the required maintenance activity including plant labour and material requirements making it possible for supervisors to program similar activities together according to location thereby reduce delays due to travel. Previously staff moved from one part of the municipality to another or returned frequently to the Operations Centre to collect required equipment and materials.

Figure 11 summarises Council's performance in audits undertaken by Local Government insurers Civic Mutual Plus. This graph of the scores provided show measurable improvement across all assets now managed in a more strategic and clearly auditable manner. These improvements have a direct impact in reducing Council's annual insurance premium.

Improved data collection also provides decision makers with a wealth of information that can be used to improve service delivery. Staff and plant utilisation can be measured; costs of specific maintenance activities can be interrogated. Decision makers can now identify the most likely cause of particular defects and identify and put in place improved measures to manage problem sites where there are multiple requests by customers, or where repaired defects reoccur suggesting underlying problems.

6 FUTURE CHALLENGES

Now that Operations Centre staff are implementing a strategic risk-based approach to asset maintenance delivering clear benefits to the community the challenge facing the asset management team is twofold. To keep the momentum going amongst staff to ensure they don't get pressured by other parts of the organisation into becoming reactive whilst spreading an understanding of strategic asset management principles to decision makers throughout the other phases of the asset lifecycle. Some work has already commenced.

COMPUTATIONAL FEA MODEL OF A COUPLED PIEZOELECTRIC SENSOR AND PLATE STRUCTURE FOR ENERGY HARVESTING

M.F. Lumentut, K.K. Teh and I. Howard

Department of Mechanical Engineering

Curtin University of Technology

e-mail: I.Howard@curtin.edu.au

Abstract: his paper presents a mathematical model of a piezo-plate energy-harvesting scheme. An analytical method is used to generate a finite element model of the coupled piezoelectric sensor element using Love-Kirchhoff's plate theory. Constitutive equations for a single layer plate element are formulated. The polarisation of the piezoelectric sensor bounded on the upper plate structure is due to ambient vibration exerted on the structure. Forced vibration of the smart structure will create strain energy within the crystalline structure of the piezoelectric material. The resulting electric field generated by the sensor element was modelled using a linear thickness interpolation function and the meshed plate elements were modelled using four-node rectangular elements with three degrees of freedom for each node. The structural eigenmodes and dynamic response of the coupled piezo- plate system were solved by using modal analysis and Newmark-β integration methods respectively. The analysis is demonstrated with both dynamic displacement and electric voltage responses to an applied step force. Further modelling of the smart structure is aimed at maximising the power generation capability.

Keywords: energy harvesting, piezoelectric sensor, Love-Kirchhoff's plate, and Finite element analysis.

1 INTRODUCTION

The investigation of piezoelectric elements as smart structures has many wide-ranging applications in the engineering industry. The ability of piezoelectric materials to transform mechanical strain, induced by ambient vibration, to electrical potential is well known, as evidenced in the direct mode by using the material as a sensor. On the other hand, piezoelectric material which has the ability to transform electrical field to mechanical strain is also well-known, as the converse mode of using the material as an actuator. Numerical analysis of these smart structures using a three dimensional finite element model was first presented by Allike and Hughes in 1970[1]. However, a three dimensional finite element analysis of the integrated piezo and plate structure was challenging and generally demanded large computational requirements. It was realized that the piezoelectric patches were too thin and two dimensional modeling of these patches was sufficient. Other numerical models using laminated rectangular plates with piezoelectric material bonded on the surface have been previously developed[2,3,4], with other researchers using multilayer composite plates[5,6]. Several publications,[7,8,9] have reported the use of numerical models to simulate the dynamic response of the coupled elastic and electric field of the smart structures.

The previous scenarios, mostly, discussed static and dynamic systems using the piezoelectric sensor and actuator bounded on the structures. Moreover, recent developments of piezoelectric technology involve the usage of sensors patched on the structure subject to ambient mechanical vibration. The induced strain energy can be converted to useful electrical energy capable of being stored on electrical devices such as batteries or capacitors. Such a technique is generally referred to as the energy harvesting technique. The development of energy harvesting techniques for powering smart structures and embedded sensors has received increased attention over the past decade[10]. Analytical and experimental analyses have been used to investigate power harvesting from PZT elements to power electric devices or for recharging of batteries. Embedded PZT materials in a vibrating machine environment can be used as the required power source provided the vibration source does not stop. A more useful development would be for the PZT element to store its energy into a rechargeable battery for later use. Further analytical and experimental studies with optimising power flow for adaptive energy harvesting and self-power harvesting have been developed [11,12,13,14].

The main objective of this paper is to present a mathematical model of an energy harvesting technique with bonded piezo-sensors on a plate element. Mechanical strain energy induces polarization in the piezo-sensor thus creating an electric field. The mathematical model introduces a four-node non-conformed quadrilateral element with a total of twelve nodal degrees of freedom, formulated using Love-Kirchhoff's plate theory. The paper presents results from a two-sided fixed-fixed plate using numerical algorithms solved using MATLAB, based on the suggested formulation.

1.1 CONSTITUTIVE EQUATION OF PLATE ELEMENT

Classical plate theory can be used to derive the equations of motion for plates by assuming that the shear deformation effect is negligible. The displacement vectors u,v, and w of an arbitrary point in the deformed element can be written in terms of the mid-surface of the plate, as described in Figure 1a and Figure 1b and equations 1, 2 & 3.

$$u = -z\frac{\partial w}{\partial x},\quad (1)$$

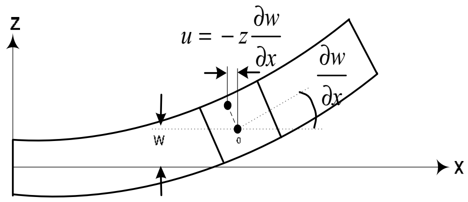

Fig. 1a. The deformations of plate element with respect to x axis

$$v = -z\frac{\partial w}{\partial y},\quad (2)$$

$$w = w(x,y),\quad (3)$$

The corresponding strain-displacement vector relationship in the x and y directions, can be formulated as,

$$\{\varepsilon\} = \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} = -z \begin{bmatrix} \frac{\partial^2 w}{\partial x^2} \\ \frac{\partial^2 w}{\partial y^2} \\ 2\frac{\partial^2 w}{\partial x \partial y} \end{bmatrix} .(4)$$

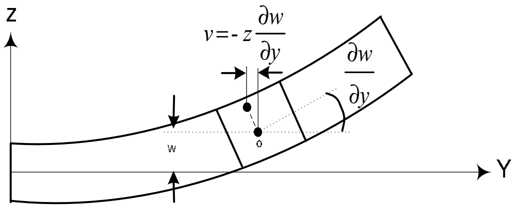

Fig. 1b. The deformation of plate element with respect to y axis.

A state of plane stress is assumed and the corresponding stress-strain relationship is,

$$\{\sigma\} = \frac{C}{1-v^2}\begin{bmatrix} 1 & v & 0 \\ v & 1 & 0 \\ 0 & 0 & \frac{1-v}{2} \end{bmatrix} \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix}, \quad (5)$$

Or

$$\{\sigma\} = [D_m]\{\varepsilon\} . \quad (6)$$

1.2 CONSTITUTIVE EQUATION OF PIEZO-SENSOR

The piezoelectric-sensor has a direct mode electrically on its material due to the exerted mechanical strain on the structure. The matrix equation relating the mechanical and electrical quantities can be written as [15],

$$\{D\} = [e]\{\varepsilon\} + [\xi]\{E\}, \quad (7)$$

where $\{D\}$, $[e]=[d][D_m]$, $\{\varepsilon\}$, $[\xi]$, $[d]$, $[D_m]$ and $\{E\}$ are the electric displacement vector, piezoelectric stress coefficient, strain vector, dielectric matrix at constant strain, piezoelectric constant, stiffness coefficient and electric field vector respectively. In this case, the converse mode gained by the actuator is neglected.

Discritised electric field {E} induced by ambient vibration generates polarisation in the piezo-sensor material, in the z-direction along the sensor plate thickness. The subsequent electrical potential is assumed linear and is formulated as,

$$\{\delta_{(z)}\} = [\Phi^S_{(z)}]\{\delta^s_{(z)}\}, \quad (8)$$

where $\Phi^{s}_{(z)} = \dfrac{z - \dfrac{t_p}{2}}{t_s}$ is the shape function over the interval tp/2 < z < tp/2 + ts.

The electrical field is a function of the electrical potential with negative gradient operator,

$$\{E\} = -\nabla\left\{\delta_{(z)}\right\} = -\left[\Psi^{s}_{(z)}\right]\left\{\delta^{s}_{(z)}\right\} \tag{9}$$

where ∇ is a gradient operator, first derivative of the shape function with respect to thickness direction, giving,

$$\left[\Psi^{s}_{(z)}\right] = \begin{bmatrix} 0 & 0 & \dfrac{d\Phi^{s}_{(z)}}{dz} \end{bmatrix} = \begin{bmatrix} 0 & 0 & \dfrac{1}{t_s} \end{bmatrix}. \tag{10}$$

2 FINITE ELEMENT FORMULATION

2.1 Discretized Element Plate Matrix

As mentioned previously, the classical plate theory can be further dealt with by establishing a 12-term polynomial function to model the non-conforming transverse displacement, w(x,y). The three degrees of freedom at each node wn(x,y), θxn and θyn can then be formulated as shown in Figure 2.

The nodal degrees of freedom for the four-noded rectangular element, can be expressed in the vector form, $\{\delta^{p}_{n(x,y)}\} \in \{\delta^{p}_{i(x,y)}, \delta^{p}_{j(x,y)}, \delta^{p}_{k(x,y)}, \delta^{p}_{l(x,y)}\}$ and $\forall$ {wn, θxn, θyn}. All variables of displacement obtained will be substituted into a polynomial function where the results will give the consistent displacement function as,

$$w(x,y) = [\Phi^{p}_{n(x,y)}]\{\delta^{p}_{n(x,y)}\} \tag{11}$$

where $[\Phi^{p}_{n(x,y)}]$ is the shape function of the displacement field for the non-conforming plate element with reference to transversal displacement function,

$$[\Phi^{p}_{n(x,y)}] = [\zeta][\zeta^{p}_{n(x,y)}]^{-1}, \qquad n \in \{i,j,k,l\}. \tag{12}$$

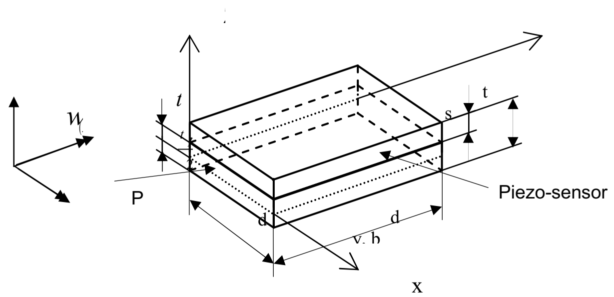

Fig.2. Geometry element of the coupled piezo-sensor and plate element.

The strain-displacement relationship from equation (4) can be expanded by forming the second order partial differential equation of shape function, equation (12), with respect to x and y axes of the element plate in each joint as follows,

$$\varepsilon=-z\begin{bmatrix} \frac{\partial^2[\Phi^p_{i(x,y)}]}{\partial x^2} & \frac{\partial^2[\Phi^p_{j(x,y)}]}{\partial x^2} & \frac{\partial^2[\Phi^p_{k(x,y)}]}{\partial x^2} & \frac{\partial^2[\Phi^p_{l(x,y)}]}{\partial x^2} \\ \frac{\partial^2[\Phi^p_{i(x,y)}]}{\partial y^2} & \frac{\partial^2[\Phi^p_{j(x,y)}]}{\partial y^2} & \frac{\partial^2[\Phi^p_{k(x,y)}]}{\partial y^2} & \frac{\partial^2[\Phi^p_{l(x,y)}]}{\partial y^2} \\ 2\frac{\partial^2[\Phi^p_{i(x,y)}]}{\partial x\partial y} & 2\frac{\partial^2[\Phi^p_{j(x,y)}]}{\partial x\partial y} & 2\frac{\partial^2[\Phi^p_{k(x,y)}]}{\partial x\partial y} & 2\frac{\partial^2[\Phi^p_{l(x,y)}]}{\partial x\partial y} \end{bmatrix}\{\delta^p_{n(x,y)}\} \quad . \tag{13}$$

Equation (13) can be simply rewritten as follows,

$$\varepsilon = z\left[\Psi^p_{n(x,y)}\right]\left\{\delta^p_{n(x,y)}\right\}, \quad n \in \{i,j,k,l\}. \tag{14}$$

Governing Differential Dynamic Equations

By invoking Hamilton's principle for a conservative dynamic system and applying Lagrange's simplification, the general dynamic equation can be expressed as,

$$\sum_{\eta=1}^{s}\left[\frac{d}{dt}\frac{\partial \Pi}{\partial \dot{u}_\eta}-\frac{\partial \Pi}{\partial u_\eta}-F_\eta\right]=0, \tag{15}$$

where,

$$\forall \ \Pi = KE - PE + PEE,$$

$$\eta \in \left\{\left\{\dot{\delta}^p_{n(x,y)}\right\}\left\{\delta^p_{n(x,y)}\right\},\left(\delta^s_{(z)}\right)\right\} ; F\eta \in \{\{Fs\},\{Fc\},\{q\}\} .$$

The kinetic energy term is given by,

$$KE = \frac{1}{2}\iiint \rho_p \left\{\dot{w}_{(x,y)}\right\}^T \left\{\dot{w}_{(x,y)}\right\} d(vol) + \frac{1}{2}\iiint \rho_s \left\{\dot{w}_{(x,y)}\right\}^T \left\{\dot{w}_{(x,y)}\right\} d(vol), \tag{16}$$

and the potential energy can be written,

$$PE = \frac{1}{2}\iiint \{\varepsilon\}^T \{\sigma\} d(vol) \quad . \tag{17}$$

The electrical energy term can be formed as,

$$PEE = \frac{1}{2}\iiint \{E\}^T \{D\} d(vol) \quad . \tag{18}$$

Work done on the system is due to the surface force, concentrated force and electrical charge density and can be written as,

$$\Omega = \iint \{\delta_e\}^T \{Fs\} d(area) + \{\delta_e\}^T \{Fc\} - \iint \left\{\delta_{(z)}\right\}^T \{q\} d(area) \tag{19}$$

The solution procedure involves substituting equations (6), (7), (9) and (14) into related expressions of equations (16) to (19) and differentiating with respect to all displacement vector parameters of the coupled sensor and plate structure. As given in equation (14), the resulting non-homogenous matrix differential equation for the smart structure can be formed as,

$$\begin{bmatrix} [M^{(ps)}] & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} \ddot{\delta}^{p}_{n(x,y)} \\ \ddot{\delta}^{s}_{(z)} \end{Bmatrix} + \begin{bmatrix} [K_{\phi\phi}] & [K_{\phi\theta}] \\ [K_{\theta\phi}]^T & [K_{\theta\theta}] \end{bmatrix} \begin{Bmatrix} \delta^{p}_{n(x,y)} \\ \delta^{s}_{(z)} \end{Bmatrix} = \begin{Bmatrix} F_{\phi} \\ F_{\theta} \end{Bmatrix}, \tag{20}$$

where:

$$[\mathrm{M(ps)}] = \sum_{i=1} \left(\iiint \rho_i \left[\Phi^{p}_{n(x,y)} \right]^T \left[\Phi^{p}_{n(x,y)} \right] d(\mathrm{vol})_i \right), \tag{21}$$

$$[\mathrm{K\Phi\Phi}] = \sum_{i=1} \left(z^2 \iiint \left[\Psi^{p}_{n(x,y)} \right]^T \left[D_i \right] \left[\Psi^{p}_{n(x,y)} \right] d(\mathrm{vol})_i \right) \tag{22}$$

$$[\mathrm{K\Phi\theta}] = [\mathrm{K\theta\Phi}]\mathrm{T} = -\sum_{s=1} \left(\frac{z}{2} \iiint \left[\Psi^{p}_{n(x,y)} \right]^T \left[e \right]^T \left[\Psi^{s}_{(z)} \right] d(\mathrm{vol})_s \right), \tag{23}$$

$$[\mathrm{K\theta\theta}] = -\sum_{s=1} \left(\iiint \left[\Psi^{s}_{(z)} \right]^T \left[\xi_s \right] \left[\Psi^{s}_{(z)} \right] d(\mathrm{vol})_s \right), \tag{24}$$

$$\{\mathrm{F\Phi}\} = \sum_{i=1} \left(\iint \left[\Phi^{p}_{n(x,y)} \right]^T \{Fs_i\} d(area)_i \right) + \left[\Phi^{p}_{n(x,y)} \right]^T \{Fc_i\}, \tag{25}$$

$$\{\mathrm{F\theta}\} = -\sum_{i=1} \left(\iint \left[\Phi^{s}_{(z)} \right]^T (q_i) d(area)_i \right). \tag{26}$$

To obtain the eigenmodes, dynamic displacement and electric voltage, the matrix differential equation (20) can be solved using Guyan Reduction to separate the degrees of freedom of the variable displacements where the equations yielded reflect more appropriately the independent equations for electric voltage and linear dynamic displacement. At this point, the Newmark-β method was used to solve for the dynamic response of the piezo-plate vibration system.

2.2 Application of Boundary Condition

Equations (21) to (26) can be solved by using integral algebra and by incorporating appropriate geometric boundary conditions. In view of the different geometrical boundary conditions for the sensors and the base plate, special attention must be taken when modifying equations (21) to (24) to reflect these conditions.

3 RESULT AND DISCUSSION

3.1 Numerical Example

A MATLAB program was written based on the proposed theory to predict eigenmodes, dynamic displacement, and electrical voltages under transient response conditions. The characteristics for the piezo-sensor using PZT PSI-5A4E (Piezo Systems, INC) and the plate are listed in Table 1 as follows.

Table 1. Characteristic data

Item	Piezo-sensor	Plate
C (GPA)	66	207
υ	0.3	0.3
ρ (kg/m3)	7800	7870
t (m)	0.000267	0.002
d31 (m/V)	-190e-12	-
d33 (m/V)	390e-12	-
ξ_{33} (F/m)	1.602e-8	-
l x w (m2)	0.25 x 0.2	1 x 0.8

The example used a two-sided fixed-fixed rectangular plate with piezo-sensors bonded on the upper surface as shown in Figure 3. The plate was subjected to an externally applied dynamic step force of 1 Newton at node 2, at time t=0 sec.

Figure 3 shows the mesh pattern for the piezo-plate structure, consisting of 16 elements (4x4) and 16 elements (4x4) of the piezo-sensors. The Piezo-sensor was bonded over the upper plate surface. The numerical methods outlined above were used to solve the resulting finite element model using the Newmark-β method with the application of the MATLAB program.

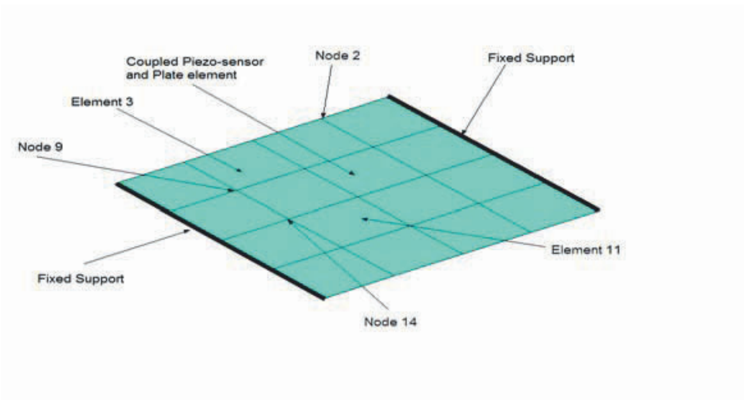

Fig. 3. Geometry of the coupled piezo-sensor and plate element.

3.2 Eigenmodes

Figures 4a to 4d show the eigenvectors corresponding to the first four natural frequencies of the composite plate-piezo structure. The eigenvector corresponding to the natural frequency of 11.22 Hz shown in Figure 4a indicates clearly the first transverse vibration of a fixed-fixed plate. Figure 4b shows the first twisting vibration mode at 14.31 Hz. The next two eigenvectors shown in Figures 4c and 4d indicate the second bending and twisting modes at 27.20 Hz and 31.23 Hz respectively. To optimize the location of the piezo patch on the plate, modal analysis can be used to understand the prediction of deflected shapes at each resonance frequency. The generated electric voltage signal from the sensors can be shown as a function of time, resulting from the transient displacement response of the piezo patch.

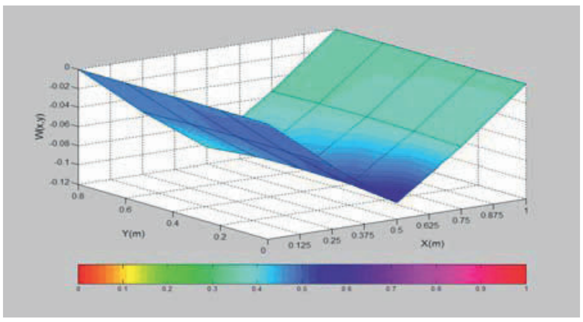

Fig. 4a. First eigenmode at ωn = 11.22 Hz

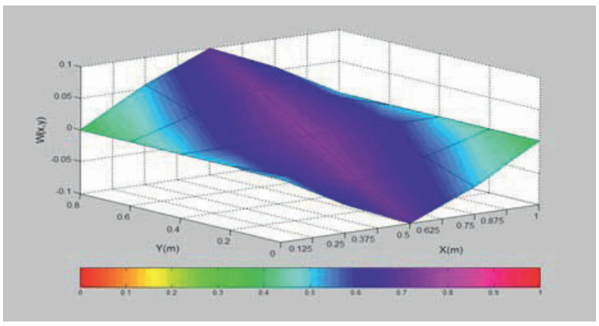

Fig.4b. Second eigenmode at ωn = 14.31 Hz.

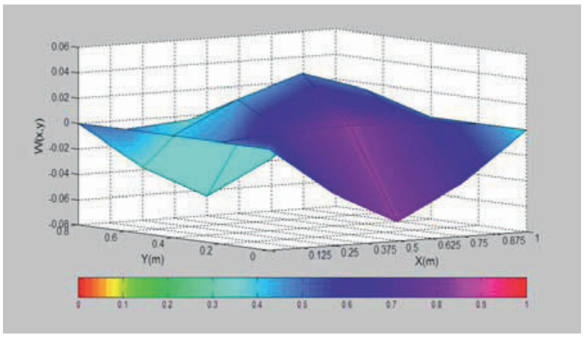

Fig.4c. Third eigenmode at ωn = 27.20 Hz

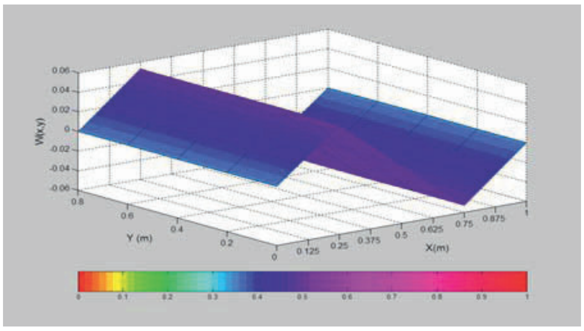

Fig.4d. Fourth eigenmode at ωn = 31.23 Hz.

3.3 Dynamic Displacement History

To illustrate the numerical method, a step force was used as an input force. As shown in Figure 3, a step force of 1N was applied to the plate at node 2 at t=0 sec. The resulting transient dynamic displacement of the plate is shown in figure 5a and figure 5b giving the resultant dynamic displacement at node 9 and node 14 respectively. To reduce the computational requirement, the number of elements in the FE model was reduced to the initial 4x4 system as shown in Figure 3. For the results shown, the sampling frequency for the simulation was chosen to be 1646 Hz. To avoid aliasing of the time domain simulation, the time history was sampled at least twice the highest eigen-frequency present in the system. Each node of the plate-piezo structure will result in a different dynamic response. Figures 5a and 5b show the response obtained at two nodes over a one second time period. Initially the simulation covered 10 seconds, to provide a fine frequency response of the structure. As evidenced from the dynamic displacement, several frequencies are present in the time waveform, with the most predominant having a frequency close to 14 Hz.

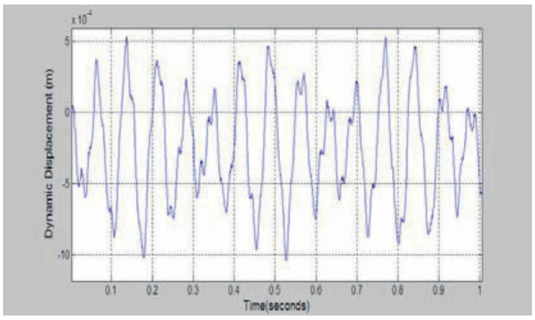

Fig. 5a. Dynamic displacement at node 9.

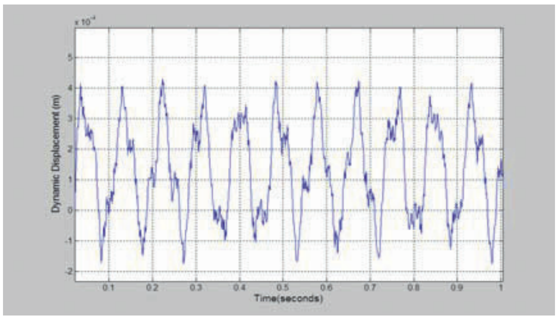

Fig. 5b. Dynamic displacement at node 14.

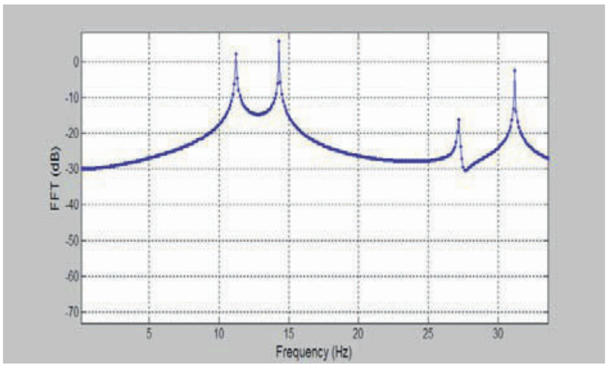
3.4 Frequency Response and the Transfer Function

The Fast Fourier Transform (FFT) was used to analyse the dynamic displacement and obtain an estimate of the frequency response of the structure as a result of the applied step force. Figure 6a shows the frequency response calculated from the dynamic displacement in Figure 5a (node 9) over the frequency range from 0-35Hz. It should be noted that the step force excited several resonances of the system over this frequency range. Closer inspection shows that these resonances are the same as those predicted from the eigenmodes as shown in Figure 4a-4d. This was to be expected as the abrupt step force would be expected to excite the resonances of the structure. The frequency response was scaled as magnitude and plotted on a dB scale.

The Transfer Function reflects the characteristic dynamic frequency and the relationship with the eigenmodes and eigenvectors of the coupled piezo-sensor and plate structure. The Transfer function refers to a specific dynamic input force and an output measurement (displacement or acceleration) of the structure. Both the FFT and the Transfer function have unique behaviour based on the chosen location for the input force and the output measurement location. Figure 6b shows the transfer function of the system calculated for the combined piezo-plate structure between nodes 2 and 9.



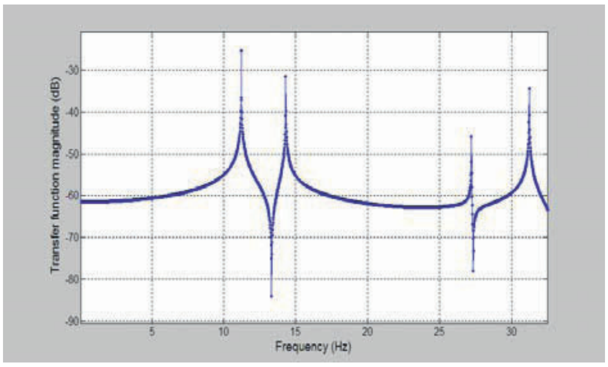


Fig. 6a. Frequency response obtained from node 9. **Fig. 6b. Transfer Function between nodes 2 and 9**

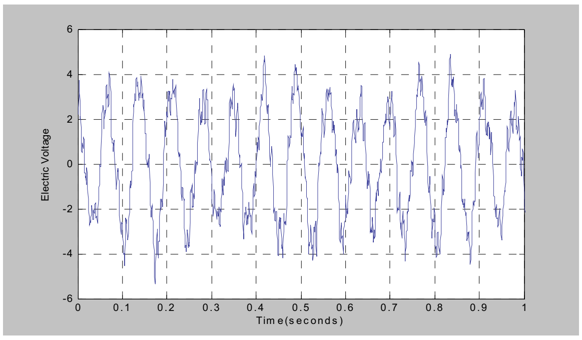
The transfer function result clearly shows the first four natural frequencies as dominant peaks, at the same frequencies as calculated for the eigenmodes shown in Figure 4 corresponding to 11.22 Hz, 14.31 Hz, 27.20 Hz and 31.23 Hz respectively. These resonances are also identical with those obtained from the frequency response as given in Figure 6a. This is further evidence of the correct simulation result obtained by the numerical method.

The theoretical model used in this paper neglects any damping effects present in the plate or piezo material. The overall heights of the transfer function magnitudes at resonance shown here are thus dependant on the frequency spacing chosen for the analysis, as the actual resonant peak in the transfer function will have infinite height. The transfer function and FFT show the direct response of the piezo-sensor bonded on the plate structure for a particular force input and dynamic response output location. The magnitudes obtained by both FFT and transfer function can be used for optimization studies to identify the best overall location of sensor patches to provide maximum piezo power output for a given frequency of input. This would require further development of the transfer function to provide the transfer function relating the input dynamic force location to the output piezo strain. For power generation optimisation studies, the FFT and transfer function relating the ambient vibration input conditions to the piezo output electric field could also be used.

3.5 Electric Voltage Time History

To further illustrate the numerical approach, the electric voltage time history resulting from the force step input of 1N, located mid-span on the fixed-fixed support of the structure shown in Figure 3 was produced. The characteristics of the electrical voltage refer to the existences of dynamic input from ambient vibration exerted of the plate where sensors are bonded on the upper plate surface. Figures 7a and 7b show the subsequent voltage time history (with zero mean) over a short time length from elements 3 and 11 respectively.



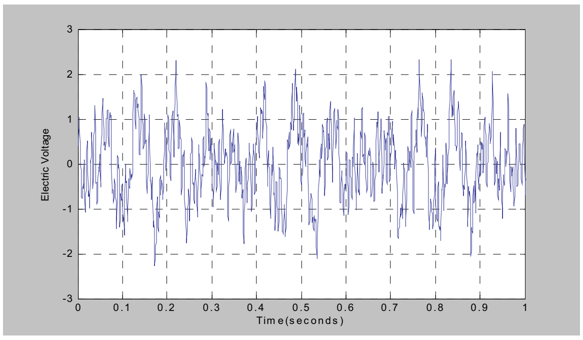


Fig. 7a. Electric Voltage at element 3 **Fig 7b. Electric Voltage at element 11**

It should be noted that the plate was initially at rest, and the input force has excited at short time interval of the structure. In this case, two elements show the characteristics of electric voltage where these depend on the strain of the elements due to the dynamic displacement. The effects of the strain generate the electric voltage at each time step of the transient response. As expected, the voltage time history contains frequency components at the structural resonance frequencies. The next step in this research will involve experimental confirmation of these results and design optimisation to maximise the power output under free and forced vibration conditions.

4 CONCLUSION

This paper has presented a finite element model of a smart structure for energy harvesting. The constitutive equations have been formulated using the Love-Kirchhoff's plate theory and piezo-sensor theory. An example was used to demonstrate the validity of the mathematical model. The dynamic equations obtained in the model have been calculated using Guyan reduction and the Newmark Beta algorithm. Acceptable results for dynamic displacement, electric potential, eigenvalues and their corresponding eigenvectors, frequency response and the transfer function have been obtained and discussed. Ongoing research is being conducted to compare the versatility of the current model with other existing models and with experimental work.

Abstract: Strategic asset management (SAM) can be simply described by two key words, which are Asset Evaluation and Asset Enhancement. Asset value herein does not imply installation cost but rather refers to a market price of the asset when sold in a competitive market. Asset evaluation is a part of business administration field and there are many verified methodologies and practical examples. Therefore this paper would rather be focused on asset enhancement. Applied to physical assets, to increase current asset value and to decrease total cost of ownership (TCO), asset management should be concentrated upon graded approaches, proactive maintenance, and long-term strategies, three key topics of this paper.

Key Words: SAM, Asset Management, Graded Approach, Proactive Maintenance, Long-term Strategy, KHNP

1 INTRODUCTION

Korea Hydro and Nuclear Power Corporation (KHNP) has introduced concept of SAM into the physical asset management processes (See Figure 1) [1,2,3,4,5,6,7]. It consists of several processes including Functional Importance Determination (FID), Performance Management (PM), Corrective Action Program (CAP), Maintenance Optimization (MO), Functional Equipment Group (FEG), Work Management (WM), Investment Management (IM), and Inventory Optimization (IO). FID process is used to classify functional characteristics of equipment and to support graded approach philosophy through preparing critical inputs to other processes. PM, CAP, MO, and WM processes allow efficient resource allocation on proactive tasks and to conduct planned maintenance prior to components' functional failures. To bring long-term strategic concept into the physical asset management, KHNP has been implementing IM and IO processes. IM process includes automated appropriation request and evaluation as well as prioritizing tools for investment decision making, and Long Term Planning. The IO process is used to define appropriate safety stock for each important material and to track obsolescence issues.

2 GRADED APPROACH

Functional Importance Determination (FID) process is used to classify functional characteristics of each component to support graded approach concept in the physical asset management. The functional characteristics of each component consist of functional importance, component type, duty cycle, and service condition (See table 1) [8.9.10].

Functional importance is determined by answering 30 questions which cover considerations for nuclear safety, power production, and regulatory and environmental effects in case the component fail to perform its intended function(s). First 20 questions target critical component determination while the other 10 questions target non-critical component determination. If the component's functional failure does not result in any one of 30 questioned effects, it is determined as no impact. No impact components are considered as Run to Failure (RTF) components on which no preventive maintenance tasks are applied and only corrective maintenance tasks are performed when failed. The Probabilistic Safety Analysis (PSA) and the Maintenance Rule (MR) evaluation results are used to define criticality in nuclear safety [11]. Functional importance is widely used in almost all asset management processes as an input for decision making.

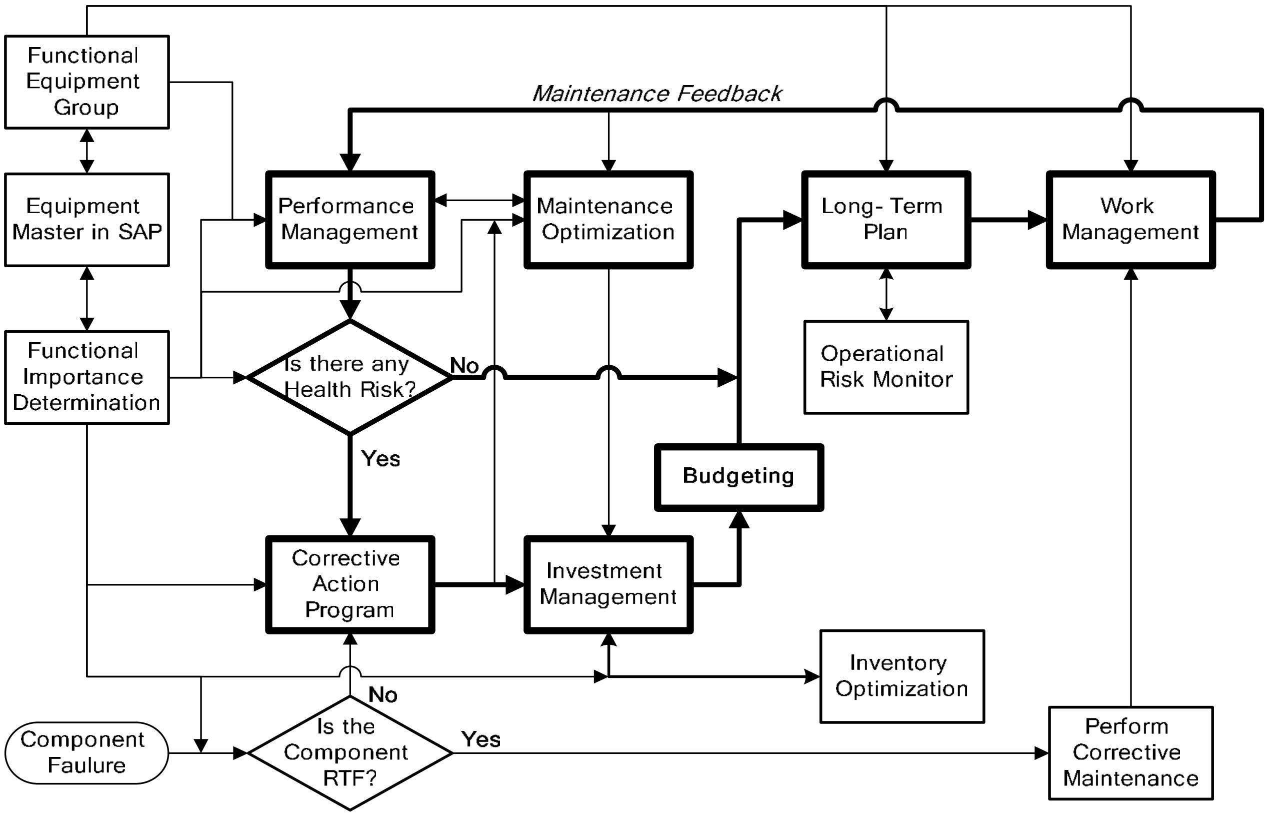

Figure 1 KHNP SAM process overview

Table 1

Components' functional characteristics determined through FID process

Characteristic	Code	Description	Comment
Functional Importance	A	Critical A	Both are fallen under "Critical" in PM program
	B	Critical B	
	C	Minor	Non-critical
	X	No Impact	RTF in PM program
Component Type	Char(4)	217 types	One type is selected
Duty Cycle	H	High	Defined by definitions developed in MO process for each component type.
	L	Low	
Service Condition	S	Severe	
	M	Mild	

If evaluated component is identified as "critical" or "minor," the component is included in scope of preventive maintenance program. We should subsequently define component type by selecting one from 217 types in terms of maintenance program since the selected component type is used directly to establish preventive maintenance program for the component in MO process. Once the component type is selected, we can define duty cycle and service condition for the component based on definitions developed in MO process for each component type. Both duty cycle and service condition are drivers for the interval of preventive maintenance task in MO process. Figure 2 shows the flowchart for the main steps of FID process.

3 PROACTIVE MAINTENANCE

Functional Equipment Group (FEG) process is used to develop FEGs which are tools used in the Work Management process and serves its purpose to electronically group works. In other words, we can easily and automatically extract work packages using FEGs [12,13,14].

A FEG is a group of equipment pieces which perform or support a certain function. Therefore a FEG boundary should be drawn based on the affecting border of a specific function. Figure 3 represents FEG development process and figure 4 shows an example of FEG boundary drawing.

The FEG process ensures consistent and accurate functional importance determination of components. After FEGs development, the functional importance of FEG is defined through FID process and the functional importance of related components can be simply defined based on the contributions to FEG's function.

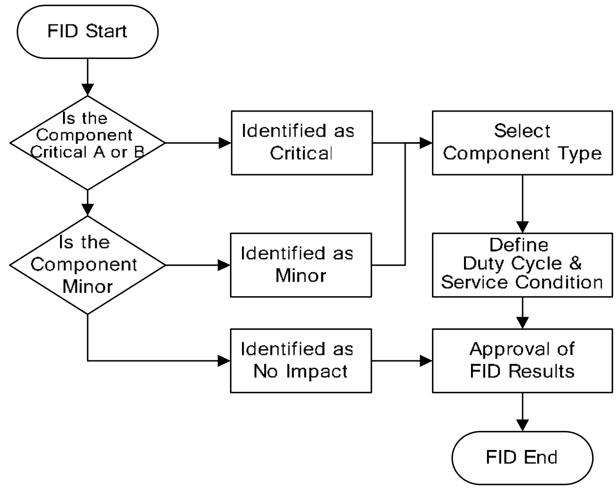

Figure 2 Overview of the FID process

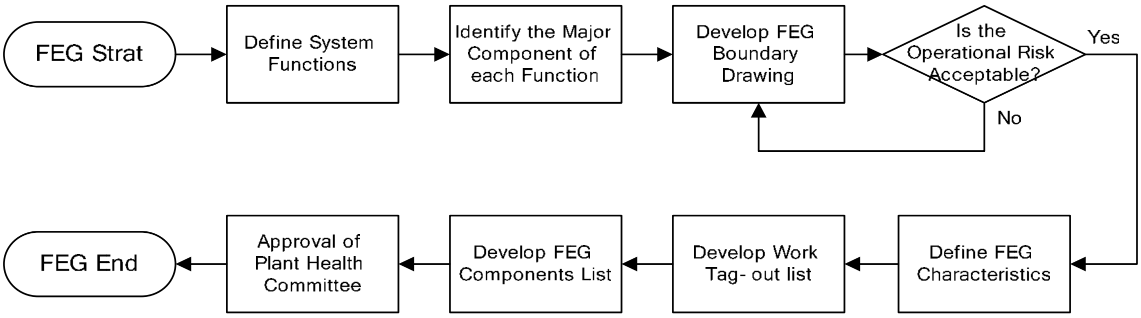

Figure 3 Simplified FEG process

Adapting FEGs into Work Management process, we can minimize the number of times important functions are removed from service thus optimize unavailability of these functions. Since FEGs are used as the basis in the Long Term Planning (LTP) and plant maintenance process, the application of FEGs reduces followings:

- The time required for schedulers to develop candidate work lists.
- Work load of Operations, Work Management and Maintenance.
- Potential for performance of work related errors.

While reducing above, FEG process maximizes the amount of work performed on-line as opposed to during planned outage while providing a link among Work-tagouts, the Maintenance Rule (MR), the Probabilistic Safety Analysis (PSA), and the Risk Monitor.

FEGs define dependencies between components and functions. Utilizing these dependencies will reduces effort necessary to assess the risk associated with the removal of components or a FEG from service.

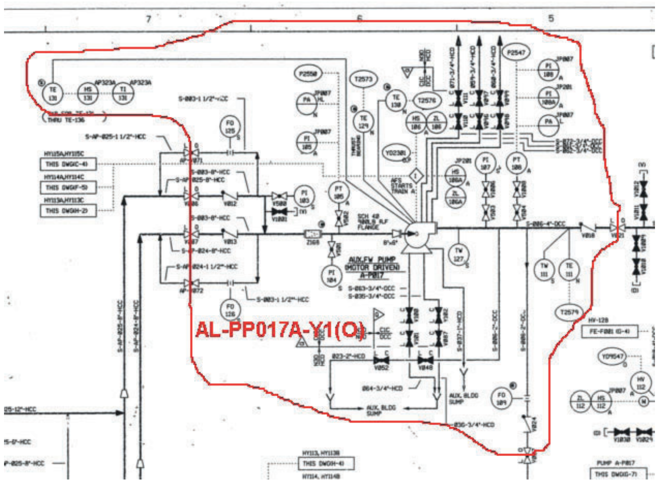

Figure 4 An example of FEG boundary drawing

Performance Management (PM) process is used to develop performance monitoring plans and to monitor the performance of plants, systems, component types, and programs according to the developed monitoring plans [15, 16]. PM process develops the utility Balanced Score Card (BSC), and establishes performance criteria and monitoring parameters for important system functions (System Monitoring Plan, SMP), component types (CMP) and programs (PMP). The BSC translates the vision and mission for the business into high level measures. Examples of performance measures included in BSC are regulatory agency's Reactor Oversight Program (ROP), WANO index, and plant/corporate Key Performance Index (KPI). BSC measures are used directly to develop lower level performance measures and to prioritize the consequences associated with health risks. Health risks include all threats to required performance level and opportunities to improve performance.

While SMPs are developed by system engineers, CMPs are developed by component engineers and PMPs are developed by program engineers. PM process ensures parameter monitoring that will identify symptoms of degradation and other types of health risks are being effectively, efficiently and consistently monitored. Most monitoring parameters are typically from condition monitoring parameters in the preventive maintenance programs which are developed in MO process.

Once any threat to plant health or gap in performance is identified, analysis of the causes is performed and required corrective actions are determined in CAP process.

SMPs are developed following completion of FID and FEG processes for a high priority group of systems. CMPs are developed prior to MO evaluation on each component types so that appropriate preventive maintenance program can be established in accordance with performance criteria in CMP.

Corrective Action Program (CAP) process is used to analyse root causes of any degraded performance identified in the PM process and to determine appropriate corrective actions.

For any type of component failure, it is directly entered into CAP process without PM monitoring. If the failed component has been classified as RTF, corrective maintenance tasks are performed without any causal analysis because RTF components are not in the scope of preventive maintenance program and only corrective maintenance strategy is applied on those. If the failed component has been classified as "critical" or "minor", consequences of the failure should be assessed whether any Maintenance Rule (MR) function is affected and tracked according to the MR program. Since the main purpose of preventive maintenance program is to identify performance degradation in advance of component failure and to conduct proactive actions, preventive maintenance program may present shortcomings for the failed component and the program is subject to a change as a result of the causal analysis.

The priority and depth of causal analysis is based on the functional importance of the affected component(s) determined in FID process. The more important component is affected, the more detailed root cause analyses are performed. Corrective actions (options for resolution) are determined as a result of the causal analysis. The options may include design changes, changes to preventive maintenance program, operational procedures, training program, or maintenance practices. All proposed options must be prioritized and the best option will be selected in Investment Management (IM) process. Action plans for the selected best option will be also developed subsequently.

Maintenance Optimization (MO) process is used to establish preventive maintenance program for each component type. The MO process is performed following completion of FEG, FID and PM process. FEG and FID processes need to be completed to ensure functional importance, component type, duty cycle, and service condition of each component have been defined in advance of MO process [17,18].

The key inputs to MO process are:

- FID results such as functional importance, component type, duty cycle, and service condition. This information can be downloaded from equipment recorder (equipment master in SAP PM Module) [19].
- Existing corporate/site preventive maintenance program (PM, PdM, condition monitoring)
- Vender recommended preventive maintenance tasks
- In-house/industry operating experiences
- Corporate/site specific performance history for the evaluated component type
- Performance criteria for the evaluated component type

PM templates are developed through MO evaluations for each component type and the format of PM template is the same as that of EPRI's PM template. The PM template includes technical basis that defines followings:

- Definitions for the component boundary, duty cycles, service conditions
- Failure locations, degradation mechanisms, and PM strategies
- Recommended PM tasks and their intervals for each MO asset group

MO evaluation for a specific component type is typically performed by an expert panel involving component engineers, system engineers, maintenance experts and external experts for the component type. MO asset group is the group of components which possess the same functional importance, duty cycle, service condition and PM basis. If any degraded condition is found in one component of an MO asset group, the other components in the same asset group are likely to be degraded and, therefore, need to be evaluated to determine whether the same degraded condition exist in them as well.

Figure 5 An example of PM template

If MO evaluation results in significant increases in the scope of PM program, health risk associated with the results of the MO evaluation should be ranked and compared to other options in IM process prior to approval of the recommended PM program to select the best option to solve the performance gap initiating MO evaluation. Once approved, the results of MO evaluation are applied and implemented to preventive maintenance program for the MO asset group in SAP PM Module.

Work Management (WM) process is needed to perform and manage scheduled maintenance works [12]. This process would be developed and implemented after other processes are established. In the new process model, all works are scheduled in Long-Term-Planning process with considerations for nuclear risk (i.e. core damage frequency) which would be caused by performance of the work candidates. Operational risk monitor is used as a scheduling sub-tool to simulate and prospect risk profile. As a result of risk prospect, some work schedule might be arranged to lower risk peak under the limited line.

All works belonging to components of a specific FEG are grouped as a work package and treated together during work management steps such as work tag-out, work permission, post-maintenance test, and returning to normal position. Performing preventive maintenance works, technicians check whether the component is as degraded as expected in MO process or not and define as-found condition code according to component's degradation condition. The coded as-found condition information is fed back to MO process and used to optimise maintenance strategy. In case reported as-found condition is better than expected, we can extend task interval and/or eliminate the related task from PM template. In the other hand, we should consider to shorten task interval and/or to add effective task(s) into PM template if the condition is worse than expected.

4 LONG-TERM STRATEGIES

Investment Management (IM) process is used to evaluate and prioritize all of the recommended options that are proposed during CAP and MO processes to resolve the health risk [20,21]. Analytic Hierarchy Process (AHP) tool is being developed to support evaluation and prioritization of these options [22]. The action plans for the selected best option are developed and approved by Plant Health Committee. Once the action plans that need to be funded are approved, Appropriation Requests (ARs) are issued in the SAP IM module and passed onto budgeting process to ensure the funds and internal resources are available to support implementation of the action plans.

If the government's approved budget is not enough to support all ARs in the specific time frame, feasibility assessment for ARs may be re-performed and defer implementation of an approved but lower ranked ARs to another budgeting period. Since KHNP was invested mainly by Korean government, the amount of annual budget is controlled by the government.

All ARs, even deferred and unbudgeted, are a part of input to **Long-Term Planning (LTP)** process. Other parts of input to the LTP come from all work activities defined in previous processes such as FID, FEG, CAP and MO. Long-Term Planning (LTP) is a cycle schedule for the plant and developed based on FEGs using FEG characteristics and rules. The LTP is used to leverage the allocation of resources and risk across FEG work windows to reduce the number of times important functions are removed from service, and to optimize unavailability of these functions. The LTP becomes gradually elaborated through budgeting process. Although LTP development for the next cycle is typically completed in advance to ensure enough time to provide required resources, the minor work items may be added at the end of the current cycle of the plant.

Inventory Optimization (IO) process is used to define appropriate safety stock and track obsolete spare parts and materials [23]. The wider application of IM process can be called as Supply Chain Management (SCM) in modern business management.

The IO process ensures the right part or material is available at the right time at the right cost by maximizing the availability of parts and materials while minimizing the cost through innovative procurement and stocking strategies.

Equipment BOM information and functional importance are key inputs to IO process to define safety stock for the important materials used in critical components. The equipment BOM provides electronic linkages between components and materials required for the maintenance works. We can easily calculate how many components are subject to maintenance work and therefore determine required amount of materials, provided that equipment BOM has been accurately developed. The PM program established in MO process for the component type provides feedback to IO process on the frequency of certain material required for replacement or refurbishment tasks. Eventually the number of materials which should be in stock is estimated using equipment BOM and PM program. This number is then weighted with functional importance to define the safety stock for the material.

Other weight factors to define safety stock for the material are the lead time to purchase the material and obsolescence issues on the material. If the material can be purchased at the right time, the safety stock for the material can be decreased. Therefore all suppliers' capability to meet critical deadline for the delivery of importance materials must be demanded and tracked. If any equipment or material is already obsolete or seems to be obsolete soon, a search for alternate items should be initiated or decision should be made to replace the obsolete component with an equivalent model.

5 CONCLUSIONS

KHNP has been implementing a number of initial SAM processes such as FID, FEG, PM and MO. The FID, FEG, PM processes have been completed corporate wide while MO process has been implemented as a pilot project on a plant. KHNP also has plans to begin implementation of other processes such as CAP, IO, IM and LTP in this year.

The major advantages of SAM processes can be summarized as:

i. The limited resources are allocated on more valuable tasks for the importance assets through Graded Approach.

ii. The focus of maintenance is moved from the reactive to the proactive to reduce unexpected equipment failure causing high plant health risk and huge O&M cost.

iii. Analysis, prioritization and management of investment plans and preparation of contingency plans for the upcoming risks can be established in advance through Long-term Strategies.

KHNP has performed Business Process Reengineering (BPR) for several SAM processes as part of the ERP project in 2002. However, it took quite long time to implement SAM processes due to lack of organization's awareness for SAM concept. As time goes by, with continuous effort to educate and bring positive changes to the way KHNP works, most people began to perceive the advantages and acknowledge necessities of SAM processes. With SAM processes, many employees showed satisfaction at the value added works they performed. KHNP became greatly confident in the successful implementation of SAM processes which entail the advanced concept for managing physical asset based on graded approaches, proactive maintenance and long-term strategies.

EXPERIENCE WITH EDUCATION IN MAINTENANCE AND RELIABILITY ENGINEERING BY OFF CAMPUS LEARNING

Ray Beebe

Senior Lecturer, Monash University School of Applied Sciences and Engineering

Abstract Physical plant assets are tending to remain in service for beyond their design lifetime. Arguably, a greater professional input is needed into the maintenance and reliability engineering of these assets, yet few universities offer such content in undergraduate engineering degrees. Accordingly, postgraduate programs have been developed. Those offered by off campus learning are more likely to meet the needs of engineers, many of whom work remote from the possibility of regular attendance on a campus. In the now 20 years since their inception, hundreds of engineers and other technical professionals have completed the Monash University programs. These have continued to evolve, and take appropriate advantage of advances in learning technology. This paper describes the development and lessons learnt during the Monash experience.

Keywords: education, maintenance engineering, reliability engineering, distance education, off-campus education, distance education, flexible learning, internet

1 INTRODUCTION

Many industrial assets are being required to not only remain in service beyond their intended design lifetime, but also to improve in performance. The focus of asset management has therefore moved beyond merely keeping plant functioning into the area of reliability improvement. A clear impact on the bottom line of a business must be shown. The term "maintenance" unfortunately implies a reactive role, but today it is increasingly seen as an investment in production capacity rather than just a cost to be borne.

Maintenance and Reliability Engineering is, therefore, clearly a professional engineering role offering great career challenge and excitement. Reliability Engineering is well developed in the military and in some technical areas such as electric power transmission. For the above reasons, these techniques are now relevant to industry in general. In Australia, the need for education of practising engineers in these areas led to programs taught by off campus learning.

Some universities around the world have recognised the need for such education, and have developed programs to suit. Some examples are: Hines (2005), Beebe and Houston (2001), Champaneri (1998), Knezevic (1997), Kerlin and Shannon(1997).

Off campus learning (sometimes called distance education) is the only practicable way of proving continuing professional development to those in this field, many at remote sites. It matches the needs of engineers wherever they live in the world. Also, research shows that:

"*Flexible learning is private learning based on course materials, providing access to teaching staff and two-way communication. Self-motivation is required, but the integration with the work scene leads to a higher capability outcome than if classroom-based" (Townsend & Cairns, 2003).*

2 ORIGINS OF THE MONASH MRE PROGRAM

The Graduate Diploma was developed in the mid-1980s by Len Bradshaw (who later left to publish MAINTENANCE Journal). The units of study were written by School staff, and differ in style in accord with academic initiative. Later, a Graduate Certificate was created for completion of the first four units.

In 1989, Dr Yousef Ibrahim developed a second graduate certificate: in Reliability Engineering. Funding supporting the development was from available Government and industry sources. It was written and is taught entirely by practising reliability engineers. The Master's degree was first offered in 1999, and designed to combine more reliability engineering material with the engineering maintenance management topics.

In 1999, an agreement was reached with the University of Tennessee at Knoxville, USA, to collaborate in offering these programs in North America. The UT Maintenance & Reliability Centre acts as the Monash agent, and arranges the Residential School in Knoxville, conducted by Monash staff.

3 THE PROGRAMS TODAY

The aim of the programs is to equip people with the knowledge, skills and attitudes to improve the life cycle performance of plant assets and thereby improve the performance of their business.

Study by off campus learning is usually half the study workload of on-campus students, but students can take a lesser load. For postgraduate continuing education, universities in Australia and the UK generally require one year of full-time study or equivalent for a *Graduate Diploma,* with a *Graduate Certificate* half of that. Requirements for Master's *degrees* vary. Two students completed the Master's degree in one year full-time, and this possibility may be attractive to others in a break between full-time work. The Monash programs in this field are:

- Graduate Certificate in Maintenance Management (GradCertMaintMgt)
- Graduate Certificate in Reliability Engineering (GradCertRelEng)
- Graduate Diploma in Engineering Maintenance Management (GradDipEngMaintMgt)
- Master of Maintenance and Reliability Engineering (MMaintRelEng)

Direct admission into the Master's is available to engineers with an Honours degree in engineering, or with a pass degree and honours equivalent experience. Admission into the Graduate Diploma is available to lower grade graduates in engineering and graduates in other professions. Others may articulate following completion of the Graduate Diploma with high grades.

There are many non-degreed engineers and others working in maintenance and reliability, often with significant responsibility for staff management or planning of maintenance. Anybody enrolling direct with Monash can study units on a "not-for-degree" basis. On completion of two units with an average grade of 65%, admission into either of the Graduate Certificates is allowed with full credit. Completion of either Graduate Certificate with 65% grades entitles articulation into the Graduate Diploma and later the Master's degree. Many such people are of high calibre and some have completed Master level.

Assessment varies with the units, with all having progressive assessment via assignments submitted through the year. Most have an examination as well, are arranged anywhere in the world. Some units have assignments done in groups at the Residential School (see later).

Students usually study four units per year, but some choose less. An unusual feature compared with other programs and other universities is that the teaching period for all units is the full year, from late February to October, rather than the more usual semester basis. This gives added flexibility to manage any workplace, personal or family circumstances.

Some hundreds of people have completed the programs, and their feedback is overwhelmingly positive. In 2005, most came from every State in Australia, but also from 13 other countries. In 2006, the programs have students in every inhabited continent. Wherever they live, students interact with teaching staff in exactly the same way as those in Australia.

4 STUDY MATERIALS

Based on feedback from students, the study materials continue to be produced in print based format, updated each year and rewritten regularly as appropriate.

There are generally three parts, with some units also having a CD of images, short videos or other resources:

- Unit Guide, which contains information about unit administration and gives the assignments and other assessment detail (many assignments relate to the student's workplace);
- Unit Book, which contains the Study Guides. These are detailed guidance to the subject matter, referring to the textbook and Reader/s where appropriate. The style of these varies with the topic and text;
- Reader, consisting of selected relevant technical papers and articles. Although items are reviewed annually, some items remain that are regarded as classic in the field.

Most units require a textbook, which is usually bought by the students. An exception to the above is the Maintenance and Reliability Engineering Project, which is workplace-related.

5 RESIDENTIAL ATTENDANCE

Study in the maintenance management units requires participation at one Residential School of 3.5 days in each year at the Gippsland Campus in Churchill. The School for the first four units is held in March-April. A feature of the September School is the presentation by students of formal papers on their project. With upwards of 20 such papers, much is learnt by all in what is effectively a quality mini-conference.

The Schools have activities from day into evening. Contents include lectures, specialist guest speakers, student presentations, group activities, and usually a relevant site visit. The Schools are regarded as essential by the students, with networking being a highly valued component. A single School each year is run in Knoxville, combining the above features.

6 TEACHING

Unit Advisers comprise full-time academics, who also have other teaching, management and research commitments, and sessional staff, who are practising engineers. Some have international reputations in their field. The author has been Co-ordinator since 1996, joining 4 years earlier following 28 years in the power generation industry.

Students maintain contact with the Unit Advisers mostly via e-mail, and less so by telephone. Assignments are submitted by e-mail, and are responded to with feedback by the Unit Adviser after grading.

The program is offers a graded coverage of subject content, designed to provide students with knowledge, skills and attitudes in each subject area. Students are expected to read widely, and present responses to assignments which indicate their understanding and appreciation of the application of the material. Sometimes there are no clear right or wrong answers!

Continual additions are made to the Monash Library collection in the MRE field, and students are encouraged to use its mailing out service. Use of other libraries is available where co-operative arrangements have been agreed with several other institutions. Electronic resources are a rapidly growing source, with electronic journals and databases enabling access anywhere in the world at a time that suits the students. Many textbooks are available in electronic versions, where each "copy" held can be accessed on line by one person at a time. Some students have access to texts and other resources held by their companies.

7 THE MOVE TO WEB-ENHANCED TEACHING

As with many other aspects of life, the computer and internet also provide great possibilities for teaching, with the aim of improving quality (Benson, 2003). Our associates at the University of Tennessee developed six units of study in this field and trialled them successfully (Hines and Shannon, 2000). A complete master's degree in a closely associated field is now proposed (Hines, 2005). Teaching takes place synchronously, i.e. with the students all logged on at the same time. Students and teacher can communicate with each other online. The teacher's presentation is recorded for later access by students.

Monash University has adopted WebCT VISTA for all units, following initial use of WebCT CE. This is called MUSO, for "Monash University Studies Online" and is the generic term used in the rest of this paper. In the interests of extending off campus delivery, development funding was provided for this program. Each Unit Adviser as the content specialist was assigned an Educational Designer, qualified and experienced in teaching. The Unit Advisers and Educational Designers worked together to learn MUSO and develop the detail of the units.

The three broad pedagogical approaches identified for development of MUSO templates rely jointly on adult learning principles and resource-based learning, and are (Bruhn, 2004):

- Basic collaboration – where teaching is to complemented with some basic collaborative tools (e.g. discussion groups);

- Case-based or Problem-based – where these philosophies are used in a unit to give selective release of cases and flexibility in organising learning environments to support students working in small groups, and the style adopted here:

- Mixed mode – for on-line interaction, provision of content offered on campus or via off campus print formats, and uses various tools to support learning: the approach taken with these units.

8 FORMULATION OF MINIMUM STANDARDS FOR WEB-ENHANCED DELIVERY

In devising a minimum standard that should apply to the units when adopting a mixed mode approach to the delivery of units online the following criteria (Bruhn, 2004) were developed for the WebCT site(s) to:

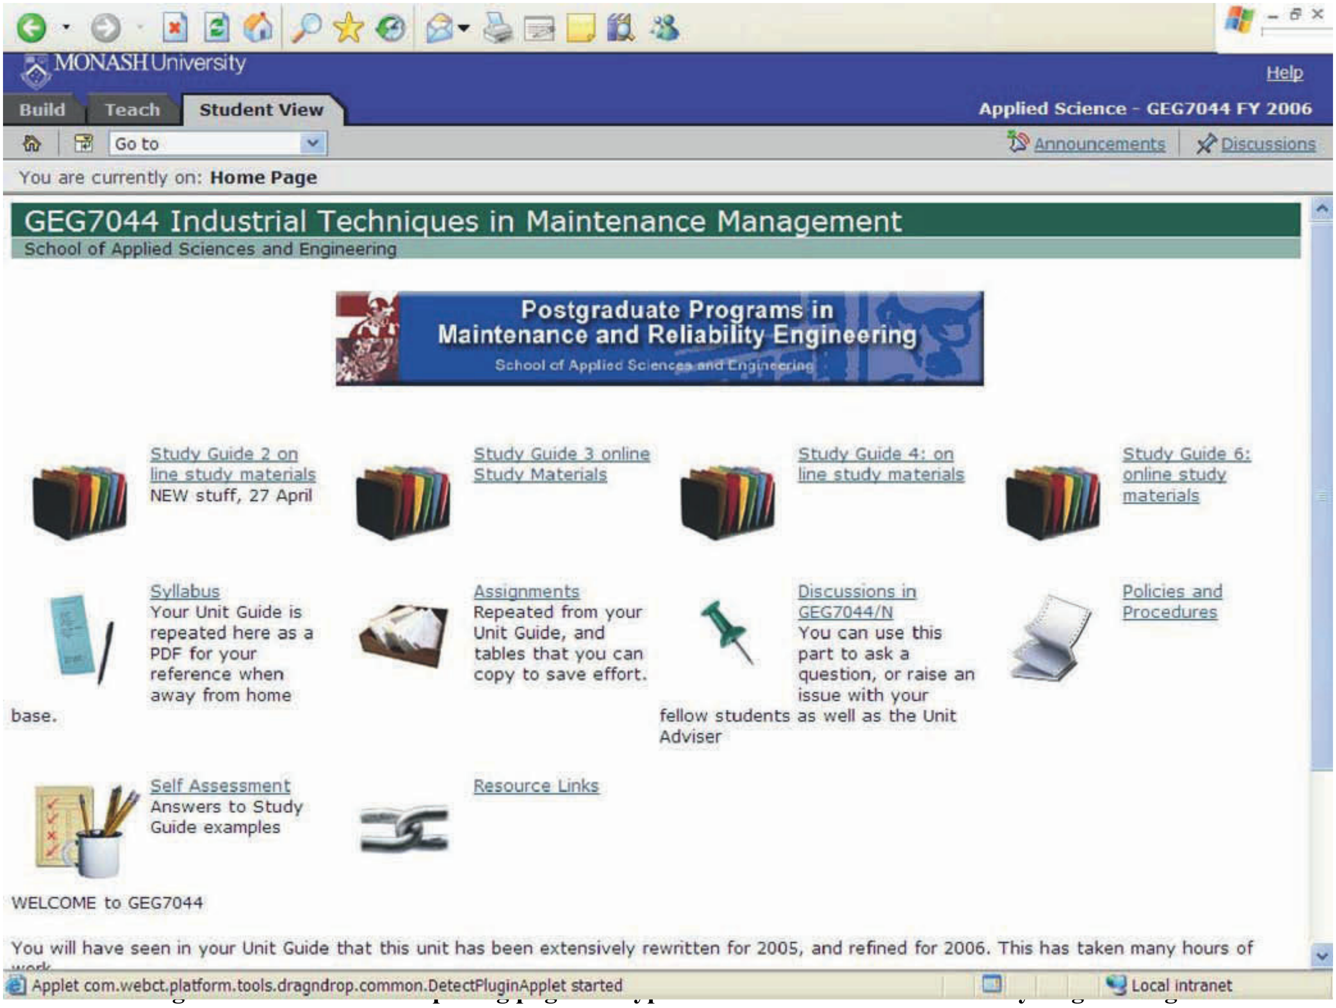
- Easy to navigate and be strong on 'visual signposts', that is, graphics and/or text on the web pages should be self-explanatory as to what will be presented if the student clicks on that icon.
- Have clearly expressed objectives or learning outcomes to define content, assessment tasks (both formative and summative) and online learning activities.
- Provide content in a form appropriate for online delivery, or give directions/guidance as to where it is located.
- Complement/enhance any print materials and not just duplicate them.
- Provide opportunities for 'active learning' through the careful integration of interactive learning tasks (which may include interactive multimedia), that is, the students should engage in activities which require them to do something (e.g. role play within a game, manipulate models by changing a range of variables, visit a web site and do a critical appraisal of its features).
- Provide opportunities for students to assess their progress in acquiring knowledge and skills through the use of quizzes and other online self-assessment activities (formative assessment) and as preparation for summative assessment tasks.
- Provide an efficient means of linking to other online resources both within and external to the University and have the capacity for the academic to provide up-to-date information that becomes available during the semester.
- Provide the means by which students can communicate with the academic or fellow students, either informally or through structured discussion groups.
- Provide the means by which students can access important information about the unit and critical dates during the semester [e.g. unit structure, prescribed texts, assignment details (including assignment and examination dates)].
- Be flexible in design to allow for changes to be incorporated as required during the semester based on the identified needs of particular cohorts of students and/or variations or additions to the content.

9 THE DEVELOPMENT PROCESS

It was decided early that internet use would be non-synchronous, as the students are spread across many time zones. It was also firmly established that the development was fundamentally being made to improve the quality of teaching and learning, not to save money, nor to just appear to be progressive. Active learning was the aim, through careful integration of learning tasks, so that a student would be required to do something, rather than be a passive reader. In some cases, the existing materials included these features, and enabled ready adaptation into a web-enhanced approach. Multi-media expertise was utilised where appropriate.

It was also decided that the study materials would remain in print-based format, supplemented with CDs for sound, images, and some documentation. All students are required to have internet access, although it is still not expected yet that all students have broadband access. Merely transferring the study materials away from provision in print to having them on-line, such that the student needs to download and probably print them, is not the best use of the internet. High quality images open quickly from a CD, but can take some time to download if on line.

The opening page of one unit is shown in Figure 1. The material content can be built up and readily modified by the Unit Adviser, who has "Designer" access.



Content pages vary with unit and teaching style, but may comprise:

- Syllabus: an outline of the aims of the unit, its assessment and administrative details.

- On-line study materials: a section corresponding to appropriate Study Guides (up to 8, depending on the unit).

- Self Assessment Questions: each Study Guide contains Learning Activities, with responses given at the end of each print section. Self Assessment Questions are available for each Study Guide, and are answered on line. After the student enters a response, the "official" answer is shown. These can be graded, but it was decided not to do this, but to use them as opportunities for students to assess their progress in acquiring knowledge and skills.

- Resources: a display of hot links to selected web sites with information relevant to the unit material. These can be chosen to open in a new window.

- Communication: consisting of two components: Discussion groups for interaction between students

Assignments: a summary or repeat of the requirements given in print.

10 EXPERIENCE

The extent of site development and particular features varied between units, as it was not desired to have the teaching pattern standardised, but to allow for individual teaching and presentation styles, as with all university teaching.

The varying number of students was also a factor, such that experiences differed between units. It took some time for both teachers and students to get familiar with MUSO, and several had some difficulty utilising all the required features. MUSO provides on line facility for drafting and eventually submitting assignments. A back-up arrangement for submission of assignments had been set up, and was in fact used by most. The intent was intended that Unit Advisers read the assignments, added comments and assessment grade on screen without printing them. Most managed to obtain this skill. However, submission by email direct to the Unit Adviser has proven to be simpler for all concerned and is now our standard method.

Towards the end of the second year of offering the units this way, formal evaluation was performed by a Senior Education Designer who had not been involved. A questionnaire was used to evaluate student experience in each of five units. For one unit, a two-hour focus group was also held. Sixteen of the 30 students in this unit responded, with some points that emerged as follows:

- Time is needed to obtain sufficient familiarity with MUSO and the unit site. Several teething troubles were encountered, and most overcome as the year progressed.

- The on-line resources were inconvenient to access compared with the print materials, and some saw as merely being a repeat of the paper materials and not adding value to them.

- Not all could access the internet when away from home when they wished to do some study.

- The volume of reading concerned some, and it is possible that this may be less of a problem for those who had previous tertiary study. Some felt that the site should include add-on information to the print materials. Student-selected resource links were suggested by some.

- Discussion groups did not occur because students did not raise issues. These need to be set up by the Unit Adviser. An early one could be for students to post introductory information about themselves (as most had never met). Although there are several public discussion boards in the maintenance and reliability engineering field, these are apparently not used as widely as it appears. As many students travel away from internet access in the course of their employment, structured discussions may be difficult to introduce.

- The self assessment questions were used by some for revision prior to the examination (which was conducted in the normal fashion). Some felt that if they had been graded and thus included in the overall assessment for the unit, they would have been given earlier attention. General experience seems to be that is that items will not be attempted unless they are required to be completed, whether assessed or not.

- Many favoured an introductory video to accelerate the learning curve for the start of the unit.

- Overall, the students rated the unit as “very good”, and much was learnt to improve it for future years.

Later, all of the units were rated against the formulation criteria. This unit fully met the criterion in 7 of the 10, and partially in the others.

11 WHO TAKES UP MRE STUDIES?

In 2005, a questionnaire was developed in conjunction with Dr Melinda Hodkiewicz of UWA and sent to a range of current and recent students. 87 responses were received and analysed. The average working life of respondents was 16.7 years

The **discipline** of engineering etc. most strongly represented was Mechanical (66%), followed by Electrical (16%), Electronic/mechatronic (7%), Management (3%), Other (6%) and Chemical (2%). 25% of respondents **described their jobs** as "reliability engineers", 47% are in "maintenance" (Engineer, Planner, Supervisor, Technician) and 23% are "managers". The two occupational terms are not used consistently. Hodkiewicz et al (2004) built on O'Malley et al (2003) and suggested that the distinction should be:

- Reliability engineers are not governed by day-to-day operations, but have a strategic focus. They develop programs that provide the framework for maintenance.

- Maintenance engineers are responsible for immediate equipment functionality and implement strategies developed in co-operation with reliability engineers.

Table 1 shows the **industry** where students in this sample work by percentage:

Mining/mineral processing/refining	37	Petrochemical	5
Defence (military & civilian)	17	Government	2
Manufacturing	15	Warehouse/logistics	2
Utility (gas, water, power)	10	Timber/pulp & paper	2
Service Provider/Consultant	8	Transport (air, road, rail)	2

12 WHAT DO STUDENTS CONSIDER SHOULD BE INCLUDED IN MRE COURSES?

The topics considered were in two categories. Each topic had some students who considered that they were competent already (remember that these are not raw engineers). The survey results are shown in Figure 2 (technical topics) and Figure 3 (management topics). Note that some of these are not included in traditional bachelor degree programs.

The Top 3 technical were: Reliability and Risk Based Inspection methods
Failure modes and effects analysis
Failure mechanisms & Root cause analysis

And the Top 3 management: Life cycle costing and NPV methods
Risk assessment
Budgeting and capital expenditure

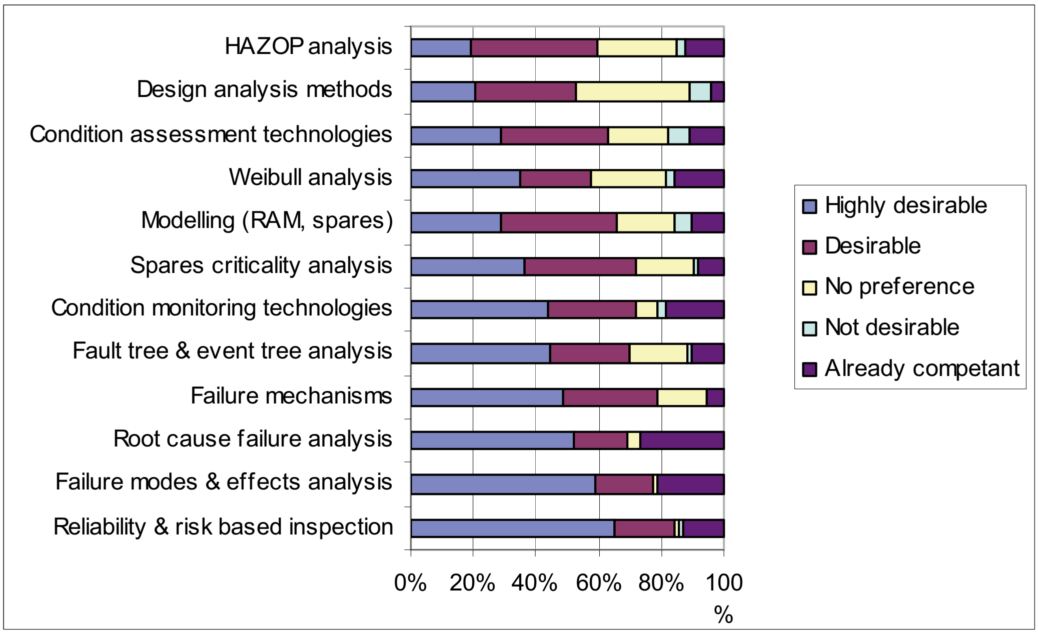


Figure 2: Value of technical topics in MRE study according to student survey (N=87)

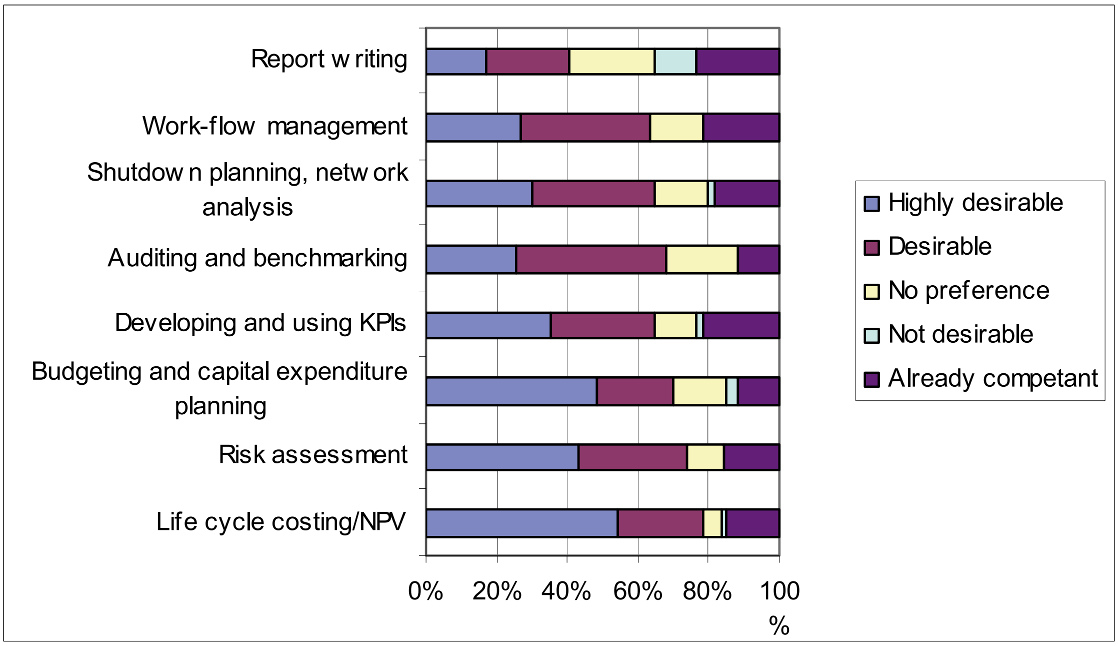

Figure 3: Value of technical topics in MRE study according to student survey (N=87)

13 WHAT OUTCOMES HAVE GRADUATES EXPERIENCED OR EXPECT TO EXPERIENCE?

Students have not been asked this until now, but reports have been received over the years of promotion and new jobs where the studies have been a major factor. Figure 4 shows the survey results. Worthwhile outcomes were apparent across the board, although the data could be interpreted as showing an individual highly satisfied in all areas, or in only some!

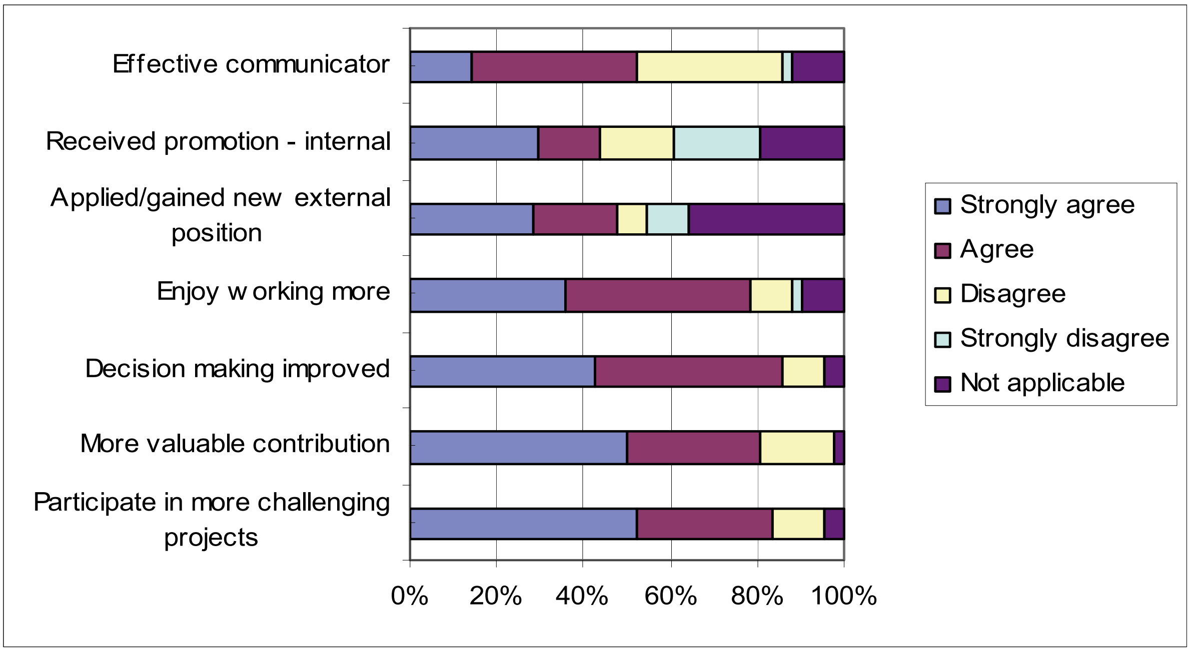

Figure 4: Outcomes experienced or expected from MRE study according to student survey (N=87)

14 CONCLUSION

Experience with web-enhanced delivery of off campus learning in maintenance and reliability engineering shows that improved learning is possible, but significant overall benefits should not be expected initially when compared with paper-based print materials alone. This should improve as higher performance internet access becomes more widely available.

In developing a unit of study for web-enhanced delivery, the academic must try to use opportunities possible on-line that cannot be provided easily in other ways. These must be integrated fully with all the other components of the study materials in a unit in line with the overall objectives of that unit: the only reason for having web-enhanced learning is to do a better job.

The survey gave some insights into what students consider about the value of topics in MRE programs, as well as the value of postgraduate study itself. It is overwhelmingly thought to be worthwhile, and gives the basis for further research into topics that should be included or emphasised. Some points:

- Reliability is a job people “move” into, not an early career choice.
- Those in the reliability field have a wide variety of educational backgrounds and experience.
- Considering the population of engineers, relatively few have undertaken PG reliability education.
- Many reliability professionals undertake targeted education in the form of university-coordinated postgraduate studies, vendor- supplied or institution organised training.

MONITORING CENTRAL GLAND LEAKAGE ON COMBINED HP-IP CASING STEAM TURBINES

Ray Beebe

School of Applied Sciences and Engineering, Monash University

Ray.Beebe@eng.monash.edu.au

Abstract: Steam turbine generators, the mainstay of electricity production, are increasingly required to run for well beyond their intended lifetime. As opening up machines for inspection is expensive, owners need to consider all relevant information in making the decision. Deposits on blades and erosion of internal clearances reduce machine efficiency and output, and can be detected and monitored using condition monitoring by performance analysis. Data obtained before and after overhaul also reveals whether any restorative work achieved the expected improvements in performance. Many large machines, including an increasing number in Australia, are of the compact combined High Pressure–Intermediate Pressure opposed-flow casing design. Increasing internal steam leakage from entry into the high pressure section to the intermediate pressure entry section has a large effect on output and efficiency. This flow through the central gland packing cannot be measured directly. Using a case study, this paper describes a method of estimating it by test that is sufficient for routine condition monitoring. The test explained observed poor performance that had led to extensive modifications to the boiler.

Keywords: steam turbines, diagnosis, condition monitoring

1 INTRODUCTION

Steam turbine generators, the mainstay of electricity production, are increasingly required to run for well beyond their intended lifetime. As opening up machines for inspection is expensive, owners need to consider all relevant information in making the decision. Condition monitoring by performance analysis is one important tool to help in such major maintenance decisions, and can point to the presence of deposits on blades and erosion of internal clearances that reduce machine efficiency and output. (McCloskey et al, 1999). Data obtained before and after overhaul also reveals whether any restorative work achieved the expected improvements in performance.

Basic condition parameters are the Valves-Wide-Open Output and Enthalpy Drop Efficiency (ASME, 1985 and Beebe, 2003). Tests are required with special calibrated instruments, but recent experience shows that useful results can be obtained on units with DCS (Digital Control System) (Beebe, 2005).

Most large steam turbine generators have separate High Pressure and Intermediate Pressure casings, followed by one or more Low Pressure casings, virtually always in opposed flow (also called double-flow: steam flows in opposing directions from admission). The greater the number of casings, the more expensive the machine and the longer the building to house it. Advances in design and materials of Low Pressure blading have led to longer last stage blades, such that a single LP casing is now possible in sizes of up to 500MW.

Another design layout that results in a more compact machine is when HP and IP turbine sections are combined in one casing in double-flow style. This arrangement is used in many sets in Australia from 350MW to 500MW capacity and elsewhere up to larger capacities. These sections have a central gland between them, sometimes known as the N2 packing (Figure I).

Even in good condition, due to the difference in steam pressures, steam leaks from the HP turbine through this gland into the IP inlet area. This leakage must be known, or at least estimated, to obtain the heat rate (i.e. inverse of the thermal efficiency) of the turbine at the acceptance test. It also reduces the effective enthalpy of the IP section steam flow, so that the enthalpy drop efficiency on test can give a misleading indication of IP blading condition (Cotton, 1993). This is important in condition monitoring of thee type machines.

This paper describes experience with a design of large steam turbine that had a poorer heat rate on their acceptance tests than expected. In early operation, difficulties were experienced in the boiler that required modifications. Special tests run later on the turbines revealed the internal leakage to be a major root cause of the boiler problems.

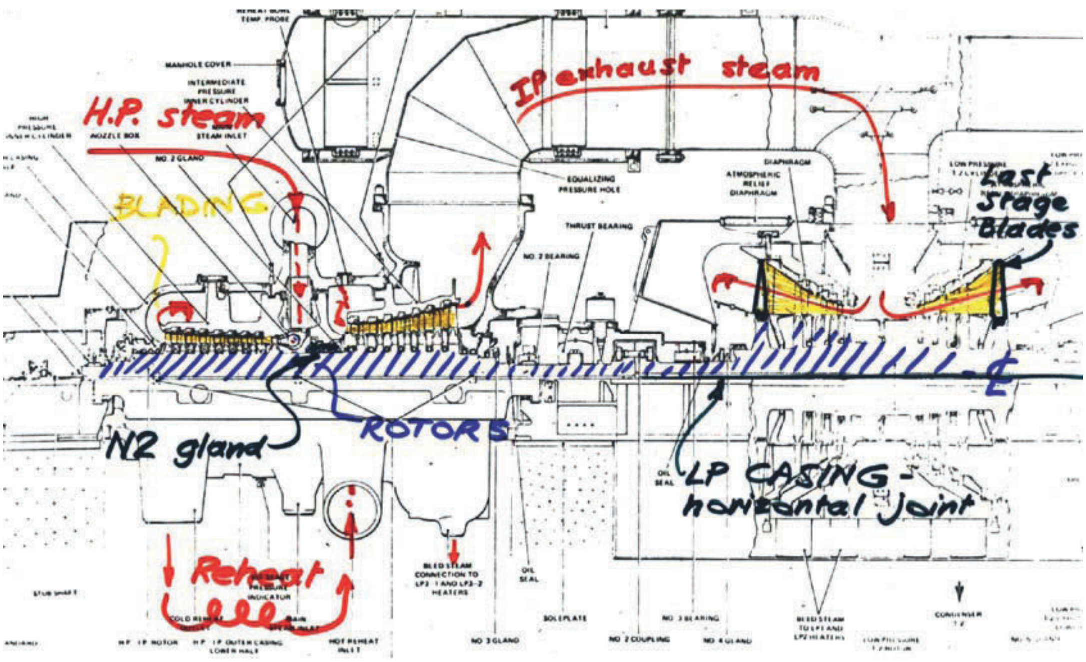

Figure I: cross-section of a typical HP-IP turbine.

2 IMPACT OF N2 PACKING LEAKAGE

This leakage is usually taken as about 1% of main steam inlet flow, although has been found to be reduced to 0.5% with a casing retrofit (Hogg & Stephen, 2005). This leakage, and any increase, means that some of the steam initially supplied to the turbine does not pass through the HP blading, then through the reheater, and back to the IP turbine, but instead directly to the IP blading. As the leakage flow effectively circulates in a non-reheat cycle of lower efficiency, N2 leakage can have a dramatic effect on turbine heat rate/thermal efficiency and output. Typically, an increase in N2 leakage of 1% of initial steam supplied to the turbine results in an output reduction of about 0.3% and efficiency reduction of about 0.16% (Koch, et al 1988).

Further leakages may occur from other places, according to the design of the machine, such as through eroded or distorted horizontal joints, and from around the main inlet pipe piston-ring type seals are possible.

As mentioned, the enthalpy drop efficiency of turbine sections is a prime parameter (ASME, 1985 and Beebe, 2003). As the N2 leakage flow enters after the steam temperature into the IP casing is measured, and is at the enthalpy corresponding to the value from the HP turbine expansion at the first stage pressure, it is lower than the enthalpy of the steam supplied to the IP turbine from the reheater. Hence the steam entering the IP blading at the IP bowl in total does not have the enthalpy of the main inlet mixture. The result is to give an incorrect high value of IP enthalpy drop efficiency. Therefore, in routine testing of such turbines, if an increase in IP enthalpy drop efficiency is found, then increased N2 gland leakage should be suspected.

Most turbines have interleaved labyrinth type seals, but a later brush seal technology has been developed by one manufacturer (Hogg and Stephen, 2003). The HP-IP rotors are usually flexible, such that they pass through a bending critical speed during starting up and coastdown operation up to or down from normal service speed. As this gland is near the centre of the rotor span, the consequent rotor deflection can cause rubbing, and thereby increase the clearances. Another packing type available new or at retrofit is retractable to prevent rubbing. They close in to running clearances when the turbine is at service speed.

3 HOW TO FIND THE LEAKAGE FLOW

Methods of finding the leakage steam flow are given in Cotton (1993) and industry papers not published for general access. Experience such as reported by Koch, et al (1988) and Staggers and Priestley (1990) has led to an EPRI research project (Haynes et al, 1995).

It cannot be measured directly without installing a bypass pipe around the emergency blowdown line, and including a flow measurement device. (The blowdown line and valve are fitted on most designs to release steam entrapped in the casings when the machine is tripped).

Another method requires IP enthalpy drop efficiency tests to be run before and after opening the packing blowdown valve. Operating this OPEN-or-SHUT valve carries some risk of damage to packing teeth. Use of this method was reported by Hogg and Stephen (2005) where the risk was evaluated as acceptable. A bypass line was fitted to obtain finer control, but later left closed and full blowdown flow enabled.

Other ways of estimating it to sufficient accuracy for routine condition monitoring are given in Cotton (1993) and Booth (1984).

One method described there requires neither modifications nor risks to the plant. Tests are run at steady conditions with some differences between main steam and reheat steam temperatures arranged. This is readily done at Valves Wide Open by holding the hot reheat steam temperature constant while reducing the main steam inlet temperature, and vice versa. Three tests are suggested. At each test, the IP efficiency is calculated, and plotted against two assumed leakage flows. The intercept enables a reasonable estimate of the leakage flow (see Fig II).

The changes in steam inlet temperatures are also likely to alter gland clearance (Koch, et al 1988). A critical assessment of the accuracy is given in Haynes, et al (1995), but it is sufficiently accurate for an economic analysis to justify the required replacement parts to be obtained and the job scheduled as part of a planned major outage.

Recent experience (Beebe, 2005) shows that on plants with DCS, and as useful information can be gained using the permanent instrumentation system for overall condition monitoring, plant owners could well investigate its use to monitor N2 leakage and save on test cost.

Steps in the process are:

1. Run a Valves Wide Open test at as close to design HP and IP inlet steam conditions as can be achieved. Ensure that steam temperature and pressure are measured at inlet to the reheat intercept valves, and at the IP turbine exhaust (where experience may confirm that more truly representative values are obtained at the inlet to the LP turbine: Cotton, 1993).
2. Using the measured IP inlet steam conditions, calculate IP Turbine Enthalpy Drop Efficiency (steam properties tables are available on the internet calculate). Plot this on the vertical axis of a graph of efficiency vs N2 leakage, for zero leakage.
3. Assume a value of N2 leakage as a percentage of IP bowl flow, and calculate by heat balance the enthalpy of the steam to the blades:

Heat flow into the IP bowl = N2 packing leakage + Heat flow at IP inlet valves = Heat flow to blades from IP bowl:

$$m_1 \times h_1 + m_2 \times h_2 = m_3 \times h_3$$

where:

- m_1, h_1 = mass flow and enthalpy of steam leaking into IP bowl through the N2 gland, taken from the HP turbine expansion line at first stage pressure.
- m_2, h_2 = mass flow and enthalpy of hot reheat steam entering the IP turbine at the valves.
- m_3, h_3 = mass flow and enthalpy of steam through the IP blading (i.e. that of the mixture of inlet flow and leakage)

It is assumed that the flow m_3 through the IP blades is constant (i.e. the greater the N2 leakage, the lesser the IP inlet flow m_2 by the same amount). For a given leakage, the flow m_3 is % leakage × m_1

By manipulation, for an assumed leakage flow of 10% of the flow m_3 :

$$h_3 = h_1 + 9\,h_2 \qquad\qquad 10$$

4. Use this enthalpy value to again calculate the IP enthalpy drop efficiency, and add the result to the plot at 10%. Make further similar calculations if desired for other % leakage values. Draw a line joining the points, as shown diagrammatically for Test 1 in Figure II.

5. Run a second test at constant IP inlet temperature, but with a lower main inlet steam temperature, within the range allowed by the turbine manufacturer's instructions. Cotton (1993) gives 40 C° below design as practical. Repeat the calculations given above. (Test 2)

6. If desired, run a further test with design main inlet steam temperature and a lowered IP inlet temperature. (Test 3)

The intersection of the lines gives a reasonable estimate of the actual leakage flow (Figure II). A close estimate is also given of the true IP Enthalpy Drop Efficiency from this intersection. A cycle modelling program can be used to calculate the impact on output and thermal efficiency of any increased leakage, and used to justify restorative action or modifications.

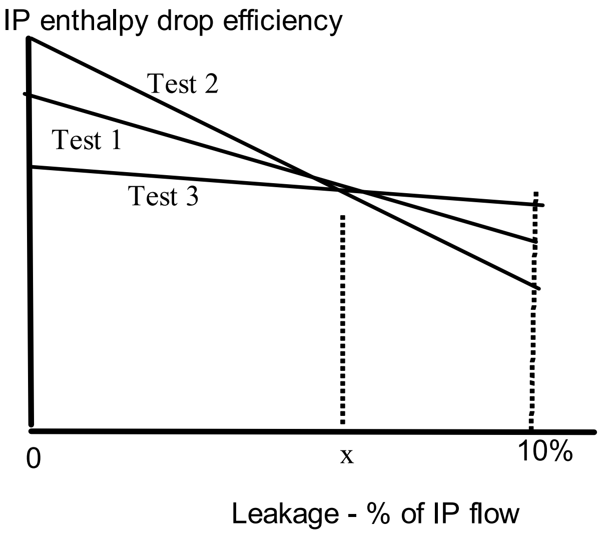

Figure II: Example plot of results for N2 gland leakage: x is estimated leakage flow

4 THE CASE STUDY

When a turbine generator of the combined HP-IP casing design was tested for acceptance, it was found to have a thermal efficiency well below that expected. The test procedures, particularly the primary flow measurement, were closely examined, but no discrepancy could be found and no reason for the shortfall was agreed. In operation of this unit, there was also difficulty in holding hot reheat temperature down to the design values. To ensure operation at design temperature, an extra desuperheating temperature control spray station was designed and installed in the boiler and 20% of the tubing in the first section reheater was removed.

Information on the N2 packing leakage tests described in this paper became available some years later, and when some routine VWO tests were arranged, it was decided to include those tests. Table I summarises results for tests of type 1 and 2.

Table I	Initial test at design conditions	Test with HP inlet temperature lowered
Main inlet steam pressure and temperature	13422.7 kPa Abs, 532.5 °C	13274.6 kPa Abs, 497.51 °C
IP inlet steam pressure and temperature	4058.8 kPa Abs, 537.5 °C	4046.6 kPa Abs, 538.1 °C
IP exhaust steam pressure and temperature	942.1 kPa Abs, 329.6 °C	951.3 kPa Abs, 329.14 °C
Enthalpy of main steam	3418.9 kJ/kg	3326.47 kJ/kg
Enthalpy of first stage steam h_1	3386.4 kJ/kg	3296.4 kJ/kg
Enthalpy of IP inlet steam h_2	3529.6 kJ/kg	3531.0 kJ/kg
Enthalpy in IP bowl if N2 leakage is 10% of IP flow h_3	3515.3 kJ/kg	3507.5kJ/kg
IP enthalpy drop efficiency with 0% N2 leakage	90.81%	91.98%
IP enthalpy drop efficiency if N2 leakage is 10% of IP flow	88.44%	88.07%

The estimated N2 gland leakage flow was found to be between 15 and 22 kg/s, or 4 to 5 times the design value. The design value had of course been used in calculating the steam flows to and from the turbine at the acceptance thermal efficiency tests. This increased leakage flow, amounting to a reduction of between 5.5% and 8% in the flow from HP turbine exhaust to the reheater, was consistent with the reduced thermal efficiency and reheater problems.

Inspection at the first overhaul some years later confirmed that the N2 gland clearances were greater than design, and had presumably been so since the acceptance tests and probably since new. Later, retractable packings were installed, but the repeat check test showed that the leakage was still present.

5 CONCLUSION

For steam turbine generators of the HP-IP casing type, N2 packing leakage tests should be part of the routine condition monitoring by performance analysis program and conducted at acceptance and with every Valves Wide Open test. If significantly increased N2 packing leakage is detected, the accuracy is sufficient to make an economic case to obtain replacement gland parts for the next planned major outage, or of conversion of the gland packing to the retractable type.

Abstract: It is difficult to monitor and assess the health conditions of the Quayside-Container-Cranes (QCCS) on the spot because of QCCs' dispersedly distributions on the docks and bad work environments. In this paper, the techniques of remote monitoring and assessing on QCCs' mechanical conditions are discussed and the corresponding system is developed. The system mainly focuses on monitoring on the stresses of the main metal structures, the vibrations of driving systems and the vibrations of rails and booms. Finally, the system realizes the remote on-line monitoring and remote assessment based on Web.

Key Words: condition monitoring, Quayside Container Crane, remote technique, MATLAB

1 INTRODUCTION

With the rapid development of container transportations, more and more quayside container cranes (QCCs) are put to use. Meanwhile, the QCC's structure gets softer and the vibration and impulsion get more serious because of its bigger size, higher driving speed and heavier hoist loading. So monitoring and assessing their health conditions efficiently play important roles in the plant managements of ports [1].

However, it is difficult to monitor and assess all of QCCs simultaneously, for their disperse distributions and bad work environments. Recently, the technology of remote monitoring makes a remarkable progress with the developments of computer science, communication technique, Internet and WWW. It was firstly implemented in the field of medical treatment [2] and was applied in the engineering field in the 90s of last century [3][4][5]. Now, the remote monitoring and assessing has become a new integrated technology.

The paper does some researches on the techniques of remote online condition monitoring and assessment based on Web, and develops a system that realizes the monitoring and assessment on the stresses of the main structures, the vibrations on the driving systems and the vibrations of the booms and rails of QCCs using the platform of MATLAB.

2 SYSTEM PROJECT

2.1 Monitoring items

Engineering practices show that the multi-parameter analysis makes the condition monitoring more efficiently and assessing more reasonably. What's more, processing data quickly is also very important to remote online monitoring. So it is of great benefit to select the monitoring items that cover more useful information and include fewer parameters.

22 monitoring items are selected and separated into 3 groups after several experiments on QCCs. (the list of items can be seen in Table 1). Group I is defined for monitoring the vibrations of motors and their gearboxes (shown in Fig. 2 and Fig. 3); group II is for monitoring the vibrations of the rails and the nearby parts on booms or beams (shown in Fig.1); group III is for monitoring the stresses of the metal structures (shown in Fig.1).

The mechanic conditions of measuring points on QCCs are denoted as the characteristic values of measurements of sensors. The vibration of the driving system, rail and boom is denoted as vibration severity (mm/s), and the strain of metal structure is denoted as stress (MPa).

2.2 System main tasks

The system realizes two kinds of functions: remote online monitoring and condition assessment based on Web.

For remote monitoring, the system demands that all of QCCs must be monitored simultaneously in the control room that is away from docks. During the monitoring, all characteristic values must be displayed and preserved in the database, and give alarms while abnormal conditions are detected.

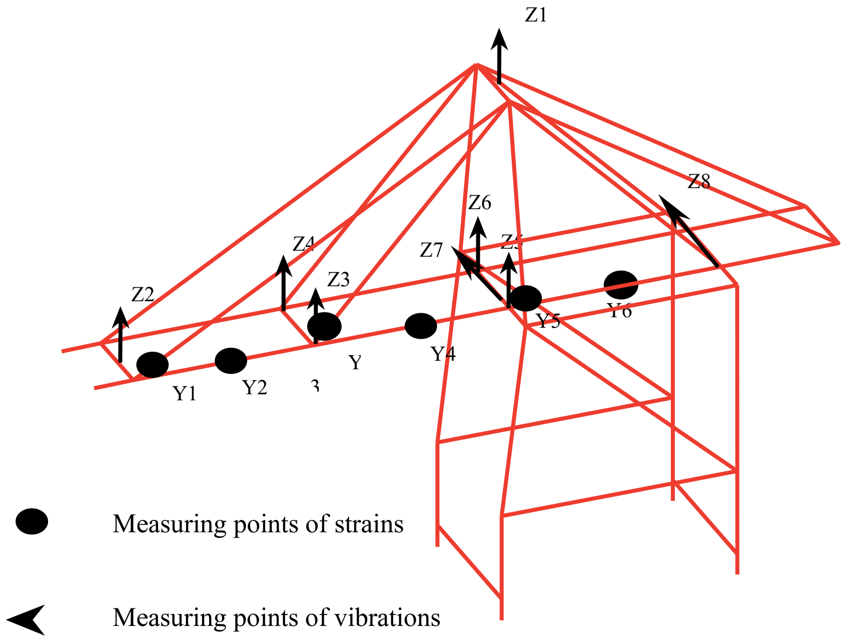

Fig.1 Measuring points on the structure of QCC

Based on monitoring data, the function of assessment is accomplished by using Browser (such as Microsoft IE) through Internet/Intranet. The assessment includes condition distribution statistic, condition forecasting and exception analyzing etc.

The paper constructs the main framework of the system by MATLAB for its powerful abilities of computations. Meanwhile, the paper utilizes the Java, MATLAB Web Server [6] to make up its shortages of network functions. Finally, the remote QCC's condition monitoring and assessment system based on Intranet/Internet are developed.

3 SYSTEM CONFIGURATION

3.1 System structure

Generally speaking, traditional remote systems adopt Client/Server (C/S) Model. This model exchange Information between clients and servers strictly through messages, so the responses are very quickly, which suits online monitoring very well. In addition, the applications based on this model can accomplish complicated functions, which satisfies the needs of users individually. In the same way, Browser/Server (B/S) Model has been one of the most popular models recently, for its three-layer structure: Client, Web Server and Database Server that divides the functions of application system definitely and independently. The work can be accomplished through browser without installing any client softwares, which avoids many troubles of installation and maintenance.

In this paper, the system integrates advantages of B/S and C/S model. In the remote monitoring subsystem, C/S model meets the need of data transferring and remote monitoring; and B/S model provides a new way for the engineers to assess and predict the conditions of QCCs based on web. Consequently, the framework (shown in Fig 4) are divided into three parts according to the functions and installed positions: RS_R (at the dock); RS_H (in the control room); RS_B (in the office).

Table 1: List of monitoring items

No		Explanations
I	H1	Axial vibration of free end of hoist motor (L)
	H2	Radial vibration of output end of hoist motor
	H3	Radial vibration of high speed axis of hoist gearbox
	H4	Radial vibration of output end of hoist motor (R)
	H5	Axial vibration of low speed axis of hoist gearbox
	P1	Radial vibration of axis of trolley gearbox
	P2	Radial vibration of output end of trolley motor
	P3	Axial vibration of output end of trolley motor
II	Z1	Oscillation in vertical direction of trapeziform girder
	Z2	Oscillation in vertical direction of sinciput boom
	Z3	Vibration of rail and nearby parts on front boom
	Z4	Vibration of rail and nearby parts on middle Boom
	Z5	Vibration of rail and nearby parts at left main joint
	Z6	Vibration of rail and nearby parts at right main joint
	Z7	Vibration of nearby parts at seaside beam
	Z8	Vibration of nearby parts at landside beam
III	Y1	Stress of first pole
	Y2	Stress of front part of the boom
	Y3	Stress of second pole
	Y4	Stress of middle part of the boom
	Y5	Stress of trapeziform girder
	Y6	Stress of middle part of the back boom

3.1.1 Dock:

The RS_R is installed on every QCC. It samples data of the mechanic conditions by means of the sensor equipments installed on every QCC, and translates monitoring data according to the requisitions of RS_H. Since the amount of crude data is usually very large, it is impossible to translate them to RS_H through network in a very short time to realize online monitoring. Only the characteristic values of these data are translated to RS_H, and the crude data are saved in the local real-time database. Simultaneously, RS_S listens connection requests of RS_H, and executes the corresponding actions after receiving requests from the RS_H.

3.1.2 Control Room:

RS_H provides the interface to set the parameters and monitor the health conditions of all QCCs. When engineers chose any QCC to observe the current conditions, the connect request will send to the chosen RS_R to get the real-time condition data. However, the un-chosen QCC are still sampling data synchronously and listening the connect requests from the RS_H.

The monitoring data are saved in the database while monitoring; meanwhile, the crude data at all RS_S are translated to the database periodically. These data are provided to condition assessing, forecasting and other analysis in the future.

The MATLAB Web Server is installed in the RS_H that mainly answers for web server for remote assessment in the office.

3.1.3 Office

Engineers in the office can assess the condition of QCCs by means of web browser (such as Microsoft IE). The RS_B needs none client-software and all works can be accomplished by the server and the results send back to the browser through Internet/Intranet. In addition, The RS_B can be embedded into the plant management of information system, which enhances the automatizations of plant managementTo achieve optimal reproduction quality, ensure that the contrast of text lettering is uniform, sharp, and dark over the whole page and throughout the paper. If corrections are made to the printout, run-off completely new replacement pages. The contrast on these pages should be consistent with the rest of the manuscript as should text dimensions and font sizes.

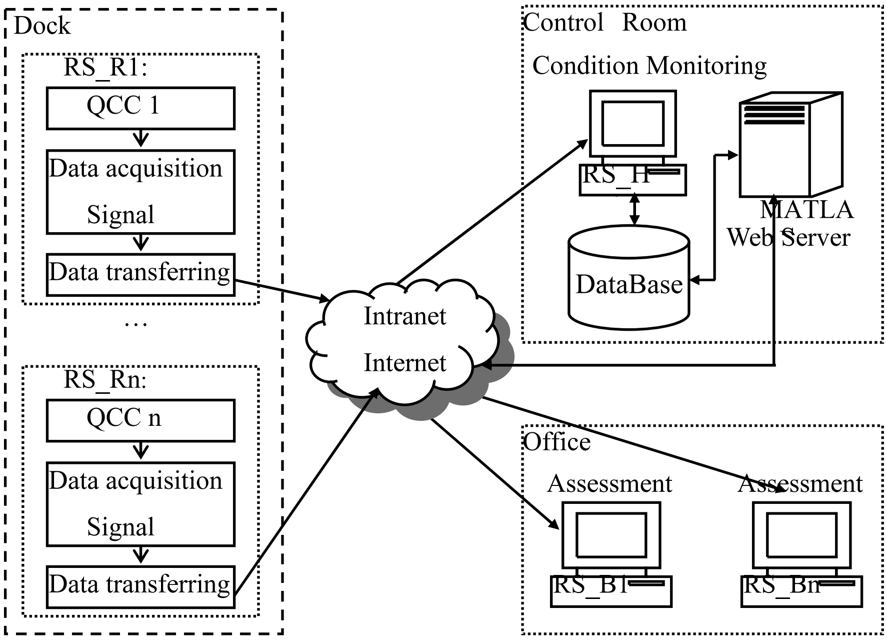

Figure 4. Structure of the system

3.2 Remote Data Transferring

The primary problem in the remote system is data translating. It needs translating the condition data between RS_R and RS_H timely while real monitoring and send parameters to RS_R precisely. Unfortunately, MATLAB lacks for the network functions and cannot support Sockets. Nevertheless, Java provides an integrated set of class libraries for network that very suit the development of remote monitoring systems in distributed measurements [8]. Users can design their special class libraries based on them, which realizes the Java's characteristics expediently. These special libraries install to MATLAB to help MATLAB to support network functions. Subsequently, two kinds of libraries for Server and Client are designed individually according to the special acquirements:

1) Class libraries in RS_R listen the requests of RS_H and translate data between each other (The detailed flow is shown in figure 5). Class HostSer is developed based on the class ServerSocket. When a new object of HostSer is created, it begins to listen possible requests from RS_H at the special port and then offers services such as sending files; accepting files; deleting files while connecting. After the connection is closed, the RS_R recurs to listens status.

2) Class libraries in RS_H are divided into five according to their functions (listed in the figure 5) that answer for accepting data from RS_R, sending data to RS_R, obtaining file lists of the appointed directory, deleting the appointed files and closing the communication individually. The five libraries are developed by the Socket class. All programs that want to communicate with the each other by means of Sockets must create objects of the Socket class.

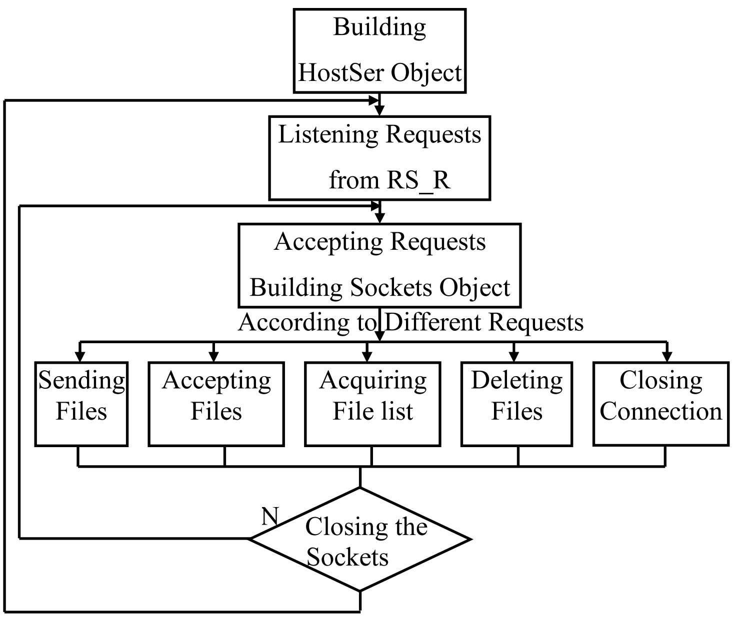

Figure 5. Flow of Library of HostSer

Further more, the network blocking must not disturb the course of MATLAB in gear. Meantime, there may be more than one RS_H that ask for connections to RS_R. Therefore, programs need the functions of multi-client connections. Based on the characteristics of Java, the system realizes the function of multi-thread that explained in figure 6 in detail

3.3 MATLAB Web Server [7]

The Web application of MATLAB is composed by two parts: one is the MATLAB Web Server (matlabserver.exe) which manages the communication between the Web application and MATLAB; the other is the Web server proxy which uses the Common Gateway Interface (CGI) to extract data from HTML documents and transfer it to matlabserver, then send back the results in manner of HTML (The basic theory shown in Fig. 7).

In this system, the MATLAB Web Server and the Web server daemon (httpd) are installed in the control room together with the database. When Users assess the conditions in the office, they send requirements to server through browser (Microsoft IE); and the server answers for looking for data in the databases, analyzing, and returning the results back to the clients through WebPages

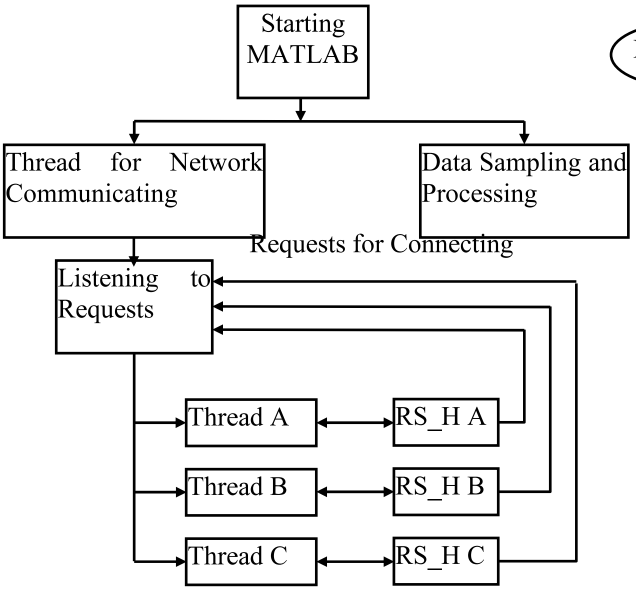

Figure.6 Principal of Multi-thread at RS_R

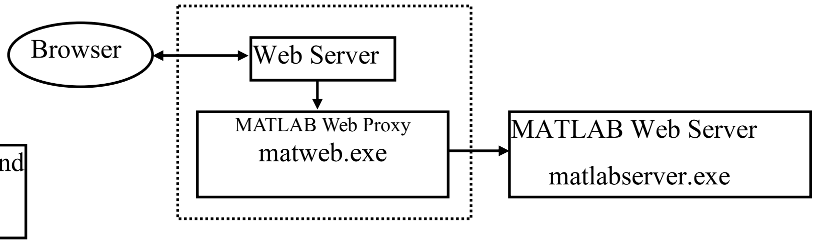

Figure 7. Basic theory of MATLAB Web Server

4 ERFORMANCES AND CONCLUSIONS

Figure 8 shows the interface of RS_H where users set parameters and monitor the conditions of QCCs. Users choice the number of QCCs and the group of monitoring items at the top of the window. Users can set different levels above which the crude data will be preserved at RS_R. These data can be used to do further researches.

When the system operates, users get the real-time data at intervals of about 10 seconds. The data of the chosen group are shown in the form of chart that moves with time, and the digitals of all items are displayed at the bottom at the current time, and the alarm lines of different levels displays in different colors.

Function of "Condition Assessment" emphasizes the condition distributions in a special period of time. The conditions are divided into 5 levels (A, B, C, D and E). Because the work environments are very complex (for instance, braking suddenly may cause violent impulsive vibrations), a few bad conditions caught cannot say there is malfunction on QCCs. Statistical analysis can makes the result more reliably and believably. Once the distributions of these conditions change, the conditions of the QCC should be analyzed in detail. Figure 9 shows the distributions of conditions of 22 items from 2005-03-07-10'55" to 2005-03-07-12'41" that covers 839 pieces of data. The green line indicates the distribution of real data while the red indicates the normal distribution whose variance and mean are equal to those of the real data, and the condition level distributions are listed in the page.

This thesis does some researches in remote online condition monitoring and assessment based on web. Some class libraries are built which enriches the network functions of MATLAB based on Sockets; and the technique of MATLAB Web Server helps to realize remote assessment based on Web.The monitoring and Assessment System is then developed to online monitor and assess to the mechanical conditions of the QCCs' main parts. Many experiments have been made to test its reliability and veracity. Now, it has been utilized in the practical operations, which enhances the efficiencies of plant management of QCCs.

DETERMINATION OF THE RISK PROFILE OF A HYDROGEN CONSUMING FACILITY USING PUBLISHED FAILURE RATE DATA

Thomas I F

Principal, I F Thomas & Associates Pty Ltd, Consulting Risk Engineers

Abstract: This paper assesses the potential consequences and associated risk levels for a major explosion following catastrophic failure of an hypothetical hydrogen-containing plant operating at elevated temperature and pressure. The plant is mooted as being located in an industrial area but with residential areas nearby. It considers the importance of fully open-air construction of such plants, of sufficient separation from surrounding communities and of free vertical discharge from pressure relief devices. It poses the question that the authorities in Australia may have got it wrong in not designating large hydrogen gas users as major hazard facilities with all that this entails. With the aid of a series of cartoons the paper brings us back from predictive mathematics to reality by indicating that common sense can be better at preventing accidents than even the best quantified risk assessment - do the risk assessment but do not rely upon it blindly. The paper concludes that an explosion of sufficient size to seriously embarrass or even close-down a major hydrogen gas using facility is possible. Likelihood of this is capable of being reduced to a negligible level by good design and by conducting a detailed risk assessment ahead of acceptance of the design. The magnitude of an explosion should such a large leak occur would also be reduced by the buoyancy effect of hydrogen, provided that the plant is constructed in the open air.

The base level of individual risk associated with catastrophic failure of the hydrogen-containing facility is established as 189.2 x 10^{-6}/person/year. This level of risk would be unacceptable if the 50% mortality distance extended into the community surrounding such a facility. The true level of individual risk associated with the same catastrophic failure but considering all of the mitigation measures inherent in the facility, is 1.78 x 10^{-84}/person/year. The latter 'risk' level is purely theoretical and shows that the failure modelled is essentially impossible. It measures the event frequency per unit of time akin to the Googolplex *(10^{100})* and to the purported number of particles in the universe *(10^{80})*. Risk levels have numerical meaning only if they are measured in units of powers of ten ranging from 0 to minus 10 or so and are effectively irrelevant once shown to be less than the prevailing criteria.

Key Words: Risk, Hydrogen, Explosion, Vapour cloud explosion, QRA, Buoyancy, Failure rate Format

1 THE HYPOTHETICAL NEIGHBOURHOOD

The property is assumed to be located wholly within an Industrial 1 Zone with most immediate neighbouring properties similarly zoned. Exceptions are public parks and nearby municipal premises. Within 500m of the centre of the site are more sensitive uses including small businesses, a busy freeway and residences. A railway line is within 500m of the centre of the premises. A dense residential zoning including some tall buildings is located beyond 500m. The latter are technically of the same degree of sensitivity as single-storey residences but contain more residents per unit of land area and large expanses of glazing. Hence the premises can be described as being ideally located in terms of immediate neighbours, less ideally with respect to impacts which may extend to 500m and even less ideally beyond 500m.

Key to whether the location may lead to adverse impacts upon its neighbours, is the extent to which these impacts may extend out into the community beyond site boundaries in particular, as far as residences. The reason for singling out residences over and above industry, businesses, road, transport and public park zones is because residences are deemed to be occupied continuously, 24 hours per day, 365 days per year. Workplaces in the form of industry and local businesses are deemed less sensitive in that they are occupied for periods per day less than this, typically from 8 to 12 hours per day. Sensitive areas such as sports grounds and open parks may be densely occupied but again, for considerably less than 24 hours per day. Classically therefore, risks of exposure to harm are orders of magnitude less for less frequented zonings. Occupants at the subject premises are considered as a special case in risk terms, because they are either in control of potentially adverse events or in immediate communication with those who are.

2 RISK EVALUATION PROCESSES AVAILABLE

2.1 Think tanks, fault tree analysis and HAZOP Studies

The facility is assumed to employ full time engineers and a safety officer and therefore to competently address both day-to-day risks and less likely, higher consequence risks. The company's engineering system is assumed to use to great effect Hazard and Operability studies *(HAZOP),* Job Safety Analysis *(JSA),* Safe Work Practices *(SWP),* hot and cold work permits and confined space entry permits. All works and pertinent documentation are assumed to be rigourously filed.

2.2 Notional (qualitative) risk assessment

The authorities almost exclusively require occupiers of potentially dangerous premises to conduct a documented notional risk assessment. This is generally conducted in worksheet or spreadsheet format, and considers adverse events called hazards, the consequence and likelihood of these hazards and thereby, the level of risk associated with them. The same or a separate worksheet then considers available risk mitigation measures and develops a program of works for addressing risks, concentrating on those hazards which present the highest risk. The use of worksheet style is beneficial in permitting presence of rows addressing each hazard and columns stating for example, the item, hazard, consequence, severity of consequence, likelihood of occurrence, risk level, mitigation and whether new action is warranted. An example of such a 'generic' risk assessment is appended.

Risk in these assessments is best provided with a number so that relative risk can be established and priorities set for attending to them. AS/NZS 4360:1999, Risk Management, addresses this. Notional risk assessment which arrives at a series of risk numbers is sometimes referred to as semi-quantitative or semi-quantified risk assessment. The example of a risk matrix shown in the standard, uses a scale of 1-5 for severity of consequences, A-E for likelihood and consequent risk levels described as E *(extreme),* H *(high),* M *(moderate)* and L *(low).* A technique considered to be more useful assigns levels on a 1-5 scale to both severity of consequence *(S)* and likelihood of occurrence *(L),* thereby permitting Risk *(= S x L)* to be established as one of 14 numbers in the range 1-25. Priority risk levels of eg 10 and above are then easily recognised.

2.3 Quantified (or Quantitative) Risk Assessment (QRA)

This is a sophisticated technique involving relatively complex mathematics to provide absolute risk levels for a defined event or series of defined events. It uses inputs such as actual frequencies of occurrence and failure rates together with analysis of probabilities. Numerous computerised models exist and are offered by various companies on a commercial basis. Models exist for overall QRA of a premises and for specific events such as an escape of flammable gas or vapour. Computer models are complex and usually proprietary. Even licenced use is restricted and often may not permit the user to know the mathematics which are employed. Outputs are contours drawn in plan around a premises, showing the **individual risk of death** per person per year. A single event in a non-complex plant on flat terrain without obstacles will yield a series of circles each representing a different risk number. They are known as contours of individual risk. Risks other than death can also be assessed but it is the risk of death which dominates these studies. A common acceptable individual risk of death contour is 1×10^{-7} *per person per year*. Levels less than this are generally considered acceptable. It is evident that the risk level is defined both by the event and by the density and degree of presence of the surrounding population at distances and locations specified.

A second and equally important output from QRA is known as the group or societal risk. This considers catastrophic events capable of causing multiple fatalities. This is not shown as contours but as a graph showing the number of deaths (N) resulting from an event which occurs at a frequency (F). This is known as an F/N plot and again, a range of acceptable levels of societal risk is published by a number of authorities. An **acceptable risk range** published by one of the authorities shows *negligible risk below a line bounded by* $N=1;\ F=10^{-4}$ *and* $N=30;\ F=10^{-7}$. **Unacceptable risk** is defined as being *above a line bounded by* $N=1;\ F=10^{-2}$ *and* $N=300;\ F=10^{-7}$. The **region between these two lines** is deemed an area of **acceptable risk but where remedial measures are desirable**. This F/N plot is appended hereto.

Quantified Risk Assessment in the 1980's and 1990's was considered by the authorities as the ultimate way of assessing risk and use of QRA was vigourously supported. Authorities even purchased their own models to independently consider the risks of particular premises. Authorities have defined and published acceptable risk levels with which the outputs of QRA were to be compared and actions developed there-following. However, examples exist where authorities have accepted the risk levels calculated for a premises even though they were outside their own criteria. QRA also gradually acquired the reputation of being 'malleable' to fit with a desired outcome. Even current, highly sophisticated models are best only used for comparison of one facility with another or of the same facility at different times where the same model was used in each case. In one instance, a government approved a new development proposal which was shown to cause individual risk levels above the criteria in nearby residential areas. In another, a QRA showed a new plant proposal involving installation of bulk monomer storage tanks close to residential neighbours. Objections led to a second QRA being performed which showed that individual risk levels increased if the proposed tanks were not installed.

2.4 The method used herein

A somewhat conservative assessment is conducted herein, involving assessing the maximum possible *(albeit unlikely)* hydrogen gas escape, converting this to an equivalent mass of the conventional explosive trinitrotoluene *(TNT)* and then establishing effects with distance of a TNT explosion of that size consequent upon explosion *(or blast)* overpressure. The technique does not take account of terrain, obstacles, buoyancy, wind, atmospheric dispersion conditions or the effects of falling structures and flying debris. Rather, it assumes flat terrain, neutral buoyancy, no wind, absence of obstacles and that there are no injuries, deaths or property damage resulting from falling structures and flying objects and does not consider the impact of atmospheric dispersion conditions. Probabilities are assigned in the *Likelihood* section hereof. The technique also assumes that an escape of hydrogen gas is similar to the escape of a heavier-than-air gas or vapour like ethylene, vinyl chloride or cyclohexane.

The method herein relies upon published works by Gugan, Bond, Brasie & Simpson, Lawrence & Johnson, Strehlow & Baker, Clancy, Marshall and Sutton. Actual references are listed in the appendix hereto. The effects of explosions with distance are defined by overpressure present at that distance. Herein, the method of Lawrence and Johnson *(1974)* is used to predict human injury effects. These are described below together with the associated overpressure :-

50% mortality *20psi =138kPa*
Lung damage *5psi = 34kPa*
Ear damage *2.5psi = 17kPa*
Penetration by 10g missiles *0.4psi = 3kPa*
Cuts by flying glass *0.2psi = 1.4kPa*

The method of Strehlow and Baker (1976) is used to predict property damage for various levels of overpressure as follows :-

Total destruction *10psi = 69kPa*
Serious damage *3psi = 21kPa*
Minor structural damage *0.4psi = 3kPa*
Glass breakage *0.03psi = 0.2kPa*

Both groups of workers agree that glass typically fails at 0.1-0.2psi *(0.7-1.3kPa)* but as a conservative measure, the *limit* of glass breakage as opposed to the typical overpressure to cause it is used namely 0.03psi *(0.2kPa).* It should be noted that glass breakage caused by outward showering of broken glass from nearer to the explosion, extends out considerably further than the pressure wave which is capable of breaking glass at a distance.

3 CALCULATIONS

3.1 Establishment of worst-case hydrogen release

This assumes that the vessel containing hydrogen is filled with 20,000L of hydrogen at a pressure of 2200kPa and at a temperature of 10ºC. Whilst essentially impossible as this would require major failings in safeguards, it is then assumed that the reactor ruptures and releases all of this hydrogen essentially instantaneously.

Using the ideal gas law, $PV = nRT$ we have
$P1$ = 2200kPa
$V1$ = 20,000L
$T1$ = 10ºC = 283ºK

Converting to Standard Temperature and Pressure *(STP)* we have
$P2$ = 101.3kPa
$V2$ = V2
$T2$ = 0ºC

$P1V1/T1 = P2V2/T2$

Therefore $V2 = 2200 \times 20{,}000 \times 273/283 \times 101.3 = 419{,}005L$ of hydrogen

Using Avogadro's Hypothesis, *1 gram mole of an ideal gas at STP occupies 22.4L*
Therefore weight of hydrogen = *419,005 x 2/22.4 = 37,411g = 37.4kg*

As this study is intentionally extremely conservative, we will proceed using 40kg of hydrogen.

Heat of combustion of hydrogen = *33,887.6kcal/kg*

Heat of combustion of TNT = *1100kcal/kg*

TNT equivalent of 40kg of hydrogen = *40 x 33887.6/1100* = *1232.3kg*

Hydrogen is considerably more prone to explosion *(detonation)* than rapid burning *(deflagration)* when compared with heavier-than-air gases and vapours. The range of *blast wave efficiencies* used by various workers is from 2% to 30%. Again because this appraisal is conservative and because hydrogen is more likely to detonate than to deflagrate *(detonation range in air = 18.3-59%; flammability range in air = 4-75%; ignition energy = 0.01mJ),* a blast wave efficiency of 30% is assumed, yielding

TNT equivalent explosive power = *1232.3 x 30/100*

= *369.7kg*
= 0.3697t of TNT (W)

The pressure wave from a TNT explosion of this magnitude will cause human injury and property damage, the effects decreasing with distance. These are expressed as distances *(d)* up to which certain effects are expected.

3.2 Human injury distances

50% mortality d $= 17.8W \times 10^{0.33}$ = **12.8m**

Lung damage d $= 35.8W \times 10^{0.32}$ = **26.0m**

Ear damage d $= 53.8W \times 10^{0.32}$ = **39.1m**

Penetration by 10g missiles d $= 316.2W \times 10^{0.33}$ = **227.7m**

Cuts by flying glass d $= 640.4W \times 10^{0.32}$ = **465.6m**

3.3 Property damage distances

Total destruction	d	= 4W x 100.33	= 2.9m
Serious damage	d	= 10W x 100.33	= 7.2m
Minor structural damage	d	= 30W x 100.33	= 21.6m
Glass breakage	d	= 430W x 100.33	= 309.6m

3.4 Total deaths

Total deaths can be estimated using criteria developed by Marshall and by Gugan as follows :-

Total deaths	= 0.05W x $10^{0.33}$	= 0.04 (considered as 0)
Total deaths	= 0.3W x $10^{0.33}$	= 0.2 (considered as 1)
Total deaths	= 4W x $10^{0.5}$	= 2.4 (considered as 3)
Total deaths	= 3.3W x $10^{0.33}$	= 2.4 (considered as 3)
Total deaths	= 55W x $10^{0.5}$	= 33.4 (considered as 34)

Predictions of **total deaths** for an explosion involving **0.3697t of TNT** therefore range from **0 to 34**.

3.5 Other scenarios considered

- A 20,000L charge of hydrogen at 1700kPa and 250ºC ***(15.6kg of hydrogen)***
- Vessel filled with 20,000L of hydrogen at 500kPa ***(8.8kg of hydrogen)***
- Vessel filled with other materials and containing hydrogen at 2200kPa ***(3.9kg of hydrogen)***

Each of these are lower weights of released hydrogen than the case pursued above. Results for each follow :-

Hydrogen released (kg)	*3.9*	*8.8*	*15.6*	***40.0***
Human injury distances (m)				
50% mortality	*5.9*	*7.8*	*9.4*	***12.8***
Lung damage	*12.4*	*16.0*	*19.3*	***26.0***
Ear damage	*18.6*	*24.1*	*28.9*	***39.1***
Penetration by 10g missiles	*105.6*	*138.1*	*166.9*	***227.7***
Cuts by flying glass	*221.0*	*286.8*	*344.6*	***465.6***
Total deaths range	*0 to 10*	*0 to 16*	*0 to 21*	***0 to 34***

Property damage distances (m)

Total destruction	1.3	1.7	2.1	**2.9**	
Serious damage	3.3	4.4	5.3	**7.2**	
Minor structural damage	10.0	13.1	15.8	**21.6**	
Glass breakage		143.6	187.8	227.0	**309.6**

The easiest way to consider the significance of distances established in the foregoing is by use of maps and plans where the effect distance 'd' is drawn as a radius centred on the location of the facility. In a purely analytical way, it is fair to suggest that effects which are confined within the facility are less devastating than off-site effects. Serious effects like death, lung damage, ear damage, total destruction, serious damage and minor structural damage in the worst case considered here, are all confined within the site. It is only lesser effects such as penetration of the body by 10g missiles, cuts from flying glass and glass breakage which extend off site. Whilst causing injury of any kind off site would lead to actions potentially resulting in plant closure, this work is purposely an exaggeration of what might actually happen.

4 THE EFFECTS OF VARIABLES NOT CONSIDERED

4.1 Wind

Wind has a more powerful effect in mitigating the extent of the consequences of an accidental release than is generally realised. The writer has developed equations indicating this for heavier-than-air releases, viz :-

$Wvc = 794.3\ u^{-0.87}$
$Wtnt = 1413\ u^{-0.85}$ where

Wvc is the weight of the leaked substance *(tonnes)*
Wtnt is the equivalent weight of trinitrotoluene &
u is the windspeed *(m/hr)*

Even a small breeze can disperse an otherwise flammable cloud to below flammable limits either quickly in the event of a single release, or at relatively close distances to the source in the event of a continuous release. An example of the latter is the B F Goodrich Chemical Ltd, Altona release of 676t of vinyl chloride over a period of 5.25hrs in 1982. Average emission rate was 2.15t/minute and windspeed was a very moderate 8-14 knots. It was calculated that at no time was more than 150kg of vinyl chloride within the flammable envelope. With complete absence of wind it was shown that more than 100t would have been within the flammable vapour cloud during the steady-state emission phase.

4.2 Emission rate

$Wvc = 0.6 \times 10^{-6} \times Qm$

$Wtnt = 1.1 \times 10^{-6} \times Qm$ where

Qm is the mass emission rate of the release (kg/hr)

4.3 Atmospheric dispersion conditions

The condition of the atmosphere ranges from highly dispersive in an upward direction to providing a 'lid' and preventing upward dispersion, depending upon atmospheric conditions and time of day. This is more important for heavier-than-air emissions than for a substance like hydrogen which is buoyant regardless of weather conditions. Atmospheric dispersion condition nevertheless is capable of slowing-down or speeding-up the dilution of a cloud of hydrogen to below flammable limits.

$Wvc = 7.41D^{-0.51}$

$Wtnt = 12.58D^{-0.5}$ where

D is the dispersion parameter = $m \times n^2/4$, where
$D = 100Cy.Cz/n$ and where *Cy* and *Cz* are vertical diffusion parameters and *n* is a dimensionless turbulence parameter.

4.4 Terrain

The relatively flat terrain of the hypothetical site and its surroundings means that this effect need not be considered. Clearly, flat terrain will lead to greater dispersion than an instance of an emission in a valley and vice versa. Most computer models also incorporate a surface roughness factor.

4.5 Obstacles

Presence of obstacles such as walls, roofs, plant, buildings and houses will influence dispersion of a leak and will also more importantly, increase the likelihood of a cloud catching fire and of detonating. Open air emissions until the 1970's were generally regarded as harmless deflagrations. It is now understood that presence of obstacles can convert a deflagrating cloud into an explosion. It is noteworthy that a vapour cloud explosion generally causes overpressure for longer than conventional explosives such as TNT. Structures designed to withstand TNT may therefore fail in a vapour cloud explosion. Increasingly, vapour cloud explosions are being implicated in major events such as Flixborough UK *(1974)* and more recently Buncefied UK *(December 2005).*

5 HYDROGEN AS OPPOSED TO HEAVIER-THAN-AIR EMISSIONS

Hydrogen gas has a very high flammability range *(4-75% in air)* and a high detonation range *(18.3-59% in air).* Together with its extremely low ignition energy *(0.011mJ @ 25ºC; 0.0051mJ @ 150ºC),* almost any release will ignite and most will detonate. Diffusion of hydrogen leaking from a pressure source will of itself, cause ignition if the pressure source is at 7900kPa or greater. Hydrogen is typically stored at 18,000kPa. Reactor pressure is in the range 400-2200kPa. Most emissions of hydrogen with which the author is familiar have resulted in detonation albeit that these have all been small for example, from G-sized gas cylinders and from continuously operating electroplating baths. Shorting of vehicle battery terminals also often results in a minor explosion. One instance is known where the battery exploded sending components and acid several metres.

Information to the contrary has been obtained pertaining to use of hydrogen balloons to float cameras inside caves. Here, the process of filling the collapsed balloon bags was described as being plagued by sparks which did not cause ignition. Disposal of such a balloon over fire has also been described as a relatively harmless, non-exciting event. However, accounts like the latter need to be tempered with the reality as first discovered by Pilatre de Rozier in the 1700s when he repeatedly demonstrated the safety of hydrogen by inhaling it and setting fire to his breath via a glass tube. On one occasion an explosion resulted from which he survived. In 1784, de Rozier went further by developing a lifting device combining a hydrogen balloon with a hot-air balloon. This time he was killed.

It has been a common misconception over a long period of time, that the infamous crashes of airships such as the Hindenburg and R101 were caused by hydrogen catching fire. This is not the case and resulted in the utilisation of hydrogen and of airships being set-back for many decades. Confined hydrogen can cause serious pressure escalations. Unconfined, a simple combustion or deflagration will usually occur resulting in overpressure up to 7kPa. A confined deflagration can raise this pressure 8-fold whilst a detonation can raise the pressure 15-fold. A confined combination of deflagration and detonation however, can lead to pressures rising 120-fold.

Provided the release is unconfined or relatively unconfined, its extreme buoyancy *(it is the lightest element known and is 14.4 times lighter than air)* will cause an emission to move away upwards from source, quickly. Despite the high propensity to ignite and then detonate, this tendency to move away is considered important in any consideration of what might happen in the event of a major release. As is common in pressurised storage, it is therefore desirable for hydrogen processes to be in open-air or at least in buildings with partial walls and partial roofs.

Buoyancy relationships show that hydrogen will accelerate upwards once released at 131m/s/s until reaching its terminal velocity of 17m/s. Hydrogen is the only element capable of reaching escape velocity *(11.2km/s)* but it is understood that this much higher velocity is only achieved in the upper atmosphere. Therefore after only a few seconds following a release, in such an unconfined situation, the gas will be tens of metres into the air and will have already dispersed considerably in so doing. The occurrence of an elevated explosion has the disadvantage of being capable of sending blast waves outwards in the way indicated herein as if no buildings or obstacles were present. Elevated residences would continue to be vulnerable if the explosive power was great enough. On the other hand, an elevated explosion also has the advantages of being more distant from the source when it ignites and being more dispersed and therefore less likely to detonate. At best, dispersion associated with the rapid upward movement will prevent ignition. The extent to which the buoyancy of hydrogen mitigates against major disaster should be capable of being established by application of one of the computer models available and also by reference to past accidents. By using windspeed relationships referred to above, it is clear that a vertical 'windspeed' of 17m/s would greatly reduce the impact of such a release. Assuming that the proposed plant is in the open air, it is reasonable to regard the hydrogen upflow as a vertical wind. This then permits application of the wind effect equation, namely :-

$$Wvc = 794.3\ u \times 10^{-0.87}$$
$$Wtnt = 1413\ u \times 10^{-0.85}$$

Where *Wvc* is the weight of leaked substance *(tonnes), Wtnt* is the equivalent weight of TNT and *u* is the windspeed in m/hr. These relationships were established for an emission rate of 33.3kg/s over a period of some 5 hours *(total release = 600 tonnes).* Taking 'windspeeds' of 17m/s, 1m/s and 1m/hr we find

$$Wvc = 54.4kg\ @\ u = 17m/s$$

$$Wvc = 639.7kg\ @\ u = 1m/s$$

$$Wvc = 794{,}300kg\ @\ u = 1m/hr$$

Windspeeds of 1m/hr or similar are unrealistic as air movement is almost always greater than this and as the weight of vapour in the explosive state exceeds the total emission in the example from which the equations were derived. It is also unrealistic to observe that more hydrogen than that present, is emitted in the 17m/s and even in the 1m/s instance. However, if it is assumed that the ratio of wind-dilution effects is the same for the modelled case and the case which provided the equations, we have

Ratio of windspeed impacts from *17m/s to 1 m/s = 11.76*

Therefore we might assume that an actual *(instantaneous)* release of a total of *40kg* of hydrogen, would reduce to

40/11.76 = 3.4kg consequent upon the presence of a *17m/s* updraft.

This derivation is not claimed to be accurate but directionally, it shows that the scale of an explosion would be reduced significantly by the presence of such an updraft. Hydrogen reaches its terminal velocity in the following distance

$v^2 = u^2 + 2as$, where

v = 17m/s
u = 0m/s
a = 131m/s/s
s = s metres therefore

s = 1.103m

and in the following time

$s = ut + 0.5at^2$ where t = time (seconds)

$1.103 = 0.5 \times 131 \times t^2$ therefore

t = 0.017 seconds

The upward acceleration of hydrogen is thus so large that within a fraction of a second and just over a metre above the source, the terminal velocity is reached. Therefore the dispersive impact of the upflow velocity as herein surmised, is pertinent. If there is no ignition source at point of emission, it is possible that the rising hydrogen will reach terminal velocity without finding an ignition source and that then, the speed of rising will disperse the emission rapidly to below the lower flammable limit *(lower explosive limit, LEL)* concentration. This further indicates the importance of the upflow effect. Actual experience however is that large releases of hydrogen involving significant dropping in pressure, almost always ignite.

6 LIKELIHOOD

This may be established by reference to industry 'failure rate data'. Published pressure vessel failure rates are for example :-

Lees, F P, 3rd Ed, Vol 3, A14/7 (general; UKAEA) :-	Failures/10^6 hrs of operation
Pressure vessels (general)	3.0
Pressure vessels (high standard)	0.3

Lees, F P, 3rd Ed, Vol 3, A7/27 (1st Canvey) :-	Frequency of initiating event x 10^{-6}/yr
LPG explosion due to spontaneous failure of storage sphere (Occidental, UR)	150
Spontaneous failure of LPG vessel (Shell)	140
Spontaneous failure of vessel (Mobil)	230
Spontaneous failure of vessel (Occidental)	90
Spontaneous failure of vessel (UR)	70
Spontaneous failure of vessel (Fisons)	100

Lees, F P, 3rd Ed, Vol 3, A7/31 (2nd Canvey) :-	Frequency of event x 10^{-6}/yr
Spontaneous failure of pressure vessels	10

Lees, F P, 3rd Ed, Vol 3, (Rijnmond) :-	Frequency of event x 10^{-6}/yr
Pressure vessel - serious leakage (A8/6)	10
Pressure vessel - catastrophic failure (A8/6)	1 (range 0.63 to 46)
P1 Major rupture of tank (A8/9)	43
U0 Catastrophic failure of full NH_3 sphere (A8/13)	0.23
U1 Catastrophic failure of part-full NH_3 sphere (A8/13)	1.8
A1.1 Catastrophic burst, chlorine tank, full (A8/14)	0.093
A1.1 Catastrophic burst, chlorine tank, half full (A8/14)	0.74
G1 Catastrophic failure of LNG tank (A8/15)	0.8
0.01 Failure of full propylene sphere (A8/16)	0.028
0.02 Failure of propylene sphere c/w 300t (A8/16)	0.233

AIChE, CCPS Data Tables :-	Failures/10^6 hrs of operation
Vessels, pressurised, metallic (Catastrophic failure, leakage < ¼")	0.0424

Thomas, I F, Frequency of event x 10^{-6}/yr :- (Chemical industry data; unpublished)	
Catastrophic failure of 12t polymeriser	196

The above data vary widely. Results are first converted to events per year assuming 8000hrs/yr of operation. Experience and confidence in high-standard nuclear pressure vessels (as opposed to low standard) leads reasonably to elimination of the 24,000 x 10^{-6}/yr (3.0/10^6 hrs) result. The average of all remaining 20 figures leads to the following

Highest 2400 x 10^{-6}/yr
Lowest 0.028 x 10^{-6}/yr
Average189.2 x 10^{-6}/yr

If this data alone represented the situation at the subject premises, the likelihood of catastrophic failure of the hydrogenation reactor on average, is 189.2 x 10^{-6} per year. This would mean that the individual risk to persons located in the community within the effect radii shown, would be

***189.2 x 10^{-6} /person/year**.*

Acceptance criteria in various countries including Australia are cited earlier herein. A community *individual risk of death* criterion informally accepted in Victoria and formally accepted in many other jurisdictions is

1 x 10^{-7}/person/year

It is shown above that risks of death and of serious injury are confined to the site for both a 40kg explosion and the second modelled, 3.9kg explosion. Therefore strictly speaking, the effects which these events project into the surrounding community would not be sufficient to cause the authorities to refuse an application to build such a plant. However, if such an hypothetical plant was to be built, and if it was capable of causing glass breakage, cuts from flying glass and penetration by 10g missiles in the community as indicated, it is suggested that this would not be an acceptable situation.

Therefore if the likelihood of a catastrophic failure of the hydrogen-using facility was actually as above, this would not be acceptable. However, the foregoing data include many incidents of such failure where a small hole and a harmless jet discharge ensues as well as actual, major disasters. Only two records of hydrogen explosions of any scale have been found in the literature *(Lees F P, Incident B33, Appendix 1/73; CRC, Hydrogen: Its Technology and Implications, 1977)*. In the first, hydrogen was intentionally vented when there was no wind and an explosion followed. In the second, the vessel burst under pressure after 12 years of operation.

7 THE ACTUAL LEVEL OF RISK OF EXPLOSION

To establish the actual failure rate of such an hypothetical facility, the most likely cause of catastrophic plant failure must be considered. This is over-pressurisation from hydrogen storage which is typically at *165bar (16,500kPa).* There are numerous safeguards to prevent this and any other adverse event in the plant and these will be discussed here-following. A simplified Process Flow Diagram *(PFD)* is appended hereto to assist an understanding of these safeguards.

In the single hydrogen supply line from storage to process there are mooted to be some 30 devices comprising manual valves, pneumatic and solenoid control valves, relief devices, pressure transmitters, flow transmitters, alarms, indicators and in addition, a sophisticated computer control system.

All components have levels of reliability enhanced by routine inspections, by preventive maintenance, by good operation, and by observation & diligence of engineering personnel. However for the purpose of this study, each component also has a prescribed failure rate for which data are contained in the literature. These are not reproduced here. Instead, a simple logic diagram showing how these components interrelate and how their failure might affect the process, is appended. This diagram shows the failure rates presumed and the reference list attached, indicates sources.

The mooted computer-control system has separate input and output cards and a back-up microprocessor. It controls all actions of all components of the hydrogen plant in accordance with pre-programmed cues. Such cues may be varied if required. If a failure of the main processor occurs, the other takes over ‘seamlessly’ so that even the operators in the plant control room would not initially realise that the change had occurred.

If the computer system fails completely, consequent on power failure or inherent failure, first, the Uninterruptible Power Supply *(UPS)* would take over and continue the operation of the system, for a period of some 12 hours. Secondly, all controlled items would 'fail' in safe mode that is, an Emergency Shut Down *(ESD)* would occur. Valves for example, would fail open or closed as required for safety. An emergency shutdown can also be caused by operating personnel, either via control room software or by buttons which are 'hard-wired' to cut power to the computer and force various items to fail safe.

Again for simplicity, a failure of each and every physical component in the system, as well as failure of the distributed control system is assumed herein and its likelihood established.

Physical component failure rates range from < $1/10^6$ *hrs, to* $9690/10^6$ *hrs*, the latter being for motor-driven compressors. When each of the pertinent failure rates are combined *(see attached logic diagram),* the resulting system failure rate for all mechanical components is $2.23/10^{88}$*hrs* of operation. Unless all components failed into their unsafe condition simultaneously, it would not be possible for high-pressure hydrogen to reach the plant.

Derivation of such a low failure rate is a consequence of the fact that most of the components must fail simultaneously that is, in Boolean algebraic terms the individual failure rates must be multiplied together at *'and gates'*. Where failure of one component or another is pertinent, values are added together at *'or gates'*. As all listed failure rates even the very high ones are fractions, multiplying fractions together rapidly yields the inordinately low failure rate number determined.

Similar logic has been used for the computer control system but simplified and as already indicated, with less reliable data. It is established that the computer will fail completely, $7.5/10^{11}$ *hrs*. Computer failure or power failure results in all components failing safe. Therefore this failure rate need neither be added-to nor multiplied-by the established mechanical equipment system failure rate. Therefore although undesirable, failure of the computer and of all operator interventions which would usually follow such a failure, would cause a safe condition to be arrived at provided that each and every item of plant responded as it is designed to do. Valves for example, are designed to fail closed or to fail open by spring pressure.

Assuming *8000 hours per year* of operation, the 'top event' failure rate becomes *1.78 failures/*10^{84} *years*. More commonly expressed, this is a failure rate of

$$\mathbf{1.78 \times 10^{-84}/year}$$

Not only is an individual risk of 1.78×10^{-84}*/person/year* acceptable in the community but essentially this is saying that the event is close to being impossible.

8 OTHER POTENTIAL FAILURE MODES

8.1 Storage vessel relief

It is mooted that storage of hydrogen is within pressurised road trailers. Each typical trailer contains 12 horizontal cylinders and each cylinder is fitted with a relief device. The principal and purported sole mechanism of failure, is operation of the relief devices which yields an intense vertical jet of flame causing little harm. Each trailer holds *374kg* of hydrogen compressed to *165bar (16,500kPa).* Two or three such trailers are generally present at a facility either to supply their contents or to be filled.

8.2 Hydrogen embrittlement

This causes drastically reduced strength and ductility of steel and also of other metals. In one example, a *1.85m dia x 6.75m* long pressure vessel with *5mm* wall thickness in operation for 12 years, at a pressure of *10,000kPa (10MPa)* burst causing damage estimated at $4 million. Material of construction was *ASTM A517-F* steel. This effect has not been considered in this study as the assumption has been made that materials have been appropriately selected. Some photographs on this topic are appended.

8.3 Use of nickel catalyst - propensity for internal reaction

In some hydrogen-using plants namely oil hydrogenation plants, the combination of spent nickel catalyst and oil is known to be pyrophoric in contact with air. In the reactor, air is absent and therefore this is unlikely to present a hazard. Other aspects of potential for adverse or runaway reaction have not been considered here. Use of low-boiling solvents in hydrogenation should be avoided to reduce the risk of ignition when catalyst is added *(Bretherick Vol 2, 1999).* A proprietary form of Raney nickel catalyst in which the finely divided metal particles are coated with a fatty amine is claimed to be free of pyrophoric hazards if it dries out *(Bretherick Vol 2, 1999*).

8.4 Inappropriate pressure relief system design

Pressure vessels should contain pressure relief devices which are either rupture discs *(RD)* or relief valves, not both. Often, the relief device is a pressure relief valve *(PRV)* with a rupture disc placed below it to prevent clogging of the PRV in normal operation. To compensate for the possibility of prejudicing rupture disc burst pressure by development of pressure between RD and PRV, a pressure switch and pressure alarm are often present. Where there is a tendency for clogging of relief valves, notwithstanding the concerns of environmental agencies, bursting discs should be used, not relief valves.

In hydrogenation plants, it is understood that there is a considerable tendency for reactants to cause blockage and gumming of relief valve components and that this is why rupture discs are present. Typical rupture discs are a composite of stainless steel and teflon, selected to fail at a pressure significantly below that of the relief valve. Provided that the interspace pressure sensor works, any condition resulting in passage of pressure beyond the rupture disc will lead to a ‘latched’ shutdown. Thus pinhole leakage and an excursion above rupture disc fail pressure, will both trigger the emergency shutdown. The latching process adds a further level of safety in that latched events are usually separately recorded and unlatching cannot be enacted without authorisation. Unlatching in this event, would be preceded by replacement of the rupture disc, cleaning, inspecting and testing of the relief valve and cleaning of the interconnecting pipeline.

Where there are sound arguments in favour of rupture disc/relief valve combinations, the solution may be to install a second relief route comprising a rupture disc only, but selected to fail at a pressure above the relief valve pressure, re-rating the relief valve at the same time as required.

8.5 Flame impingement

Flame temperature at the stoichiometric fuel/air ratio *(31.6% H_2 by vol)* is a maximum of *2403ºK (2130ºC).* This is very high and means that it is particularly important to ascertain all potential sources of emission and to design a plant so that flame impingement upon critical components is not possible *(CRC 1977).* The oxy-hydrogen flame is used for high temperature cutting and welding of very thick sections of metal. A jet leak of hydrogen would burn less fiercely than a stoichiometric mixture of hydrogen and oxygen but ramifications could still be serious.

A figure for reactor failure rate by this route has not been found. Prevention would depend on control of leaks, a high level of ventilation and the absolute absence of ignition sources. The former is difficult in view of the small size of the hydrogen molecule.

Flame impingement from a flange leak onto a pipeline was alleged to be responsible for escalation of the 1974 UK Flixborough explosion. Some are of the view that this was the initiating event but others *(Gugan, Bond, Alexander, Thomas*) do not support this view.

8.6 Computer viruses

A recent instance of production plant forced shutdown as a result of a computer virus, suggests the need to consider this possibility in the present context. It is assumed that in plants which are controlled by computer, the computer is a 'stand-alone' system and is therefore not readily liable to virus attack. However, the Holden Adelaide plant which was the subject of the above-mentioned failure, is also understood to have been a stand-alone system.

If a virus caused the subject plant control system to fail this would simply lead on to an Emergency Shut Down (ESD) as indicated elsewhere herein. Although this would have financial ramifications it would not prejudice plant safety.

9 OTHER CONSIDERATIONS

9.1 Societal risk

This is established by assessing the actual population inside the effect distances previously established. In regulatory compliance terms, only societal *(or group)* risk of death is considered and as none of the modelling herein performed indicates deaths off-site, no attempt has been made to establish societal risk.

9.2 Wind direction effects

It is common in modelling like that performed herein, to establish the wind rose for the location and to consider the predominant direction in which an effect travels and then to calculate individual risks for communities in several compass directions around the source. However, this has not been performed as an explosion produces blast effects which are essentially equal in all directions.

10 MORE ON THE PROPERTIES OF HYDROGEN

Ignition temperature is *847ºK (574ºC).* This is high and for example, means that a lighted cigarette or cigar will not ignite it. Smoking should not be permitted however, as the energy in a lighted match or lighter is sufficient to cause ignition.

Flame emissivity is *0.10*. This is low and means that burning is unlikely unless the flame impinges on the person. The low emissivity however, means that the flame is invisible in normal lighting conditions and therefore an observer may be in the flame without knowing it until burning has occurred. The latter effect is enhanced further as hydrogen is also odourless.

Hydrogen is an æsphyxiant gas. Together with absence of odour this means that a considerable æsphyxiation hazard is present in any *confined* plant where hydrogen is in use. A multi-point, cyclic ambient monitoring system analysing oxygen level should be installed in such a plant.

The hydrogen molecule is so small that prevention of all leakage is almost impossible.

Flange leakage can be more properly managed than taping and periodic use of a hand-held analyser, by the banding of flanges and passage of a designed outlet tube to a safe place.

The extreme lightness of the hydrogen molecule means that in unconfined situations such as transfer pipelines, explosion is unlikely consequent upon propensity for leakage to disperse upwards. Although the ignition energy is extremely low, detonation energy is high. The converse of this is the case as soon as any form of *confinement* is present. Even the 'confinement' of an open plant structure has been shown to increase the likelihood of explosion *(Flixborough Disaster, UK, 1974; CRC 1977).*

Sudden release of hydrogen at *7900kPa (79bar)* or greater can cause spontaneous ignition as a result of the reverse Joule-Thompson effect. Presence of fine particulate metal or rust can increase likelihood of this *(CRC 1977*).

Occurrence of flash fires and explosions on discharge of the hot products of catalytic hydrogenation of vegetable oils have been attributed to presence of *phosphine* from the *phosphatides* present eg in rapeseed and linseed oils *(CRC 1977).*

CONCLUSIONS

- If a confined or semi-confined hydrogen explosion occurred at the facility of the scale considered herein, sufficient injury and property damage would be caused on and off site, to cause authorities and the courts to take actions which might lead to its closure

- *40kg* of hydrogen leakage is somewhat unrealistic as practices indicate that this could only happen if numerous safeguards were breached or failed

- A more realistic but also unlikely event is the emission of *3.9kg* of hydrogen, leading to explosion. This too would cause some off site effects and on site, anguish and possible loss of life

- It is likely that an actual hydrogen escape would rise away from the facility so quickly that an explosion if it occurred, would be in the air above the plant rather than within it, provided that its design allows a sufficiently open structure to permit this. Consequently it is considered that the extreme buoyancy of hydrogen would mitigate strongly against an event being as significant as indicated herein

- The individual risk in the surrounding community using raw pressure vessel failure data, is below the criterion informally used for the control of major hazard facilities by the authorities in Australia

- The quantity of hydrogen gas used or generated at such facilities is sufficient to warrant their definition as Major Hazard Facilities *(MHF)* under the *Occupational Health and Safety (Major Hazard Facilities) Regulations 2000*

- Individual risk criteria and likelihood of explosion occurring at all, are so low that no personnel present on such a site face an unacceptable level of risk

- The actual explosion risk level calculated for the whole system comprising the hypothetical hydrogen-using plant is such as to indicate that an explosion of the scale considered, is essentially impossible

- The all important conducting of *HAZOP* studies in instances like this must involve all of the right personnel and free flow of information without embarrassment and without holding back. Without this, the process however rigourous, would fail

11 FOOTNOTE

Appendices are omitted herein due to space limitations but will be presented at the conference and on request. They comprise :-

- *A series of four cartoons highlighting the importance of applying common sense as well as mathematics to risk assessment*

- *A notional risk assessment worksheet where risk is depicted in the range 1 to 25 and serious risks are 10 and over*

- *Detailed list of references cited (some are included in the text)*

- *Maps of human injury radii*

- *Maps of property damage radii*

- *Process flow diagram for the hypothetical plant*

- *Control system logic diagram for the hypothetical plant*

- *Hydrogen brittle fracture and vessel failure photographs*

A COMBINED OPERATIONS AND MAINTENANCE STRATEGY FOR IMPROVED PLANT PERFORMANCE: SURVEY RESULTS ANALYSIS

Fernando MR and Cheong F

School of Business IT, RMIT University, Australia

Abstract: We present, discuss and analyse the findings of a recently completed questionnaire survey conducted within a large Australian organization in relation to a case study based empirical research project on above topic. Key aspects of the topic, including its research trends, rationale, barriers, influencing factors and performance measures are discussed. The results, representing perceived views of a population sample consisting of maintenance and production staff on relevant aspects, are analysed and discussed. Overall results were encouraging with a majority of participants in favour of the concept. There was also significant opposition or disagreement, challenging potential implementers to properly address the needs of this opposing minority and gain their support prior to the introduction of such strategies.

Key Words: Maintenance Strategy, Plant Performance, Empirical, Performance Measures.

1 INTRODUCTION

Having invested heavily in the state-of-the-art, automated plant and machinery, modern manufacturers have managed to reduce their production or processing costs significantly with improved delivery and customer service performance. However, there remain future challenges, especially in terms of initiating continuous improvements to further improve their plant performance; a challenge that confronts plant managers in an ever increasing competitive pressures due to globalization [1, 2].

Traditionally, the function of production has been considered as primarily value adding and directly responsible for processing of product or service. However, with the introduction of high technology, automated plant, maintenance is now becoming a key driver of plant performance, due to its contribution through expert technical and reliability support. While bad maintenance leads to unreliable plant, outcomes due to poor operational practices could be drastic [1, 2]. An identifiable dynamic interaction [3] exists between production and maintenance, causing adverse effects on overall plant performance, more often than not. Hence, the challenge is to eliminate such negative outcomes through a common focus on overall plant performance. This is achievable by understanding the value adding role of each other, towards the overall plant profitability and competitiveness.

This dynamic interaction has prompted research attempts to combine maintenance with production and other manufacturing disciplines [3, 4]. Encouraged by demonstrated positive outcomes of such initiatives, we proposed a Combined Operations and Maintenance Strategy (COMS) [5], as one solution aimed at improved plant performance through collaboration teamwork between production and maintenance, by focusing on common business objectives. A well-defined COMS, jointly formulated through an interactive team process, could provide modern manufacturers with a distinctive competitive edge. Furthermore, initiatives similar to COMS could play an important role in modern, automated plant, where maintenance play a dominant role in providing timely solutions to enhance uptime and plant reliability through highly skilled technical staff. Therefore, it is to the benefit of both production and maintenance managers, that they exploit the potential benefits of COMS and its effective implementation. Hence, we believe an empirical study on COMS is justified, to serve the above purpose.

2 SURVEY DETAILS

Our study involved a recently completed questionnaire survey targeted at an audience comprising of maintenance and production staff of a large Australian organization, seeking their perceived views on COMS implementation. The organisation provides collection, distribution and delivery services of various articles across Australia, serving a wide range of domestic and international clients. This survey was conducted within seven of their processing plants situated in major cities of Sydney (SYD), Melbourne (MEL), Adelaide (ADE), Brisbane (BRI-1 & BRI-2), Perth (PER) and Canberra (CAN).

The organisation employs nearly 23000 people with annual revenue of $ 4.3 billion and $ 525 million before tax profit reported during 2004-05. With a total asset base of $ 3.8 billion, the organization has invested in modern, the state-of-the-art processing plants in each state, and has a highly sophisticated road and air transport network. A population sample from both maintenance and production staff participated in the survey, except in SYD and BRI-2, where timely approval could not be obtained for the involvement of production staff. A total of 148 staff members from maintenance (Maint) and 116 staff members from production (Prod) participated the survey, with a targeted audience comprising of technicians, team leaders, technical managers, production managers, process leaders and production operators.

We visited all sites and personally invited staff to participate in the survey, except for CAN, where the survey was carried out by respective managers according to guidelines. Since the focus of study is maintenance management, we invited all staff from maintenance function to participate, except for those who were on leave. Due to very large production staff population, only a representative sample of production function was invited to participate. A breakdown of all participants is shown in Table 1 below. Response rate of maintenance staff is shown in Figure 1.

Table 1

A Breakdown of all Participants

	MLB		ADE		BRI-1		CAN		PER		SYD		BRI-2		Overall	
	Prod.	Maint	Prod.	Maint	Prod.	Maint	Prod.	Maint	Prod.	Maint	Prod.	Maint	Prod.	Maint	Prod.	Maint
Manager	3	1	2	0	2	1	2	1	3	1	0	1	0	0	12	5
Team Leader	13	9	16	3	20	4	11	5	9	0	0	4	0	2	69	27

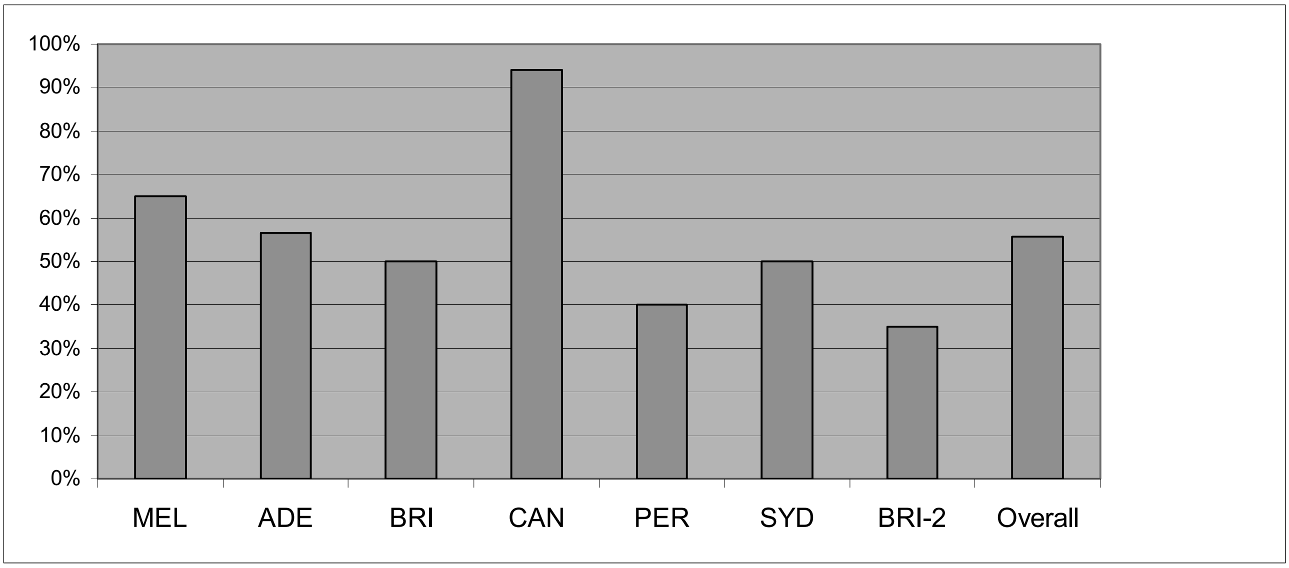

Figure 1.Response Rate of Maintenance Staff

3 RELATIONSHIP BETWEEN PRODUCTION AND MAINTENANCE

Poor maintenance causes disruptions and unavailability of plant. Lack of maintenance planning affects production performance through redundant manpower and loss of output, eventually declining the overall business performance [2]. It is also evident that poor production practices, lack of production planning and basic operator care, often cause reliability problems and downtime. Although maintenance has been historically blamed for equipment down time and for higher costs, current research reveals that a majority of maintenance costs are driven by bad design, poor production practices and process controls [6, 7].

The above dynamic interaction between maintenance and production necessitates close liaison and coordination between the two functions, because they can no longer be treated in isolation. Instead, the two functions should complement their mutual efforts to achieve overall business objectives. Eventually, both functions have to realign their individual strategies based on common priorities, including a most important one in continuous improvement of plant performance [5].

In our survey, we sought the opinion of staff on the relationship or interaction between production and maintenance. They had to choose between two options; (a) *Independent* of each other, each contributing separately towards plant performance, and, (b) *Interdependent & Interacting* with each other to influence plant performance. A comparison of their selections is illustrated in Figure 2.

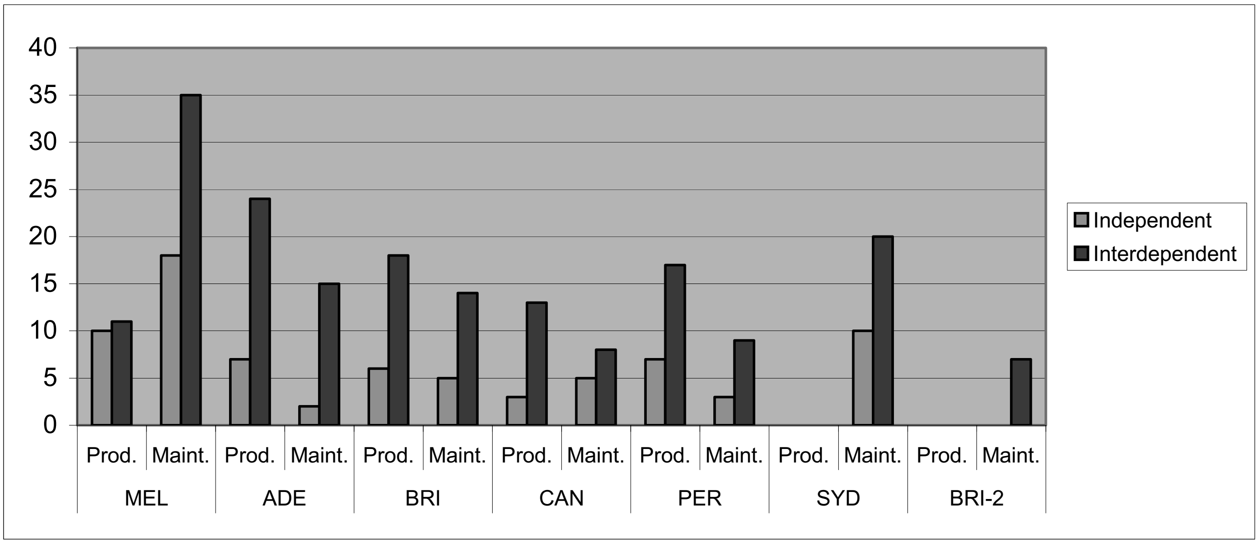

Figure 2.Relationship between Production and Maintenance

The results indicate that a majority of staff from both production (Prod) and maintenance (Maint) consider these two functions as *interdependent and interacting* with each other to influence plant performance.

In terms of the contribution of each function towards influencing overall plant performance, we invited staff to rate each function, between a scale of 1 to 5, 1 representing a very high, and 5 being a very low. The results are illustrated in Figure 3.

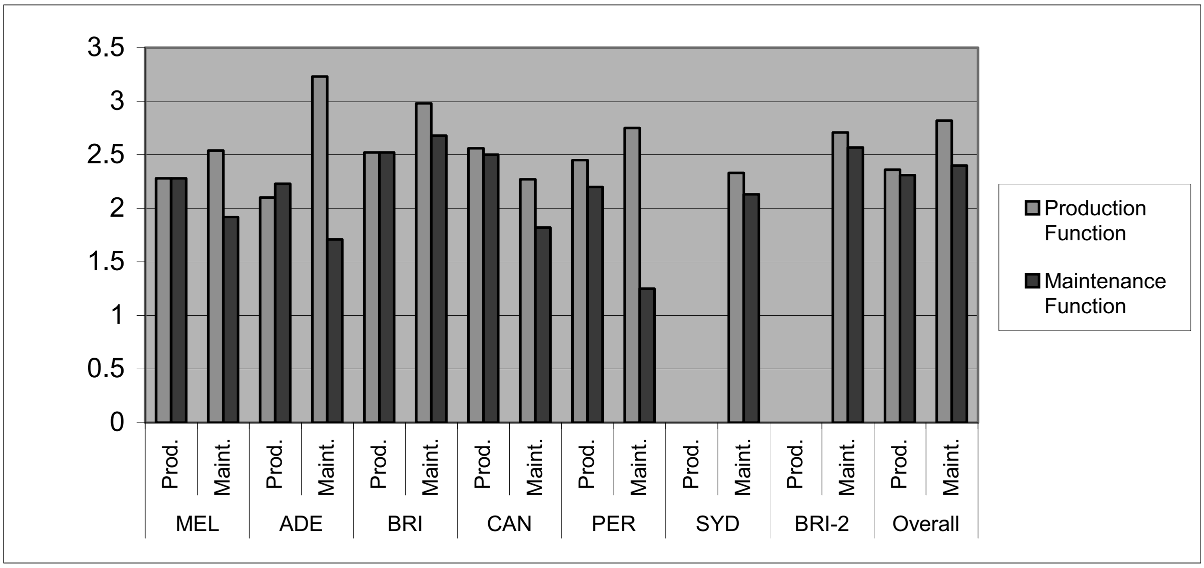

Figure 3. Contribution or Level of Influence over Plant Performance

It is evident from the results, except for a slight variation from production staff in Adelaide, both production and maintenance staff at all plants placed maintenance at a higher rating than production. This confirms that they believe maintenance has a greater influence over plant performance. In general, ratings of both functions are much closer to each other, suggesting that staff considered both functions playing equally important roles.

4 RESEARCH RATIONALE

Maintenance management has emerged from being considered a marginal activity or an unavoidable cost, to that of a strategic function which provides cost effective solutions to achieve overall business objectives. Many researchers have identified the need to combine maintenance with other manufacturing disciplines such as production. A majority of these research initiatives have demonstrated positive business outcomes [3, 4, 8-11].

Although production is the primary value adding plant function, there is enough evidence to show that maintenance adds value to production process by providing an essential support service to ensure plant quality and reliability. Highly dominant role played by skilled technical staff in maintaining high technology plant in many sites demand maintenance staff to be equally competent in handling all production situations with confidence. Similarly, production staff has to be fully aware of the nature and complexity of high technology plant, in order operate the plant effectively and confidently. A well-defined COMS, involving combined team efforts between the two functions, will help both maintenance and production functions to achieve these goals, leading the plant to high profitability and competitiveness.

The following extracts from current research also justify the need for COMS or similar initiatives.

- Resource utilisation is critically linked with plant availability, which again depends upon maintenance reliability. Hence, a sound maintenance policy maximises profits [3].
- Competitive pressures demand strict cost control through reassessment of maintenance practices, where technical staff should gain high production process competency [10].
- An approach to link performance with a combined maintenance and production strategy would supplement the existing theory and practice of operations strategies [2]
- The involvement of all disciplines, is an essential feature towards achieving overall production efficiency [12].

In the survey, we invited staff to select from the following three options, the best choice that they think, would improve plant performance:

Option A Separate strategy for each department, in line with their functional objectives.

Option B Separate strategies formulated by each department, but in consultation with one another, in order to complement the business objectives of each function.

Option C A combined operations and maintenance strategy (COMS), jointly created, through an interactive team process, in line with the overall business strategy.

The level of responses received by each option for this enquiry is shown in Figures 4 and 5.

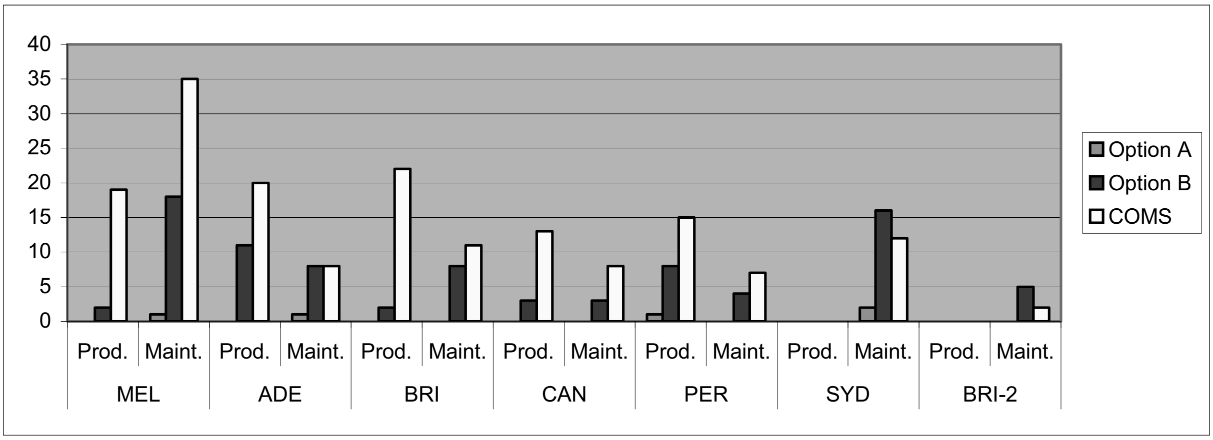

Figure 4.Best Strategic Option, Perceived by Staff from Each Site

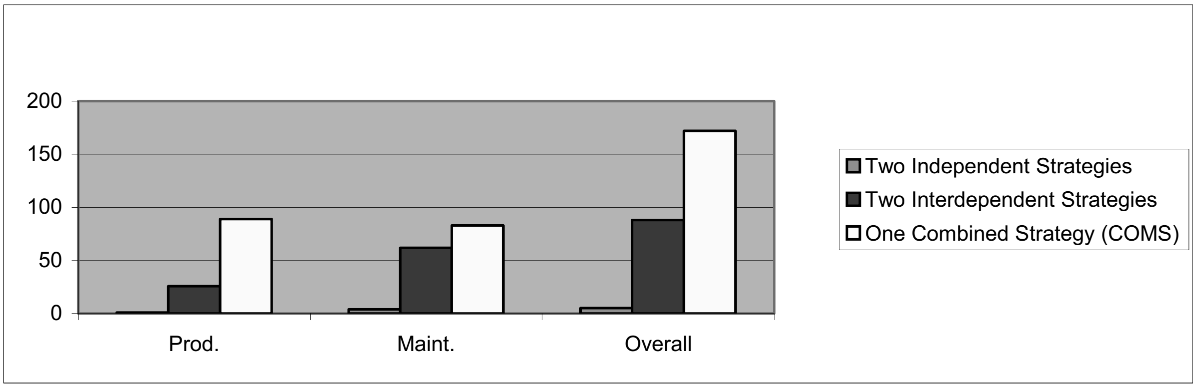

Figure 5.Best Strategic Option, Perceived by Overall Staff

The above results demonstrate a strong support for COMS among production staff at all sites. However, the opinion of maintenance staff varied between sites. While a majority of maintenance staff at MLB, BRI, PER and CAN preferred COMS, a majority of maintenance staff at SYD opted for two interdependent strategies (option B). ADE remained neutral.

Although a majority (80) of maintenance staff was in favour of COMS, a significant number (60) preferred option B. This could mean that any future COMS implementation attempts may face with resistance or reluctance to participate, especially from this section of maintenance staff. Technicians at MLB and CNB will possibly offer more support and lesser objections, and they would make ideal sites for future pilot programs or field experiments on COMS.

The results relating to the current strategic approach taken by management, as perceived by staff, are shown in Figure 6.

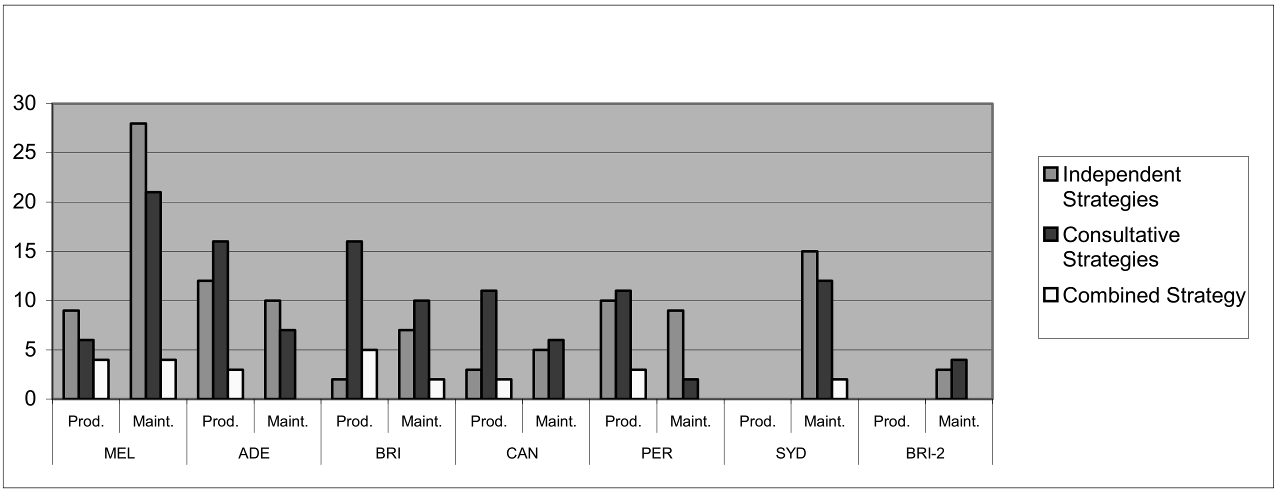

Figure 6.Current Management Strategy, Perceived by Staff

Many believed that current approach is consultative. Given the choice to decide on their own strategy, the staff selected the given strategic options as illustrated in Figures 7 and 8.

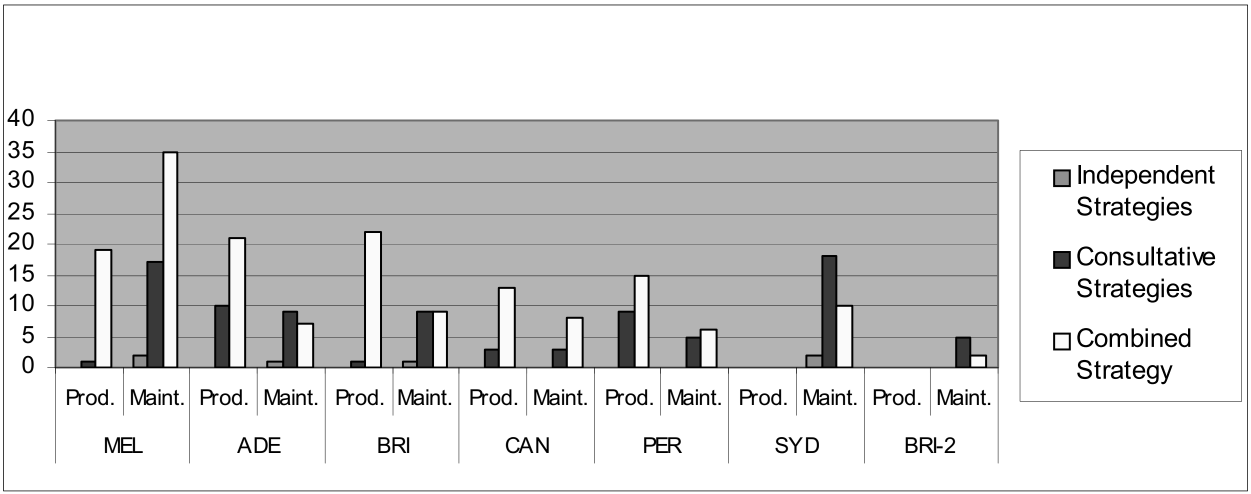

Figure 7.Strategic Approach chosen by Site Staff

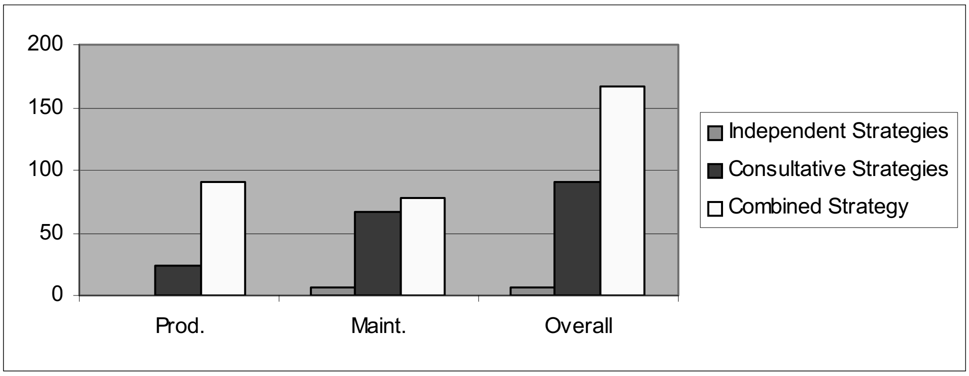

Figure 8.Strategic Approach chosen by Overall Staff

While production staff preferred COMS, maintenance staff was equally divided between consultative and combined approaches. When asked, whether they consider COMS, based on common business objectives, as a genuine industry need for their current plant environment, the staff responded in a way as shown in Figures 9 and 10.

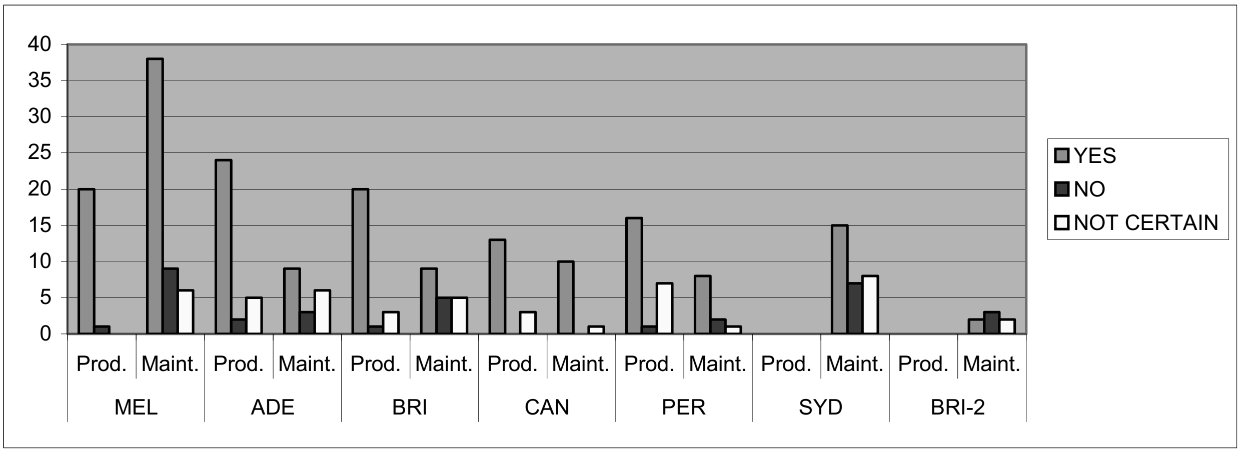

Figure 9: Is COMS a genuine Industry need? - Site Staff

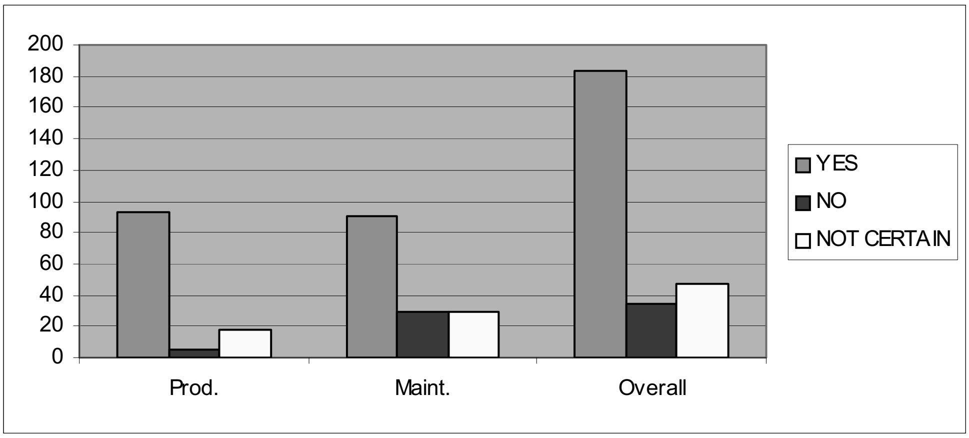

Figure 10.Is COMS a genuine Industry need? - Overall Staff

The above figures indicate that a clear majority consider COMS as a current industry need.

5 BARRIERS OF COMS

Research identifies a historically existing conflict of interest between operations and maintenance, due to lack of communication, and other reasons. A successful COMS could only be achieved through total elimination of such internal barriers through strategic change. However, implementing strategic change involves risks. Risks often discourage decision makers. Sutton [13] claimed that 70% of change project initiatives in the UK failed due to lack of planning, shared vision and team involvement. Other barriers confronting COMS are natural human fear and resistance to change due to uncertainty and the loss of power and authority [14].

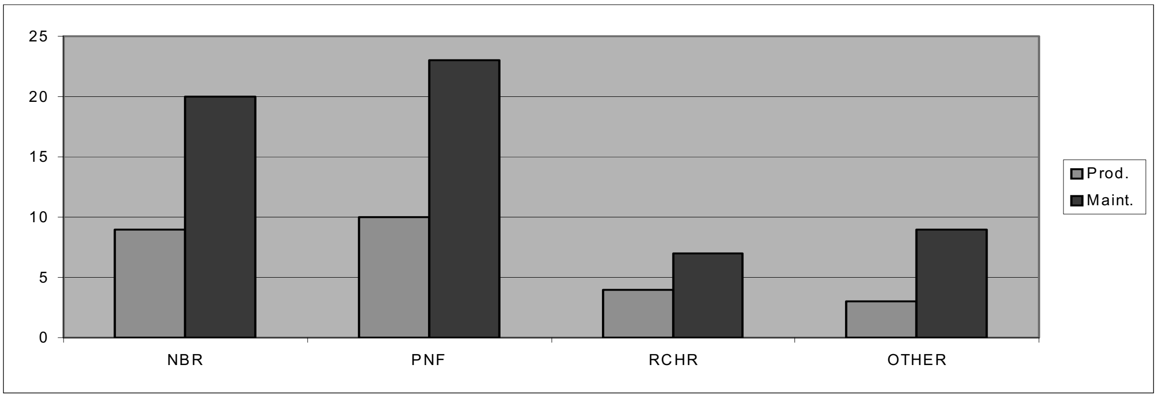
From those who preferred two interdependent strategies, but not COMS, we asked them to select their possible reason for not selecting COMS, from four given options:

Option 1 COMS will not bring any better results than two interdependent strategies (NBR)

Option 2 COMS is practically not feasible for their plant (PNF)

Option 3 COMS is too radical and the risks involved are too high (RCHR)

Option 4 Others, please specify (OTHER)



The number of times each option was selected by the staff is shown in Figure 11.

Figure 11.Reasons for not selecting COMS

The above results indicate many believed that COMS is not practically feasible for their site, or they did not believe that COMS will bring in any better results than two interdependent strategies.

From those who preferred options A & Option B in section 3 above, we asked them to identify major barriers of combined or collaborative strategies, from four given options as follows:

Option 1 Fear and resistance to change by management and staff (FRC)

Option 2 Opposition from those who may lose their power and authority (OPP)

Option 3 Reluctant or failure by plant management to identify such a need (RFM)

Option 4 Lack of communication and understanding between functions (LCU)

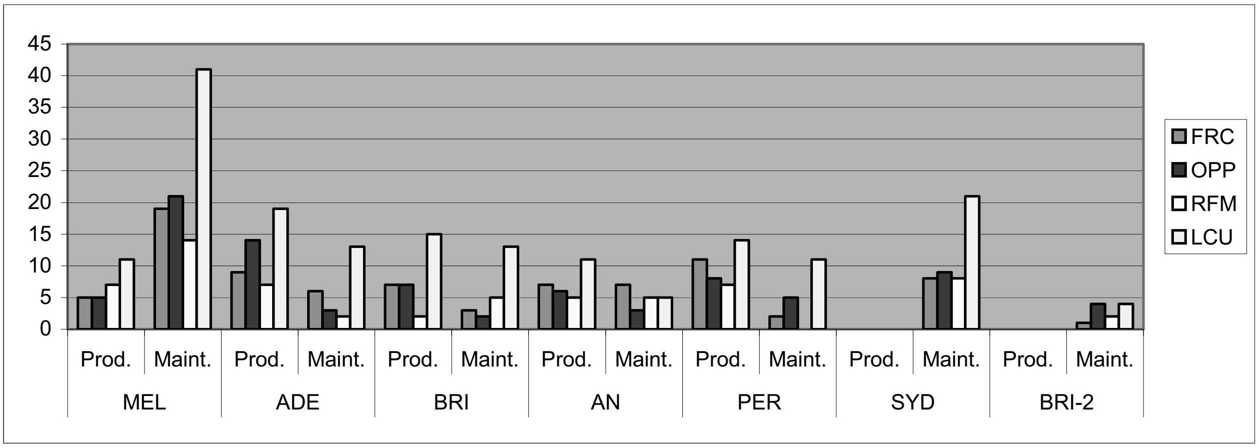


Figure 12.Barriers confronting COMS, Site Wise

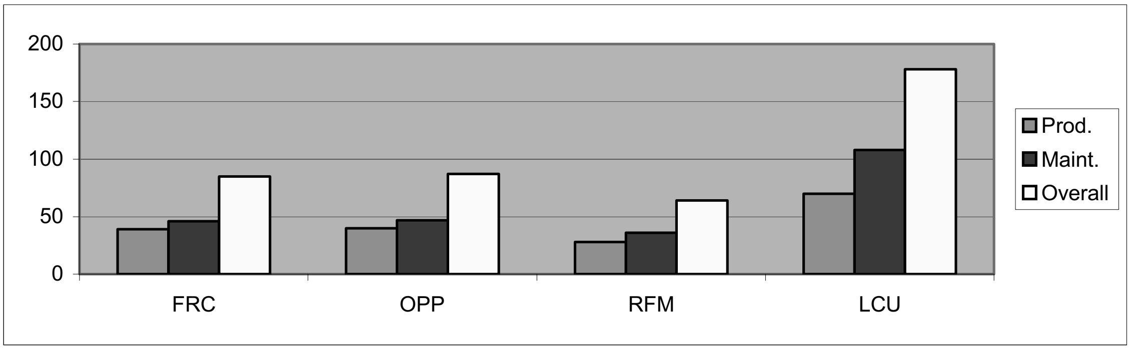

Figure 13.Barriers confronting COMS, Overall

Total number of times each option was selected, are shown in Figures 12 and 13 above, and the results confirmed our earlier research finding that lack of communication is a major barrier of COMS, and proves that improved communication and better understanding is vital to make COMS a successful initiative.

6 PROMOTING COMS

Communication gap between the two functions can be reduced by understanding and focusing on common business goals and by having a shared vision. Once production and maintenance clearly identify each other's strategic role in adding value to the overall business, their mutual efforts could be supplemented. Multidisciplinary teams or autonomous groups [12] may help to have better understanding of mutual needs and lead to improved harmony. Education and training also play a vital role in bridging such gaps through regular meetings and focused groups, fostering collaboration.

A remarkable lack of trained technical personnel to perform primary maintenance activities has been lately identified. This gap will have a greater impact on the availability of researchers involved in maintenance related areas [15]. By promoting industry based maintenance research through sponsorships or grants can encourage maintenance professionals into active research. Participation of academics and experts in industry-based research could also help.

In our survey, we asked those who preferred combined or collaborative strategies to rate the level of influence of the following action items, towards promoting such strategies.

Option 1	Initiate open dialog between the two functions (IOD)
Option 2	Involve operators and Technicians in decision making (IDM)
Option 3	Promote and create cross-functional teams (PXFT)
Option 4	Educate plant management on COMS (EPM)
Option 5	Establish sound theoretical knowledge of COMS (EST)

Weighted average rating of each action item, as perceived by staff, is shown in Figure 14, with 1 representing a very high and 5 representing a very low.

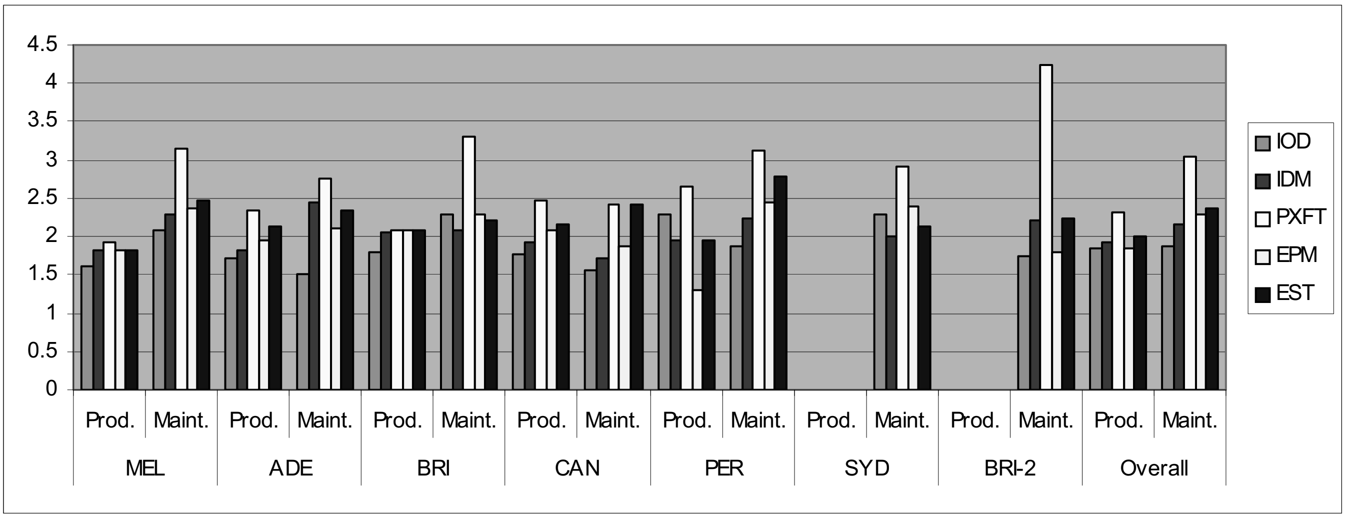

Figure 14.Factors influencing Combined Strategies

In all sites, both production and maintenance staff rated IOD (initiating open dialog) as the most influencing action item. Production staff also found EPM (educating plant management) equally important. Staff from both sides identified the need to initiate open dialog between them, possibly reassuring us of an existing lack of understanding between the two functions. With the exception of PXFT (promoting cross-functional teams), all staff in general found all action items of having a more than average influence in promoting COMS. It is also evident that maintenance staff do not favour PXFT, clearly giving us an indication that technicians prefer to have their own identity.

7 MEASURING PERFORMANCE UNDER COMS

Success of any business entity depends upon its ability to meet the desired level of performance. Hence, it is important that we establish suitable indicators of plant performance, and use those yardsticks to measure our business success. There are a few performance measures we have identified as more appropriate under COMS like initiatives.

We found Overall Equipment Effectiveness (OEE) as the most relevant performance indicator for COMS. OEE is easy to understand, flexible, can be used by operations and maintenance, and OEE tracks progress on equipment improvement on regular basis. The strength of OEE is its ability to represent the combined efforts of both operations and maintenance in one measure. OEE is defined by the following equation [12]:

OEE = Equipment **Availability** x **Performance** Efficiency x **Quality** Rate

Whereas;	Availability	= Uptime / Scheduled Time	Industry Benchmark = 90%
	Efficiency	= Actual Output / Scheduled Output	Industry Benchmark = 95%
	Quality Rate	= Production less defects / Total production	Industry Benchmark = 99%

Therefore, Benchmark of OEE = 90% x 95% x 99% = 85% [16].

One drawback of OEE however, is its focus on equipment types, but not on the plant as a whole. Therefore, OEE can only be applied to plants where equipment can be separately identified with clearly established boundaries. OEE has no direct financial interpretations, and therefore, may not attract financial managers and investors.

An alternate solution to OEE, is the Balanced Scorecard (BSC). BSC is an indication of four strategic perspectives of performance, namely, financial, customer, internal processes, and learning and growth. BSC translates strategy into more tangible and actionable objectives, related measures, targets and action plans. BSC could focus on key maintenance related factors, which are critical towards contributing to business success. BSC, while being capable of providing a holistic assessment representing a range of critical issues, is complex and calls for a higher level of understanding. While OEE may be suitable at functional level of the plant, BSC is more suitable at strategic business level [17].

On scale of 1 to 5, with 1 indicating a very high and 5 indicating a very low, we invited staff to rate most relevant and realistic performance measure from four given options, namely OEE, BSC, Unit Cost (UC) and Return on Investment (ROI). The weighted average ratings of each measure, as per results are shown Figure 15.

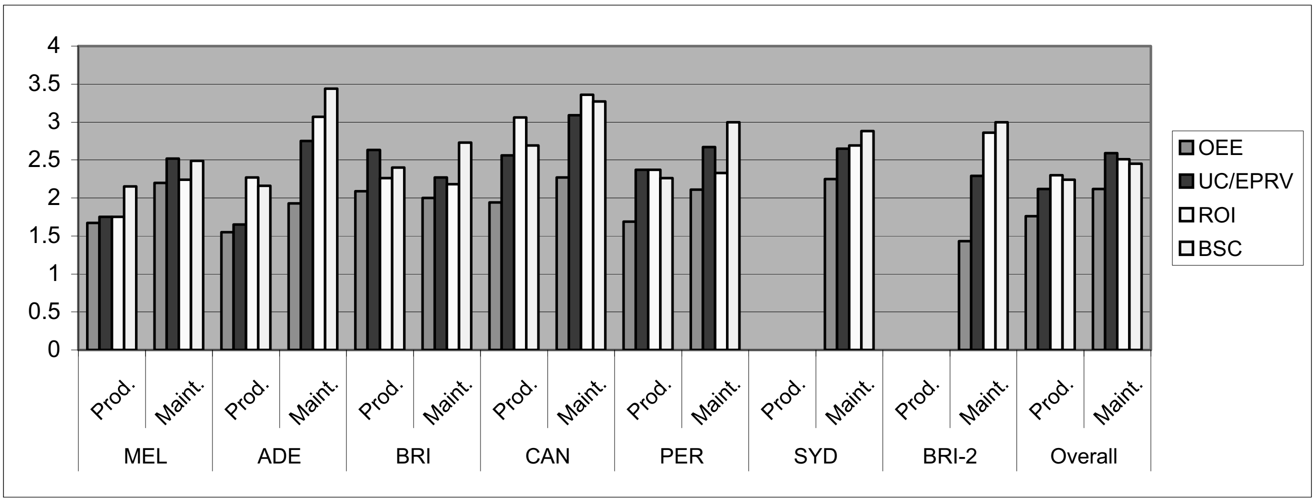

Figure 15: Key Performance Indicators, Weighted Average

From the results, it is evident that OEE is the most preferred option, naturally due to its awareness among the staff within all sites. BSC was not preferred by both production and maintenance staff. Rating of ROI as the second best choice indicates a strong bias towards ROI among all the staff. This appreciation of business returns by the staff is encouraging and the introduction of a monetary based KPI, could motivate the staff towards optimum results.

8 CRITICAL FACTORS OF COMS

There are many concepts and philosophies associated with maintenance management. Most frameworks consist of a critical set of strategic elements, which are needed to be addressed in an appropriate manner to steer the process towards desired goals. These elements could be critical action areas [12] or critical variables which control the effectiveness of the process [4]. Model based approaches usually call these as variables. The effects of these variables, direct or indirect, along with relationships they hold with each other, determine the effectiveness of our process.

We have come across a myriad of variables relating to COMS. We have carefully selected a few case sensitive variables from the organization of our study for our survey. They were; goals and strategy, human resource aspects, organizational aspects, support mechanisms, and tools and techniques [17]. Our participants were invited to rate the contribution of each component on a scale of 1 to 5, with 1 representing a very high and 5 representing a very low. Weighted average ratings given to each option are shown in Figure 16.

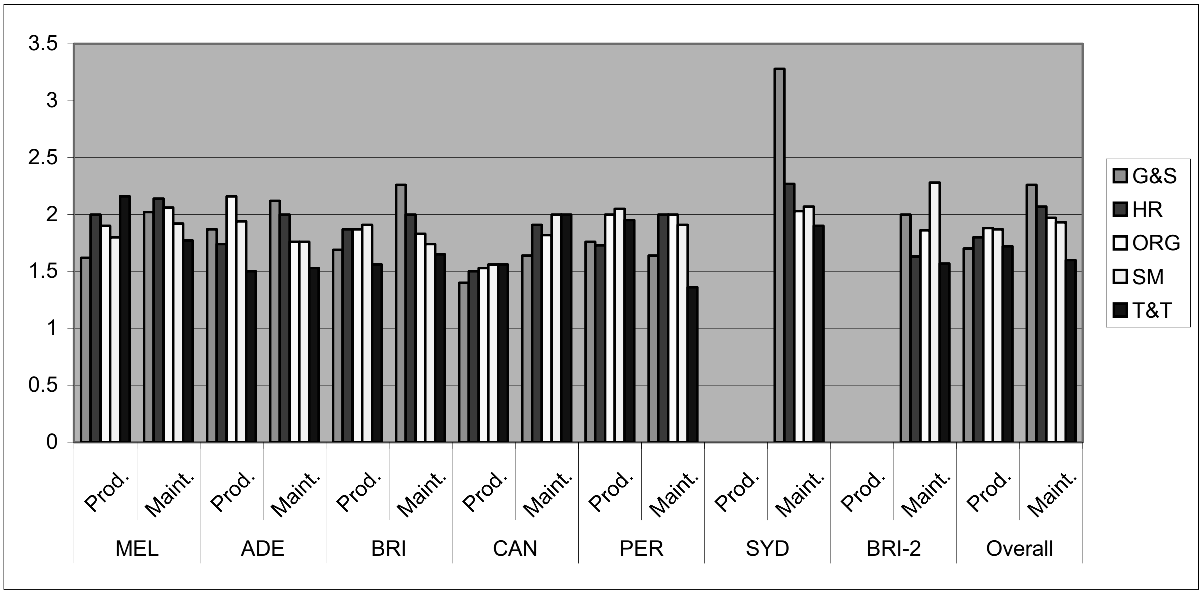

Figure 16. Contribution of Strategic Components

Production staff rated all variables of having equal rating, whereas maintenance considered tools and techniques as having higher influence and goals and strategy with a lower rating.

9 CONCLUSION

Continuous improvement of plant performance is a challenge faced by modern manufacturers striving for profitability and competitiveness. Survey results confirm that maintenance play a dominant role in effectively contributing to this task, especially in these heavily automated high technology plants. Proposed combined strategy aimed at exploiting the true potential of the dynamic interaction between maintenance and operations to improve plant performance, has been accepted by a majority. However, there was a significant number who preferred collaboratively implemented, separate functional strategies. They reasoned that a combined strategy may not bring in any better results than having two collaborative strategies. Feasibility of COMS implementation in these sites was seen by them as impracticable.

Justification of COMS in similar plant environment is strengthened by the acceptance of COMS as a current industry by a vast majority. The lack of communication (and understanding) and fear (and resistance) to change, are two major barriers confronting COMS initiatives. Initiating open dialog between the two functions was seen by many as key influencing factor, overcoming many barriers. OEE was accepted by a majority as an appropriate performance measure, with a significant number demonstrating their appreciation of ROI, also as a key measure.

The overall results of our survey were encouraging, with a clear majority in favour of COMS. However, there are key issues to be addressed before we could gain support from a doubtful, but a significant minority who still prefer two individual strategies. Even though the results seem to verify current research findings on this topic, the final outcome of successful COMS implementation will depend upon the ability of both production and maintenance managers in overcoming the barriers and hence reducing the communication gap.

GALVANIZED STEEL IN ASSET DESIGN

Peter W. Haberecht[a] and Emmanuel Pimentel[b]

a: Materials and Environments (MATENV) PO Box 18061 Collins Street East Vic 8003

b: Galvanizers Association of Australia Lvl 5 124 Exhibition Street, Melbourne 3000

Abstract: After Fabrication Hot Dip Galvanized Steel is used extensively in infrastructure and large engineering applications. Galvanized steel is increasingly being considered as a "composite material" rather than a component of a duplex system (coating on substrate) and its economic and physical advantages extend beyond its traditional role of corrosion protection. This paper will examine the economic and engineering advantages of using galvanized steel. It will be argued that the capabilities of hot dip galvanized steel should be assessed with all engineering materials, at the design and specification stage and not just as an after thought for asset corrosion protection. An emphasis on a more holistic and specific maintenance approach into the life cycle of assets and their component materials has great economic and efficiency benefits. The example used relates to studies performed on lattice towers found in power distribution.

Key Words: zinc, after fabrication hot dip galvanizing, structural steel, durability, AS/NZS4680, duplex systems, cost benefit analysis

1 INTRODUCTION

The extraction of iron from its ore initiates an irreversible and natural process: its corrosion and tendency to return to its natural state. Unless steel is protected, it will corrode in most environments and compromise the structural stability or usefulness of the fabrications that it composes.

Corrosion of steel and its mitigation, repair and ultimate replacement is estimated to cost Australia between 3 - 5% of GDP (this is similar to studies done in the USA). On current GDP statistics, this equates to a figure of $25 - $41 billion. Thus, corrosion prevention and mitigation are not only an essential element in the economic utilisation of steel, but also in the increasingly scrutinised use of both public and private funds. [1] [2]

The selection of the appropriate corrosion protection for steel can result in initial economic savings coupled with substantial economies in service. These economies can be the result of the reduction or elimination of maintenance and their associated labour costs and lost service time and also in the deferral of the replacement of structures and equipment.

Hot dip galvanized steel is used extensively in most infrastructure applications. Although galvanizing is traditionally regarded as a corrosion protection system for steel, it has other benefits such as improved abrasion resistance and ease of transport (due to the fact that the hardness of the iron-zinc alloys formed during the galvanizing process can be around 50% greater than that of the base mild steel) and greater variability in the conditions under which it can be installed. In fact, the hardness of the iron-zinc alloys formed during the galvanizing process can be around 50% greater than that of the base mild steel.

Galvanizing specifically uses zinc to cover and protect steel from corrosion and it does this via a number of different mechanisms: physical barrier protection, the development of a carbonate patina envelope, and cathodic protection. Although the most easily identifiable examples of galvanized structures include road crash barriers, boat trailers and electricity transmission towers, galvanizing is now used in most structural engineering applications requiring corrosion protection or abrasion and impact resistance.

One of the methods of protecting a steel substrate is the application of a paint coating. Paints have a durability that ranges from a few years to a couple of decades. While paint types and chemistry can influence this durability, it is predominately the prevailing environment, the quality of application and the aspect of exposure the painted surface has to the environment, that dictates the degradation rate and ultimately the life of the coating.

Rarely do two different sides of a building or structure share the same prevailing environments. In buildings that are several stories in height, each elevation of approximately 10m presents a new set of environments. This pragmatic approach to structures and the increasing requirement for long term durability of 50 years or more, takes the process of management of an asset to a level of macro-management using risk based assessment concepts and techniques to determine the level of corrosion and maintenance. [3] [4] [5] [6]

The typical result is to assume that the worst conditions will prevail and conduct cost benefit analysis (CBA) to determine the value of patch painting on the worst areas until the rest of the asset degrades to a point where the economics of large-scale repair become viable. Given the rising cost of insurance, litigation and more restrictive and costly OH&S rules, the cost to conduct outside maintenance is escalating at a significantly greater rate than the consumer price index (CPI).

This paper will attempt to illustrate the economic effects and importance of treating galvanized steel as a composite material with varied options for design and maintenance depending on the prevailing conditions in use and the utilisation of particular assets.

The Hot Dip Galvanizing Process (AS/NZS 4680)

The application of a zinc coating onto steel members prior to installation at a site is normally achieved by dipping prepared steel into a bath of molten zinc. The resulting chemical reaction between the steel substrate creates a complex alloy of zinc and iron (steel), resulting in a thick protective layer which has distinct constituent layers.

The hot dip galvanizing process is relatively simple compared to most other corrosion protection systems and it is this simplicity that makes it economically efficient and technically effective. Most galvanizing that is specified for a long design life or for use in moderate to highly corrosive environments is performed to AS/NZS 4680 *Hot-Dip Galvanized (Zinc) Coatings on Fabricated Ferrous Articles*. [7]

The preparation process for steel prior to galvanizing involves the removal of scale, rust, oil paint and other surface contaminants. This is usually achieved through cleaning in a caustic solution followed by immersion in an acid bath. The steel is then rinsed in water prior to its immersion in a warm flux tank, usually made up of a 30% zinc ammonium chloride solution. The flux solution removes the oxide film that forms on the surface of the steel after the acid clean and also prevents further oxidation prior to the actual galvanizing process.

The galvanizing bath is made up of molten zinc and some trace alloys such as aluminium. The bath is normally heated in the range of 445°C to 465°C. On immersion in the galvanizing bath, the surface of the work is completely covered and the molten zinc reacts with the steel to form a series of zinc-iron alloy layers. This metallurgical reaction between the molten zinc and the steel is another factor in the reliability of galvanizing. The coating continues to form until the steel has reached the temperature of the molten zinc and the reaction is complete. The steel is then withdrawn from the bath at a controlled rate and an outer layer of molten zinc is carried with it. This solidifies to form the predominately pure outer zinc coating with its characteristic grey colour.

Because the metallurgical reaction and subsequent alloying of the galvanizing process can only take place once the steel has reached the temperature of the molten bath, the process can vary from several minutes for light articles to many times longer for heavy structural articles.

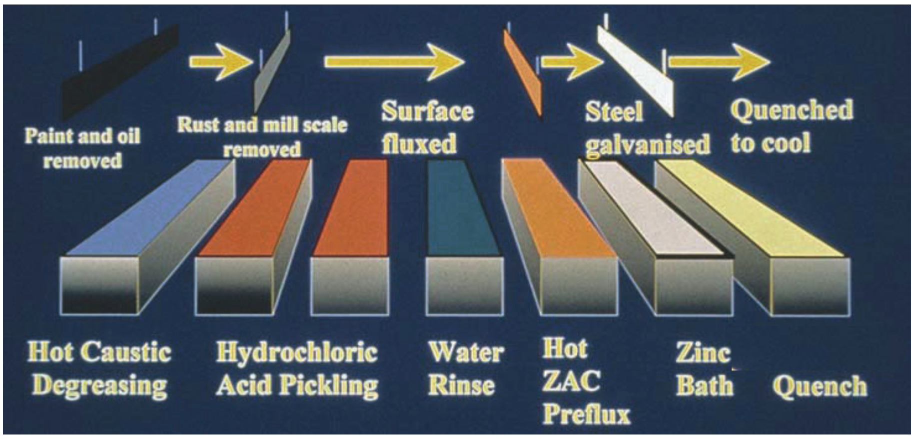

Figure 1: Hot Dip Galvanizing – General Process

2 PHYSICAL PROPERTIES OF GALVANIZED STEEL

The metallurgical alloying process of galvanizing provides galvanized steel with a number of unique properties. Since the process of galvanizing demands that the steel is fully immersed in the molten zinc bath, all surfaces of the work are completely covered, both externally and internally. This means that corners, edges, holes, welding seams and any recesses are completely covered and protected. This produces a uniform coating of zinc and zinc iron alloy layers over the complete article, no matter how complex in configuration, and specifically in areas that are potentially "corrosion hot spots" for other coating systems.

Secondly, because the zinc and zinc iron alloy layer thickness is determined primarily by the thickness of the steel, a standard minimum coating thickness is automatically applied to all areas regardless of orientation and access.

Figure 2: Large structural member: A large bridge beam measuring 12.5m in length, 1m through the web, and weighting 10.5 tonnes. This was a bridge beam for the State Rail Authority in NSW

Table 1 of AS/NZS 4680: Requirements for Thickness and Mass for Articles That Are Not Centrifuged

Steel Thickness (mm)	Local Coating Thickness Minimum (µm)	Average Coating Thickness Minimum (µm)	Average Coating Mass Minimum (g/m^2)
≤ 1.5	35	45	320
> 1.5 ≤ 3	45	55	390
> 3 ≤ 6	55	70	500
> 6	70	85	600

(AS/NZS 4680:1999 *Hot-dip Galvanized (zinc) Coatings on Fabricated Ferrous Articles* p8)

Corners and narrow edges actually produce a slightly thicker galvanized coating, thus providing greater protection from corrosion and impact on the areas most likely to suffer these. This contrasts with other coating systems, such as paint, which thin out in these critical areas and require expensive design and application modifications to improve their performance on such surfaces. Also, the predicted life to first maintenance of painted surfaces in AS/NZS 2312 applies to planar surfaces, not edges, crevices and other areas that may require further additional protective steps to improve their durability. [8]

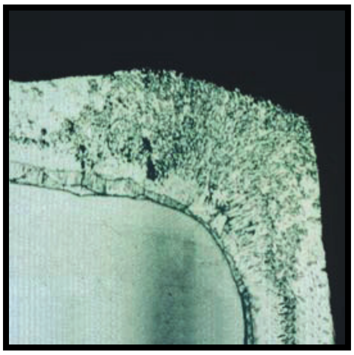

Figure 4: Micrograph of galvanizing on edge of steel

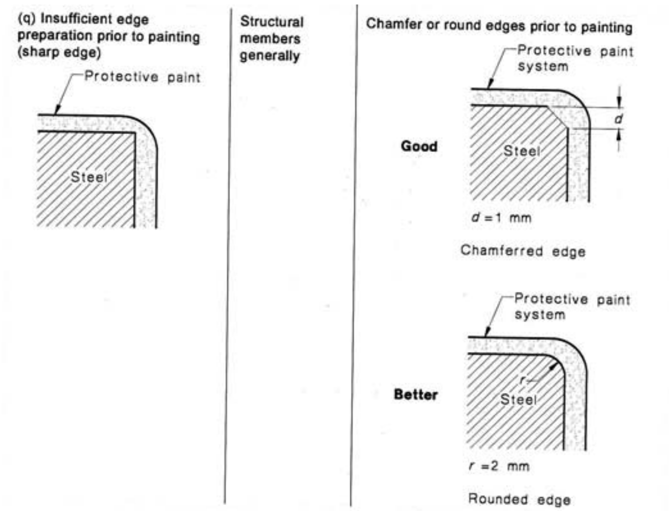

Figure 5: AS/NZS 2312 requirements for edge corrosion protection for paint systems. Note engineering design required to insure integrity and effectiveness of corrosion protection. This is not required for hot dip galvanized articles and results in less engineering expense.

The substrate of a galvanized section is nearly 100% iron while the most outer part or surface of the galvanized coating is 100% zinc. The intermediate layers have fixed ratios of zinc and iron progressing from ~25% Fe/ 75% zinc to ~10% Fe/ 90%

zinc, to 6% Fe/ 94% zinc, and finally pure zinc. These alloy layers can constituent more than 60% of the sectional thickness of the coating material.

The actually coating thickness is directly related to the substrate thickness, and thin substrates typically have thin coatings, while thick steels have thick or very thick coatings. Coatings are measured in either the thickness of the coating (µm) micro-metres, or by the weight per unit area g/m^2. The coatings found on thin material may be 100 g/m^2, whereas heavier sections of steel may be 600 g/m^2.

A feature of the galvanizing process is that the lower alloy layers are significantly harder than the base steel. In fact the delta layer can be around 50% harder than the base steel. This provides galvanized steel with much greater resistance to abrasion and mechanical damage. The advantage of this is not only seen in service, but also during transportation, handling and erection. It eliminates the need for expensive handling and transportation procedures and also the costly and labour intensive requirement of repair on site to insure the integrity of the corrosion protection system. These properties combine to make galvanized steel a legitimate engineering material that should be considered at the design and specification stage of a project. The correct design of a project can make the use of galvanized steel even more effective than just the usual expectations of its corrosion protection performance.

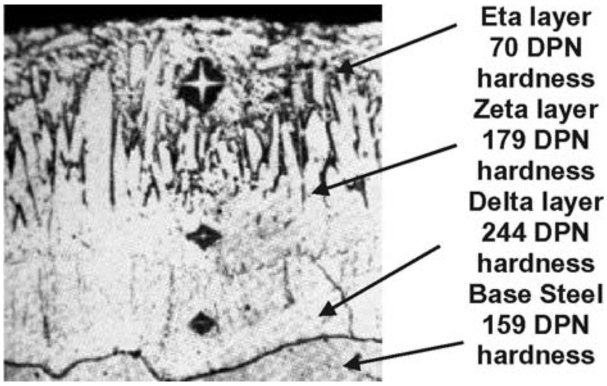

Figure 6: Galvanizing alloy hardness

3 HOT DIP GALVANIZING: PROTECTION MECHANISMS

Galvanized steel is protected from corrosion via a number of different mechanisms. As discussed above, it also provides physical protection in the form of greater abrasion resistance due to the increased hardness of the zinc iron alloys.

Barrier protection, as its name implies, works by providing an impermeable barrier over the steel item. Galvanizing provides barrier protection in two ways: firstly, the galvanized layer provides a protective physical envelope around the steel; secondly, the galvanized layer also develops a protective patina on its surface upon exposure to the environment. This is made up of insoluble zinc oxides, hydroxides, carbonates and basic zinc salts depending on the nature of the environment. Once the patina stabilises, it reduces the exposure of the base galvanized steel to the environment, thus considerably slowing the corrosion process. This patina regenerates itself after damage by very slowly consuming the zinc outer coating. Once the pure zinc of the outer layer has been consumed, the iron-zinc alloys are exposed to the environment and their corrosion resistance is up to 30% greater, providing even longer life.

The barrier protection qualities of galvanized steel are also enhanced by the fact that it is immune to ultraviolet radiation and thus will not degrade on exposure to Australia's harsh environment. Most other corrosion protection coatings will degrade on exposure to solar radiation. In fact, solar radiation is one of the key limiting factors to the performance of such coatings.

In the event of severe mechanical damage and exposure of the base steel to the environment, galvanizing also provides **cathodic protection**. The galvanizing performs in a similar way to other sacrificial protection systems, except in this case the sacrificial anode is distributed over the article to be protected and electrical continuity is assured. The cathodic protection characteristics of galvanizing ensure that mechanical damage does not result in the concealed under-film corrosion and potential catastrophic failure prevalent in some other protective coatings.

4 DURABILITY OF HOT DIP GALVANIZED COATINGS

There is a variety of data available from different sources on the durability of galvanized steel. Since the process has been utilised virtually unchanged since 1837, a large amount of empirical data has been recorded from case studies in a large number of operating situations, locations and corrosive environments. In fact, one of the major advantages of hot dip galvanizing to design and specification engineers is its extensive history of use and the fact that much of this is on record. This history of use also assists maintenance engineers in planning for infrastructure life, maintenance and remediation. The corrosion rates for galvanized steel in a variety of situations are readily available and these can be used to efficiently and accurately plan maintenance and asset life cycles.

Engineers can choose to use empirical data from selected sources such as Porter (1991), Slunder & Boyd (1983), Porter (1994) and Zhang (1996) or refer to standards that address corrosion rates for various metals and corrosion protection systems such as ISO 9223 and AS/NZS 2312. [9] [10] [11] [12] [13]

Table 2 Corrosion Rate of Galvanizing on Vertical Surfaces in Various Environments (Note 1)

ISO 9223 Corrosion Category	AS/NZS 2312 Corrosivity Description	Typical Environment	Average Zinc Corrosion Rate µM/year
C1	Very Low	Few alpine areas, dry interiors	< 0.1
C2	Low	Arid/rural/urban, Interiors - occasional condensation	0.1 - 0.7
C3	Medium	Coastal High humidity interiors	0.7 - 2
C4	High	Sea-shore (calm) Swimming Pools	2- 4
C5	Very High	Sea-shore (surf)/ offshore	4 - 8

Note 1: It should be noted that the corrosion rates given in this table provide only generalised guidance and other factors, such as specific microclimates and unwashed areas, may have an influence.

AS/NZS 2312 provides advice on the use of various corrosion protection systems including galvanizing. This standard is also useful to the design engineer as it highlights design issues to be considered when using different systems.

5 DUPLEX SYSTEMS FOR HOT DIP GALVANIZING

In circumstances where the galvanized coating may be attacked by a particularly corrosive environment, the application of a suitable inert coating which insulates the zinc from that environment will prolong the life of the galvanizing. Usually this coating is either paint or powder coating. The main areas of significance are in highly coastal or marine service, in areas of high and persistent rainfall and in industrial locales. It is worth noting that the impact of industry in Australasia, in particular acidic fallout, is low and has diminished considerably over the last 40 years with the demise of high sulphur fuels and the development of environmental protection agencies. [14] Notwithstanding, there remain many situations where painting enhances the service life of galvanizing and the synergistic increase in service life of duplex coating systems in high corrosivity locales has been well documented in such situations. [9]

The requirement for enhanced durability not only applies to a general locale or macroclimate, but also may apply to a quite specific microclimate. In particular, areas exposed to airborne contaminants, but protected from the cleansing influence of rainwater, can be considerably more vulnerable to corrosion than areas on the same structure exposed to the elements.

The corrosion rate of well-applied duplex coatings on washed surfaces in use is normally greater than the sum of their separate life expectancy. Typically if applied in severely polluted climates, the increase factor for a duplex coating is 1.8 to 2.0 times the sum of the life of each system, in sea water 1.5 to 1.6 and in rural climates 2.0 to 2.7 times. [9]

Another advantage of painting over galvanizing is that the time to first maintenance can be deferred well beyond the criterion for first maintenance of steel over-coated with organic paints alone. Specifically, AS/NZS 2312 sets the criterion for the maintenance painting of steel when "about 0.2- 0.5% of the steel in any particular area is showing signs of rusting". For painted galvanizing, the threshold for maintenance painting is set at 2%. This is because an effective duplex system resists corrosion beneath the paint finish. Without the anodic influence of zinc, corrosion of ungalvanized steel can proceed under the paint film before it becomes visible on the surface. In addition, when breakdown of the metal substrate occurs, the aesthetic impact of the whitish zinc corrosion products tends to be less than the red/brown iron stains of non-duplex systems.

The main criteria for painting galvanizing, such as preparation techniques, paint selection and paint application are the same as for painting bare steel.

Careful selection of paint systems is crucial in high corrosivity environments. An effective corrosion inhibitive primer and adequate total paint thickness is usually a prerequisite. Indeed, many failures of paint systems over galvanizing in arduous service conditions can be traced to either an inappropriate primer or insufficient paint thickness. [15]

Examples of the durability of such duplex systems abound.

Figure 7: Duplex system used in high corrosivity conditions in Spencer Gulf

Figure 8: 130 year old galvanized telegraph pole recovered in Far North Queensland

5.1 Hot Dip Galvanizing and Infrastructure

The oldest known galvanized structures still in existence in Australia are telegraph poles that were used in the first Morse Code line in far northern Queensland. Towers recovered from the Charters Towers line are over 130 years old and have survived in the moist tropical environment with their galvanized coatings still above the thicknesses demanded by the current Australian Standard. The coatings are expected to last into the next century!

The use of galvanizing in the electrical industry is extensive and has a long history. In many areas, galvanized tower construction is considered to outlast the economic life of the system and such towers are more likely to be replaced due to system redesign rather than degradation. In many power companies, the proven performance history of hot dip galvanizing has led to minimum design life requirements to first maintenance of at least 50 years.

There are transmission towers in Victoria in environments of varying corrosivity that are still in operation approximately 80 years after commissioning. Surveys of electricity transmission companies indicate that towers in even the most severe coastal exposure are achieving 30 years of life without any maintenance or before any sort of maintenance is even investigated or considered. Many Australian companies now base their system designs on an average life of 50 years for galvanized structures.

Because the galvanizing process has been around for many years, this provides a significant resource in understanding the relationship or correlation between environmental conditions and corrosion rates of galvanized steel [16] [17] [18] [19]. A fortunate relationship prevails for most industrial, urban, coastal and rural environments, in that the corrosion rates of the zinc is significantly different at each site but after the first year of exposure, is typically a constant corrosion rate. That is, as constant as the average environmental factors such as meteorological conditions over the year can be.

In laboratory studies, similar consistencies in the corrosion rates were found leading to the widely held concept that corrosion rates are steady. In fact this is actually conservative, as it has recently been shown that the development of the complex corrosion products on the zinc surface physically and chemically restrict the chemical process of corrosion and slow the rate significantly. [20] [21] [22]. So the corrosion rate of older steels with well established corrosion products tends to be lower. It is interesting to note that the development of corrosion products as time goes by, in the vast majority of environmental conditions, actually improved the performance or corrosion resistance of the galvanized coating system. However, this “linearity” of the sacrificial consumption of galvanized coatings makes maintenance planning a much simpler task and reduces the complexity and onerousness of the inspection process. An added feature of such systems is that even after most of the galvanized coating has sacrificially been consumed, the lack of under-film corrosion means that the exposed steelwork is basically in its original condition.

The remote location of many electrical installations and associated infrastructure also places great demands on the transportation of steelwork that will minimise damage to corrosion protection coatings. The robustness and increased abrasion resistance of galvanized steel makes it particularly suited to such applications.

5.2 Other Coating Systems

5.2.1 Electroplated zinc

A common coating system is electroplated zinc onto the steel as found on light weight components, often suitable only for indoor use due to the thin zinc coating and resulting readiness to corrode after a relatively short exposure outdoor. The coating method does not promote the development of a complex layer system, more than a few atoms in thickness, between the coating and the substrate, and can be considered as an added layer.

5.2.2 Paint Coatings

Paint coatings offer protections basically by providing a barrier protecting the substrate from the environment, or as a barrier with anodic or corrosion protective flakes of metals in the coating. The coating does not combine with the substrate but is conformal and takes the shape of the substrate.

Paint systems do have ranges of expected performance or durability for different environmental conditions, of which the most significant are thermal, moisture, and UV[23]. The paint application process requires significant surface preparation [24] [25] which needs to be done correctly if adhesion to the substrate is to be maintained over the life of the coating. Painting is a logistical and time consuming process for protection of 5-20 years (environment dependant). This significant contributor to the cost for maintaining structures is also recurrent and painting effectively locks the maintenance program into a cycle where patch painting or full painting, which are more economically viable than excessive surface preparation. This assumes the management of the asset is proactive in maintaining the condition of the asset.

6 GALVANIZING AND ASSET MANAGEMENT

The galvanized zinc coating is significantly different in performance and the way it is bound to the substrate, compared to electroplated or painted coating systems. This distinct difference can be best described as a type of layered or laminar composite system of several Zn/Fe alloys.

The broad performance expectations of the coating in numerous general environmental conditions is known and subsequently the performance can be readily predicted, as noted in AS2312 Standard [8] [26].

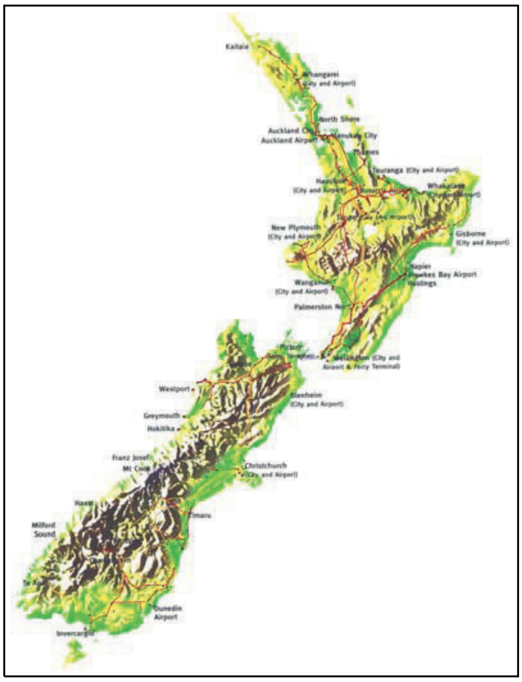

Figure 1: Power Distribution lines in New Zealand [27]

In the following section, the economics and issues of management are discussed with reference to the power distribution towers in New Zealand. This group of assets number more than 25,000 and are spread throughout the country with particular higher intensity in industrial and urban regions of Auckland. In addition the major power source for New Zealand is the hydro power generation plants in the alps of the South Island, while the majority of the population live in the warmer climes of the top of the North Island. This fact has resulted in very long tracts of transmission towers running in a South to North direction.

6.1 Lattice Tower for power distribution in New Zealand

The use of galvanized steel in lattice tower construction, in comparison to other coatings has several advantage and empowerment of best practice management procedures which are unique to this coating.

The design criteria of the asset is to have a life of 50 years and to be in a condition at the end of that period which will permit refurbishment. Basically, the structural steel would need to be in present at the end of the period such that a paint or other coating can be applied.

The maintenance management have several options;

1. No maintenance - Coat with zinc and do no maintenance.
2. Reactive maintenance – Coat with zinc, occasionally monitor and repair when they are in a serious structural condition that may impair function
3. Proactive maintenance – Monitor regularly and maintain with spot repair if economically viable or proceed with full maintenance.

On close inspection it becomes apparent that to achieve the durability objective, one or more of the three management styles can be applied to each of the environmental conditions. If the primary goal is to have the asset, at the end of 50 years, to be as structurally sound as it was at the time of construction, then it is possible to identify the benefits and limitations of the management styles.

Figure 2: Heavy duty High Voltage Tower in Christchurch (NZ).

Figure 3: Corroded tower with some rust of steel (dark red) in USA.

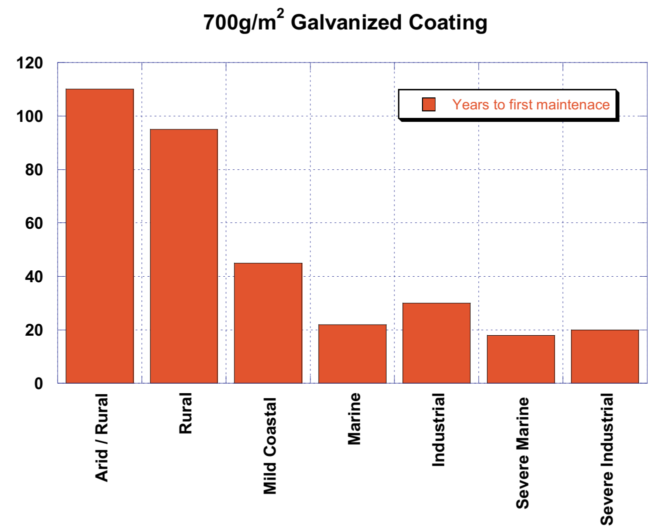

Figure 4: Corrosion rates of zinc (100gm/m^2) in various Australian environments [28]

6.2 No Management of Towers

With reference to Figure 4, operating a No Management style, which is surprisingly common, would work for all lattice towers in the environmental conditions of arid/rural, rural, and possible some location with very mild coastal exposure. Towers located in all other environments would very likely be severely corroded and exhibit a high risk of failure. The economical advantages of this style are in the significant cost reduction of the need for maintenance but the down side is that there is likely to be a significant shortfall in skilled persons when periods of high demands are required. The economic rationalists can argue that the industry has paid for the protection of the tower when the items were galvanized and the best use of that resource is to let it all corrode away. However the maintenance contractors readily note that the highest cost in painting is the surface preparation. In fact it is currently 8 to 10 times more costly to prepare rust with a grit blast than to prepare aged zinc with a high pressure water blast.

6.3 Reactive Management

The Reactive Management style or commonly referred to as 'fighting spot fires', can maintain the current conditions with arid, Arid/Rural, Mild Coastal, and Industrial locations, but is likely to be swamped by demand from the Marine and Severe environments. In economic terms, there is a fine balance between programs that are heavily subjected to spot repair processes such that it becomes cheaper to do a total repair on a lattice tower.

6.4 Proactive Management

The Proactive Management style is ideally suited for the management of lattice towers which are located in the high corrosion areas and by default, the inclusion of the towers in other environments would be relatively easy. The management of individual towers with respect to coating performance is based of the premise that the towers are inspected and the conditions are reported at least once every 10 years. The predictability of the degradation of galvanized coatings allows forward planning and management of the limited financial resources to achieve the objectives.

6.5 Maintenance of Galvanized Structures

One of the issues in maintenance is the cost effectiveness of maintenance. If we were without an policy of zero structural loss after 50 years, then such a policy would dictate the level of management of the assets. In the power industry, the periods of outages in the supply of electricity potentially are a very costly business and the government regulators are very keen to keep these to a minimum. Without considering these objectives, there are four procedures that can be implemented at each tower. These are:

1. Complete Replacement:

This complements the 'No Maintenance' program and this has significant merit if in isolated or difficult to access locations, and if only a short life time is required. The lattice tower is made from thin sections (braces) and heavy sections (legs) and given the elevation and different orientations, no two sides or elevations will have the same corrosion rates of the zinc. It is common that significant replacement of light section steel, bolts and some patch painting would occur prior to the cost effectiveness of total replacement becomes apparent. In favour of total replacement which has the benefits from having new zinc (galvanized steel) and subsequently many years before first maintenance.

2. Painting after galvanizing fails:

Paint galvanized steel after the occurrence of the deep red steel corrosion product indicates that some loss of steel section has occurred and that the surface preparation re3quires the use of the grit blasting process. The relatively high cost of this process and the physical issues for the contractors, including a significantly high OH&S risk level, puts this as a marginal option. The estimates [29] put the rust removal process increases costs by at least 20% (2004/5). The CBA for this method may be very close to the price for complete replacement of a tower, and the benefits from a new tower is the new thick zinc coating (galvanizing) and many years before first maintenance.

3. Painting before the galvanizing fails

The rationale of painting galvanized steel before the appearance of sheets of red rust is to obtain the full benefits of the zinc coating and to minimize the costs in surface preparation. This procedure is also combined with a replacement of light steel section and fasteners (where needed). This methodology fits well with the proactive management process as there are effectively only small windows of 2-3 years for painting in moderate to severe environments.

4. Duplex System – Paint over new galvanized steel

The application of a high performing coating system over very quality galvanized steel has economical advantages where the lattice tower is in a very corrosive marine or industrial location., where typically the tower life would be relatively short. The cost of painting is at the lowest and the quality is at the highest since the operations are typically inside and fully access to all surfaces is possible. The CBA would be favourable again in locations where access is difficult and a history of high corrosion.

Costings

A recent publication (Nov 2005) [29] provided details on the costs of tower painting and tower replacement for a typical double circuit 220kV tower with a surface area of 420m^2.

The following details may provide an insight into painting a tower with easy road access and in a moderately corrosive environment [29].

Painting		CBA	
(220kV Double circuit tower)		Initial asset value	NZ$60,000
Surface preparation and painting	NZ$49/m^2	Discount rate	7.5%
Rust removal	NZ$70/m^2	Period	100 years
add zinc rich primer	NZ$25/m^2	Annual patrol cost	NZ$100
		5 yearly condition assessment	NZ $250
		10 year routine maintenance	NZ $2,000
		Painting maintenance after 15 years	NZ $8,000
		Similar condition at end	

Table 1: Costing Values for lattice towers in New Zealand (2004/5) [29]

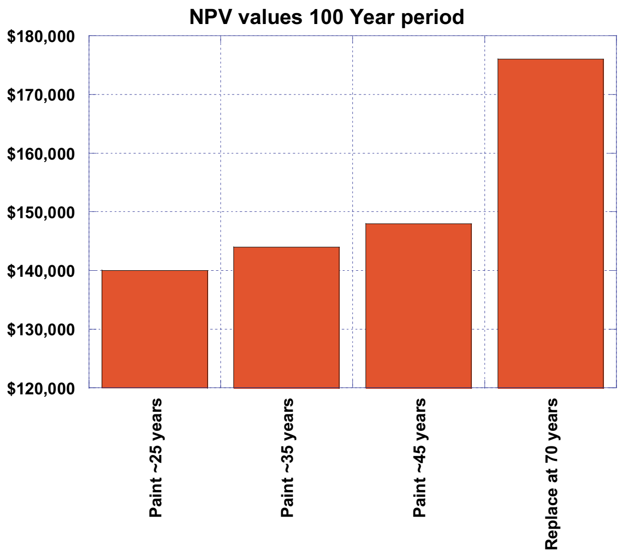

Figure 5: The NPV for the options of painting or tower replacement [29]

7 CONCLUSION

The hot dip galvanizing process has performed effectively in a wide range of conditions and applications for over 150 years. As the cost of steel, infrastructure and labour increases, it is essential that engineers consider their economic responsibilities both to the public and the private institutions that use, operate and invest in such infrastructure. Hot dip galvanized steel provides an ideal solution as an engineering material since not only does it protect the increasingly valuable underlying material of steel, but it also reduces the need for maintenance, costly inspections and potential catastrophic failure due to under-film corrosion.

The proper use of galvanized steel requires some understanding of design requirements and total cost analysis of its advantages over the life of a structure. Life cycle analysis and the costs associated with the choice of design and engineering materials are becoming increasingly relevant to the way that infrastructure is planned and designed. The galvanizing industry is currently working on developing further rigorous life cycle analyses for use by industry. These will include the utilisation of existing case histories to make the information as relevant and practical as possible.

The alloys layers that exist on galvanized steel set this coating apart from all other coatings which are adherent or at best form weak chemical bonds. This fact makes the concept of galvanizing as a layered or lamella composite of zinc rich alloys, is an apt descriptor.

Galvanizing offers substantial corrosion protection performance that can well exceed 50 or even 100 years and is related predominately to the level of exposure to the prevailing environmental conditions (temperature and moisture) and includes pollutants such as marine salts and industrial types.

It has been reported that it is prudent to extract the maximum life out of the zinc coating on a lattice tower and before there is any requirement for abrasive blasting, the tower should be painted. This is significantly cheaper over 70 years compared to replacing the whole tower.

[b] *Ergon Energy, Queensland, Australia. c University of Queensland, Brisbane, Queensland, Australia.*

Abstract: This paper describes the background to research currently underway associated with asset management (AM) of degraded cable networks in North Queensland. In the paper the main failure mode of cables installed twenty years ago is identified as the growth of water trees through the cable insulation. The costs of managing water tree degradation in a large distribution network are considered and the economics of cable replacement in a regulated monopoly are examined. Condition monitoring techniques for assessing the condition of cables are reviewed and the possibility of silicone liquid injection as an alternative to cable replacement is discussed: a research methodology to support improved cable AM is also presented.

Key Words: XLPE Cables, Water Trees, Cable Refurbishment, Insulation Diagnostic Testing

1 INTRODUCTION

High voltage underground cable systems utilizing XLPE insulation were developed in the United States in the 1950s. After about one decade of service insulation failures started to occur that were found to be caused by the ingress of moisture into the cable insulation. Considerable research into this phenomenon has been conducted over many years and it has been established that moisture is induced into the cable insulation by the a.c. electric fields. Water progresses across the insulation under the effect of the electric field in microscopic channels with frequent branches. These water channels are referred to as “water trees”. The main factors contributing to the initiation and growth of water trees have been established and a range of diagnostic techniques for the identification of the presence of water trees in cables have been examined. In recent years new types of cables have been developed that effectively preclude moisture or resist the encroachment of water trees, and techniques have been developed by a few companies for removing moisture from cables in-situ and filling the vacant channels in the insulation with insulating fluids, thereby restoring the cable insulation.

Water trees had not been discovered in Australian cables until repeated failures of 22 kV cables in North Queensland were attributed to the presence of water trees. Subsequent investigations suggested that the conditions leading to water tree development occurred in a significant proportion of existing cables. There was therefore a requirement to establish procedures for managing degrading cable networks to maintain high reliability whilst at the same time keeping down costs. To do this it is necessary to effectively utilise the results of the very considerable body of research that had been done on water trees over several decades. In this paper we consider fundamental factors influencing asset management of degrading cable networks and describe research currently underway that is directed towards to proving information needed to improve decision making in allocation of resources.

2 FAILURE MODES OF DEGRADING CABLES

2.1 Water Trees in XLPE Cables

In the cables investigated there is one cable per phase in three-phase systems with a voltage between the core of the cable and sheath of $22/\sqrt{3}$ kV. Cables are either buried directly in the ground or are pulled through buried ducts. Moisture either permeates through the insulating sheath or is drawn into the intestacies of the stranded core. Water trees in the insulation may be observed by making thin transverse slices of the recovered insulation and staining the thin sample: water trees observed microscopically in a sample of insulation taken from [1] are shown in Figure 1.

As water trees grow through the insulation electrical trees with carbonised tracks may develop at the tips of the water trees. Electrical trees may cause very small transient currents through the cable insulation that are known as partial discharges (pds). Such discharges are not expected with water trees alone.

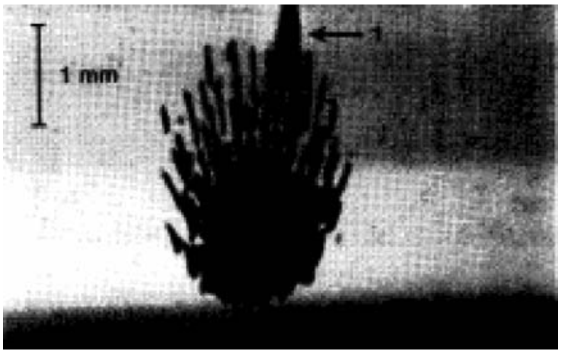

Figure 1. Vented Water Tree in a Polymeric Cable [1]

When trees completely bridge the cable insulation a high current may flow and an electric arc may be established causing damage to the cable before the electrical supply to the cable is automatically disconnected. The damaged part of the cable needs then to be repaired. First the exact position of the fault has to be identified by one of several methods. For direct-buried cables the faulty part of the cable must be excavated, the damaged section of the cable must be replaced and a new length of cable inserted using two high voltage joints. In some cases location of faults is difficult using existing technologies and it may be necessary to purposely cause further damage at the fault point to establish a good connection to ground to assist fault position location: this is done by connection of a high-voltage/high-current supply to the damaged cable to burn out the fault – this process is known as "thumping" the cable. Cable repair may take several days during which period customers fed by the cable may be unavoidably deprived of electricity supplies.

2.2 Other Cable Failure Modes

The insulation quality of a cable system is affected not only by the insulation of the cable itself but also the insulation of joints and terminations. At the time of installation of the original cable, lengths of cable are joined by special high voltage joints that are buried in the ground: over time additional joints may be introduced when cables are repaired as described above. Special insulating terminations are required at the ends of the cable where the high voltage conductors are connected to other equipment. Faulty materials or poor workmanship may lead to gradual degradation of the insulation of both these types of cable ancillaries.

Failure of the insulation may also be accelerated by abnormal voltages and currents occurring in the cable network. For example voltage surges due to lightning or switching, whilst limited by protective equipment such as surge arresters may trigger the failure of degraded insulation. Overloading of the cable for short periods will increase the cable operating temperature and may also accelerate insulation failure.

3 ECONOMIC CONSIDERATIONS

3.1 Costs and Regulated Income

Cables of the type discussed above are part of electricity distribution networks. Currently companies operating distribution networks in Australia may be privately- or government-owned monopolies the income of which is fixed by rules formulated by independent government-appointed regulators. In Queensland rules are fixed for distribution network companies by state regulations [2]. In order to examine the factors affecting decisions regarding the management of cables it is necessary to consider both the costs and the income from this class of deteriorating assets.

The costs of operating a cable with degrading insulation from the present time can be considered as being:

(a) Costs of operating the cable until replacement or refurbishment

Costs are mainly those associated with making diagnostic tests to ascertain the condition of the cable and costs of repairing intermittent failures of the cable insulation. The costs of cable repairs at this time comprise only the costs associated with locating faults and jointing in a length of new cable. In the regulatory regimes currently in force in most Australian states for electricity distribution there is no effective penalty for prolonged loss of supply to customers due to network faults.

(b) Costs of replacement/refurbishment plus operating costs of the new/refurbished cable.

Costs of cable replacement include: excavation, removal and disposal of the deteriorating cable; purchasing of the new cable; laying, jointing and reinstatement costs for the new cable. Refurbishment of the cable by silicone fluid injection will include cots of the injection and replacement of terminations and joints by special equivalents that allow flow through of the silicone fluid. Once cables are replaced or refurbished there are on-going operational costs of the type described in (a) above.

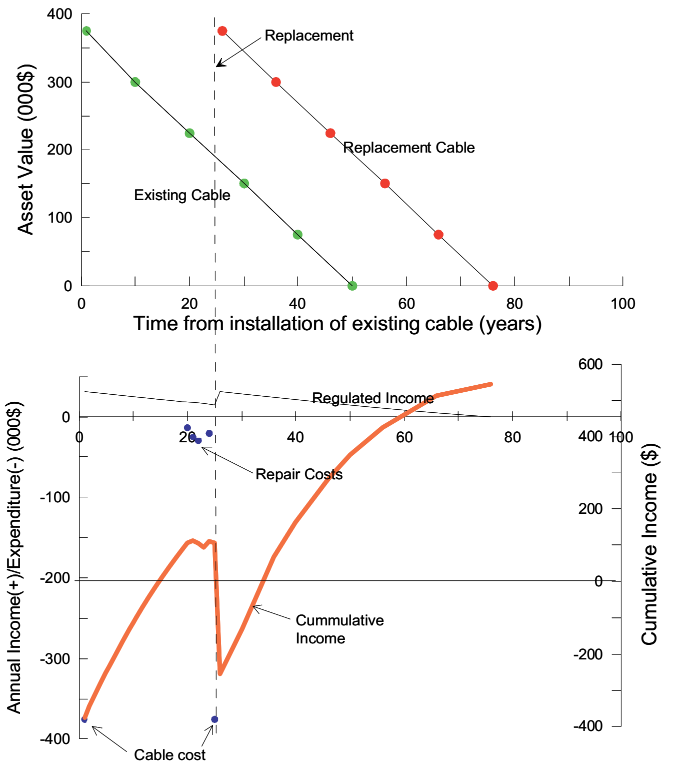

Figure 2. Costs and Income of a 1 km 22 kV Cable

Regulated income to the cable owner is based on a formula that includes components for capital and operating expenditures. The capital-related component is estimated from a depreciated optimised replacement value (DORC) of the network multiplied by a weighted average cost of capital (WACC). Individual groups of components of networks such as cables are ascribed an average lifetime and depreciated by straight line relationship. Cables have been a long-life asset and lifetimes of 40 or 50 years are generally fixed for all cables. Each cable circuit can therefore be regarded as producing income as well as having operating costs. In Figure 2 we have illustrated this situation for a hypothetical 22kV cable circuit of length 1 km. The upper graph in Figure 1 shows the depreciated values of the original cable installed in year zero and a replacement cable installed in year 26. The lower graph in Figure 2 shows annual income and expenditure associated with the cable circuit with all amounts being expressed in today's dollars. In Figure 2 large negative expenditures are shown in year 0 and 26 for cable purchases. Accounting practice also requires that the "book value" of the replaced cable should also be deducted at the time of replacement. This is not shown in the Figure which includes only "real costs'. Typical costs of repairs are shown between years 20 and 26 and income generated with a WACC of 8.5% is also included. The total cumulative income from the cable circuit is also shown in Figure 2 over a 76 year period. It can be seen that after about year 14 the cable circuit begins to generate a financial return but failures followed by replacement of the cable delays return on capital invested until about year 33. This is provided that there are no further failures of the new cable.

In Australia DORC of distribution networks are periodically adjusted upwards by the regulator about every five years [3]. This adjustment has not been at the same rate as changes in the CPI. It is therefore desirable when making long-term comparisons to estimate the net present value of changes in the future income from the circuit when making decisions about replacement.

3.2 Community Costs

Whilst at this time there are no financial drivers for cable owners to take into account prolonged loss of electricity supply that may be experienced by customers supplied by circuits during repair periods, there are clear community pressures to try to minimise electricity "outages". Research into costs of unavailabity of electricity indicates that, whilst the current cost of electricity to the domestic customer is about 0.1$ per kWh, the cost of the unavailability of power to the community may be of the order of $10 per kWh. On this basis the loss of an average load of 1 MW for a period of only two days would incurr a community cost of almost $500,000: this dwarfs the repair costs shown in Figure 2 and emphasises the undesirability of permitting repeated cable failures.

3.3 Network Expenditures

In ageing cable networks there may be considerable numbers of cables at risk of insulation failure possibly due to deterioration of cable insulation, water trees or to poor installation practices. In network companies there will be only a limited amount of capital available annually for cable replacement and consequently there is a need to prioritise replacement of degraded circuits. This needs to be done in such a way as to minimise disruption to electricity supplies whilst at the same time maximising the overall cumulative income for the cable network. In the next section we discuss current research activities that are directed towards realising these objectives.

4 ASSET MANAGEMENT RESEARCH

4.1 Techniques for Identification of Degraded Cables

Cable failures in the Ergon Energy 22 kV network have been attributed to both water trees in cable insulation and failure of the insulation of underground joints. The identification of the cause of failures requires forensic evidence from the point of failure and other part of the failed cable. Generally the site of the failure suffers damage at the time of failure but using well-established procedures [4] adjacent parts of the insulation may be microtomed, stained and microscopically examined to reveal pictorial evidence of water trees of the type shown in Figure 1: the condition of the cable may be established by the tedious process of sampling insulation to estimate the number and length of water trees present in the cable insulation.

The identification of the state of cable insulation from non-invasive electrical measurements has been the subject of research for many years and several useful methods have been developed. High voltage "Withstand Testing" with Very Low Frequency (VLF) (typically 0.1 Hz) requires large and expensive equipment. This type of testing produces similar dielectric stresses to power frequency tests at the same voltage and a VLF voltage of 2.5-3.0 rated voltage is applied for up to 60 minutes [5]. Several companies manufacture VLF units. Only a single result is obtained from this test and it is not possible to obtain information on the degree of ageing and continued serviceability of the cable. Perhaps the most interesting diagnostic techniques for overall condition rely on changes occurring in the dielectric properties of the cable insulation as a result of in-service ageing due, for example, to water treeing and useful results have been obtained from the dielectric response of cables measured in either the time domain or frequency domain. Measurement of time-domain polarisation/depolarisation current (PDC) or return voltage following application of a dc voltage have been used. Hoff and Kranz [6] have developed a system using Isothermal Relaxation Current (IRC) analysis tools for the determination of the ageing status of polymeric cables and they claim that their system can assess residual lifetime and residual insulation strength in a quantifiable way. IRC system is now commercially available.

Frequency-domain spectroscopy (FDS) [7] facilitates measurement of permittivity and dielectric loss factor in the frequency range 0.1 mHz to 1kHz. A sinusoidal voltage is applied to the cable and the complex dielectric constant is determined from the amplitude and phase of the resulting current. Variation of these parameters with voltage and frequency provides insights into the condition of cable insulation and it has been shown [8,9] that the features of the dielectric response obtained from FDS correlate well with water-tree content and breakdown voltage. When the dielectric response increases more than proportionally with increasing test voltage it has been suggested [10] this may flag the presence of long water trees. As the magnitude of the breakdown voltage in degraded XLPE cables is related more to the length of the water trees than their number[10] it is possible that FDS may prove to be a useful diagnostic method. Werelius et al [7] have introduced a classification of different types of response and relate these to the degree of water-tree deterioration of the cable insulation: this research on dielectric spectroscopy has led recently to the development and manufacture of a commercial instrument incorporating a HV supply. Hvidsten et al found that the condition of old cables with a high density of vented water trees was correctly assessed by all test methods [11]. Their results indicate that in order to avoid dielectric breakdown during diagnostic study, the test voltage should be below twice rated voltage. They also noted that the response from installed accessories should be known in order to avoid wrong interpretation of cable condition. Hoff and Kranz [12] however were unable to draw any definite conclusions from their work as they felt that the influences of other factors due to the environment and pollution needed explanation. At this stage dielectric response methods provide interesting possibilities for detecting the condition of water treed cables but further work needs to be done to build up confidence in the use of these techniques for lifetime prediction of degraded cables. Methods of monitoring cable condition based on the measurement of partial discharges are well established. At rated voltage even cables with long water trees may not produce pds. Techniques have been developed that involve the application of higher test voltages for a short time (0.3 – 1.0 sec) with measurement of the associated pds [13]. There are, however, concerns that even the temporary overvoltage may cause failure of the cable. Several workers including colleagues at University of NSW [14] have developed "on-line" systems for the measurement of pds and that might provide early warning of cable failure but at this stage correlations between measurements from such systems and cable failures need to be established.

4.2 Cable Replacement and Refurbishment Options

A silicone fluid known as CableCure™ manufactured by Dow Corning has been developed for treatment of XLPE cables with water trees. The fluid is injected into the stranded conductor of cables. It slowly impregnates the insulation and bonds with water molecules, drying the cable, and filling microvoids. It is claimed [15] to heal water-tree damage and retards the growth of new trees. The breakdown strength of the cables improves by around one-half percent each day, continuing to increase for up to two years as impregnation continues. The cost of refurbishment was found to be 30 to 50% of the cost of replacing cables

Electrical utilities in Oregan [15], New York [16] and Norway [17, 18] all report very good experience with medium voltage cables injected with CableCure™ . The treatment is shown to give significant increases in 50Hz and impulse breakdown voltage of the water treed cables and one utility reports reduction of failures from hundreds to fifty. A 1994

UTILX/Dow Corning paper [19] reviewed the use of CableCure by utilities in North America and Europe up to that time. Acording to this paper "silicone dielectric enhancement technology" was a reliable alternative to cable replacement for failing underground cable rated at 15-25 kV. Problems were ascribed to under-penetration and non-uniform distribution of fluid through the insulator but new silicone fluids were claimed to have largely overcome these problems. Independent researchers [17] concluded that: CableCure restoration strongly increases the residual 1.2/50 μs lightning impulse breakdown strength of water-tree aged XLPE cable but CableCure must remain in contact for a long time in order to obtain a permanent effect. On the basis of previous experience with CableCure™ silicone dielectric enhancement technology for cable refurbishment appears to be an attractive alternative to cable replacement. It is known however that the progress of water trees is profoundly affected by cable temperature and from the foregoing it can be seen that all documented experience to date has been in somewhat colder climates than North Queensland. It is therefore prudent to further examine silicone injected cables to ensure that the improvement found elsewhere will be obtained here.

4.3 Research Directions

4.3.1 Accelerated Cable Ageing

In developing research to support asset management of degraded XLPE MV cable networks it is seen that there are two key areas requiring further clarification. First is a need to establish confidence in silicone injection techniques in hot, wet climates and, second, is the need to improve knowledge of the effectiveness of a range of diagnostic techniques in identifying the condition of insulation of cables and other parts of cable circuits such as joints and terminations. In order to examine the silicone treatment it was considered necessary to carry out long-term ageing experiments on real cables from the Ergon network that had been injected with silicone oil. A standard ageing test [20] recommended for new extruded cables requires that cable samples be immersed in water and energised at higher-than-rated 50 Hz voltage with simultaneous thermal cycling by variation of cable current. This a test is designed to produce insulation failures of ten samples of new cables over a period of two years: from the test results it is possible to estimate the parameters of the Weibul failure distribution of the cable.

Figure 3. Test Rig for Comparison of New and Silicone Refurbished 22 kV XLPE Cables

In our research we are currently using the standard test [20] to compare the long-term performance of samples of silicone injected refurbished cable with that of new cables. A view of the experiment is shown in Figure 3. The supply voltage is three times rated phase voltage (38 kV rms). Water is maintained in the baths at a temperature of 50°C and a current of 350 A in the cable produces a maximum operating temperature of 75°C in cable core. Water has a small amount of additional salt to produce free ions which have been shown [21] to permeate into the insulation and affect the growth of water trees. The cable current is cycled between zero and maximum on a daily cycle to simulate the normal variation in cable loading: the variation in temperature assists pumping of moisture into the core and sheath.

4.3.2 Condition Monitoring and Forensic Analysis

The condition of cables in the experiment shown in Figure 3 are being periodically monitored using a variety of methods including pd, FDS, PDC and IRC. The experiment is generating a unique database of condition monitoring information for new and refurbished cables from start of life to end of life. Forensic analysis of failure sites from slices of the cable insulation, some of which is to be dyed and some of which will be examined using sensitive chemical methods, is also expected to provide useful data about the failure modes of the cables. It is anticipated that this project will provide definitive links between the condition of cables as indicated by various tests and the likelihood of failure thereby improving considerably the errors in lifetime prediction that are inherent in the estimation of life from all existing CM techniques.

4.3.3 Monitoring of Cables in the Field

A program of cable condition monitoring is also being undertaken on cables in Ergon's 22 kV network in North Queensland. From these measurements a data base of field CM information is being compiled that will, when combined with the insights provided from the ageing experiment, give an estimation of the condition of the field cables and, their remaining life.

4.3.4 Prioritisation of Cable Repair and Replacement

The improved information about lifetimes of new and refurbished cables from the ageing experiment and the improved knowledge of cable condition from field CM will enable technical assessments of cables to be made and further refinements to the assessments should be possible by considering environmental and network conditions to which particular cables are subjected. However, in order to make decisions based on this information it is necessary to also consider economic factors such as those discussed in section 3. A further economic consideration is that there will be limited capital available annually for management of the degrading cable network. It is therefore necessary to prioritise refurbishment or replacement of affected cable in such a way that disruption to electricity supplies by cable failures are minimised and that the maximum network improvement is obtained overall for funds expended. A computer program that will facilitate the optimisation of the prioritisation task is currently under development.

5 CONCLUSIONS

This paper has described aspects of research currently underway in support of AM of degrading MV cable networks in North Queensland. It is shown that the AM task is complex with key information about the performance of degraded and refurbished cables presently unknown, and the linkage between CM results and cable life not known. The main thrusts of a large engineering experiment currently underway is shown to be aimed at providing unique data on cable life and relationships between CM results and life of a cables in a systematic way on an engineering scale that has not been attempted hitherto.

Abstract: Insulators manufactured from polymeric materials are widely used by many electricity companies although there is concern about how degradation of the polymeric material of insulators might affect their lifetime. The question arises as to how utilities might best manage large populations of degrading composite insulators that are often dispersed over great geographical areas. In this paper the complete life cycle costs of polymeric insulators in large electricity networks are examined and it is concluded that failures of inexpensive components can generate significant real costs to the network owners and great indirect costs to the community. The policy of replace on failure is discussed and it is suggested that the application of condition based maintenance is needed to reduce costs. Failure modes of insulators are reviewed and a new technique for determining numerical indicators of insulator condition, developed by the author and co-researchers, is described that is based on analysis of samples of polymeric insulation taken 'live' from the high voltage network. The condition indicators developed for EPDM and silicone rubber insulation are described and results from sampling in 11 kV and 132 kV networks are presented.

Key Words: Life Cycle Costs, Non-ceramic Insulators, Composite Insulators, Condition Assessment

1 INTRODUCTION

Electricity distribution networks contain large numbers of components, each of which affects the overall performance of the network. Failures of a single small component can often lead to functional failures of major parts of the network with severe consequences. With greater emphasis being placed on financial accountability in the electricity supply industry, it has been recognised as important to examine the real costs of components over their whole lifetime to ensure that informed decisions can be made about the management of the network assets.

Since that late 1980s polymeric insulation has been used in electricity distribution networks at an accelerating rate but polymeric insulation often has much shorter lifetimes than ceramic insulation used in previous generations of equipment. Whilst there are many advantages accruing from the use of polymeric insulation the problems associated with repair and replacement have not been addressed. Many items of equipment are small inexpensive components such as overhead line insulators, surge arresters and bushings. Often these components are replaced on an ad-hoc basis on failure of the previous components and location of the replacement polymer-insulated item is not recorded. There is therefore a situation developing in which equipment with polymeric insulation is being spread in a haphazard way throughout geographically immense areas.

Increasingly, regulators drive network companies to increasing the use of more sophisticated maintenance procedures than the "replace on failure" or periodic maintenance regimes that have been common in distribution networks. There is increasing condition monitoring of components, outcomes from which are used to ensure that maintenance is done only when it is needed. The intention is that condition based maintenance will give lower costs than periodic maintenance with greater reliability than "replacement on failure". The emerging situation with polymer-insulated equipment is not amenable to condition monitoring by existing technologies. In this paper an attempt is made to explore the life cycle costs of large populations of insulators and the progress in the development of new techniques for condition monitoring polymeric outdoor insulation.

2 .ASSET MANAGEMENT OF POLYMERIC VOLTAGE INSULATORS

2.1 Life Cycle Costing Principles

Consider a population of N identical components in a power system. The components may be insulators, line cross arms, connectors, or transformers, or any other large population of network components. In a simple analysis the annualized cost of the component population, C, may be expressed as:

$$C = P + Q + R$$

Where P is an annual interest charge based on the installed cost of the components. Q is the cost of any periodic maintenance and condition assessment made in the year. R is the cost associated with any component failures in the year: this is equal to $Npan$ where p is the probability of component failure in the year under consideration, a is the component cost, n is a dimensionless cost multiplying factor that incorporates the cost of replacement of a component on failure, b, and the costs of the consequences of the component failure, d. We define n as:

$$n = (b + d)/\ a$$

To calculate p we consider the component population to have a mean life L with a standard deviation ΔL based on a normal failure distribution.

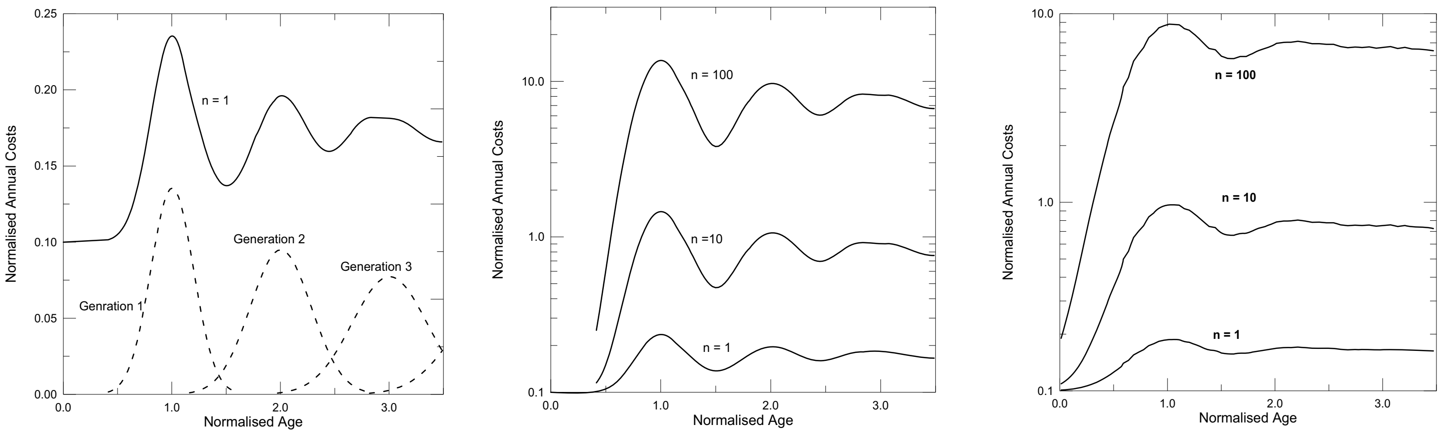

Fig.1(a) $\Delta L/L$ = 0.1 **Fig. 1(b) $\Delta L/L$ = 0.2** **Fig. 1(c) $\Delta L/L$ = 0.3**

Figure 1. Component Costs as a Function of Age of the Asset. Rate of interest 10%. Annual maintenance costs not included.

Normalised annual costs are plotted against normalised age of a population of components in Figure 1. In this figure all costs are normalised by dividing by the initial cost of the population of installed components, ***Na,*** and the age of the components is normalised by dividing the age of the component population by the mean component life, L. We assumed that at year zero the entire component population was installed and that when failures occur components are replaced with identical components.

From Figure 1(a) we see that annual costs are initially constant from year to year and are only interest charges. The costs of the various generations of components are shown as dashed lines in Figures 1(a) and 1(b). These costs are additive to the interest charge costs. Total costs for different values of cost multiplying ratio (n) are included in Figure 1(b). It can be seen from Figure 1(c) that populations with a larger failure spread there is a continuing high cost after the first lifetime due to overlapping of failures of the first and second generation populations.

The above considerations lead to some interesting conclusions about life cycle costing of electricity network equipment.

- Firstly, the life cycle costs of components in a major functional element of a network are inextricably bound up with the relative lifetimes of the components and the major functional element of which they form at part. If components have to be replaced several times over the lifetime of the functional element then life cycle costs need to include the costs of replacing the component possibly several times over the life of the functional element.
- Secondly, the life cycle costs may well be dominated by the costs of replacement of small components.
- Thirdly, it is not possible to estimate life cycle costs of electricity network equipment, unless there is some reasonable information about the life of the component.

2.2 Evaluation of Life Cycle Costs of Polymeric Insulators

In electricity networks it is possible to discern two main types of populations of components. These are: very large populations of rather simple, low cost items (Group A) and smaller populations of expensive items that are often technically complex (Group B). The estimation of life cycle costs of components in Group B is sometimes attempted by distribution network companies. The method adopted is to first estimate the anticipated life of the component and to estimate the total maintenance expenditure based on periodic maintenance carried out at intervals specified by the equipment manufacturer. The life cycle costs appear generally to be determined as the net present value of the purchase price plus the anticipated maintenance expenditure over the life of the component. In the past distribution network companies often had no information about the location or number of Group A components in their networks and the estimation of life cycle costs of components in Group A generally has not been attempted.

In the following section life cycle costs of polymeric insulators are examined. Only costs of purchase, repair and maintenance are considered. The costs of losses and cost of damage to third parties due to failures of the network assets are also not included. All costs are in 2006 Australian dollars and interest or other financial cost multipliers are not considered at this stage.

Insulators in overhead lines may be replaced when they exhibit obvious problems such as cracking, an increase of discharge activity, loss of insulating properties or mechanical failure. Recent examination [1] of some types of MV polymeric insulators, however, has indicated substantial weathering of the insulator sheds of one type of composite insulator after only 3 to 4 years of exposure in coastal locations in the sub-tropics. In this section we will compare the life cycle costs for 11 kV and 132 kV equipment.

In 11kV overhead lines the installed costs of ceramic insulators is about \$20 and composite (polymer) insulators about \$30. There may be about 65 insulators per km in a typical line. Failure of insulators may lead to insulator replacement costs of about \$200. With cost of unserved energy of about \$0.1 per kWh and community costs of unserved energy are between \$2 per kWh and \$10 per kWh, loss of load of 1 MW for two hours leads to costs of \$430 for insulator failure and unserved energy, and community costs of between \$4,000 and \$20,000. Over a 30 year life total life costs of replacing failing insulators with a mean life of ten years would be: \$29,900 per km not including cost of lost load, \$55,900 per km including costs of unserved energy and over M\$ 2.6 per km including the highest values of community costs. In this case the value of ***n*** may be 150 to 680 depending on community costs.

The costs of ceramic insulators for 132kV lines is about \$30 per disc or \$240 for a complete 132 kV string. composite insulator costs about \$400. Typically there are about 9 insulators per km. Repair costs are about \$1200 if a single ceramic disc is replaced by live line methods and about \$6000 per insulator if a composite insulator is replaced. A typical outage time for a composite insulator replacement may be 12 hours. If the line has to be de-energised whilst composite insulator replacement is carried out with consequent loss of load, the cost of unserved energy to say a 30 MW load for a period of 12 hours would be \$3,600, with an additional \$720,000 to \$3,600,000 for community costs. Fortunately loss of this magnitude of load would be rare because of the fact that alternative supplies are generally available.

The above examples are not intended to provide exact life costs. They do, however, provide interesting insights into expenditures in electricity networks. In particular the examples highlight the fact that the repair-on-failure policy can lead to high life costs in MV overhead lines. Life cycle costs will be very high when community costs of lost load are included in calculations and costs are greatly increased if the lifetimes of components are much shorter than the functional element of the network in which they are incorporated.

2.3 The Role of Condition Assessment in Reducing Life Cycle Costs

Traditionally the condition of insulators in distribution network equipment has been assessed from periodic observations from the ground, a technique which provides no information about the condition of polymeric insulators other than about gross degradation such as for example splitting of the plastic housing of the insulator. There is obviously a requirement for some technique to provide numerical indicators of the condition of insulators.

As Group A assets such as insulators are widely distributed over large geographic areas in distribution networks, it is unlikely that measurement of condition indicators of all members of these large component populations will be economic. An alternative approach is to sample the population with particular attention being paid to assets in important locations or in situations where rates of degradation might be expected to be high. If ages of components are recorded, sampling of condition indicators will, over time, enable companies to build up models of the rates at which components age. This information will enable sampling procedures to be refined. Components approaching end of life could be monitored more frequently and replacement programs devised that will avoid failures.

3 CONDITION ASSESSMENT OF POLYMERIC INSULATION

3.1 Failure Modes

Polymeric insulators usually have a resin-impregnated fibre glass core rod for mechanical strength. The core rod is encapsulated by a polymeric housing with weather sheds and protects the structural glass fibre core from the combined effects of moisture, pollution and the electric field. Housings are manufactured from ethylene propylene diene rubber (EPDM) or silicone rubber (SIR) which may also include inert fillers, colouring, stabilisers and UV inhibiters. Commonly insulators of this type called composite or non-ceramic insulators. Composite insulators have two dominant types of failure. The first type of failure occurs when the insulators experience electric flashover (arcing) around the external surface of the housing. The voltage at which such flashovers occur is reduced by the presence of wet pollution on the external surface of the insulator. There is evidence that the surface properties of the insulator play an important role in defining electrical performance during wet and polluted conditions. Aging of the polymer EPDM material can cause a progressive reduction in the surface properties of the material and with it a reduction in electrical performance. Although this reduction may in many cases simply reduce the performance of the EPDM insulator to that of a similar ceramic insulator, it is possible that deterioration can continue further reducing performance and increasing the risk of pollution induced outages. Wet pollution flashovers also occur on SIR insulators but to a lesser extent as low molecular weight oil from the rubber tends to encapsulate surface pollution and maintain surface hydrophobicity which reduces electrical discharges on the insulators surface which are the precursor of flashover. The second type of failure of the housing can occur due to erosion of material caused by intense arcing during wet and polluted conditions or due to degradation of the material leading to the formation of splits in the housing material. The consequences of such failures can be tracking of the glass fibre core leading to mechanical and/or electrical failure. It may be appreciated that both types of failure are preceded by changes in the surface of the housing material and it has been proposed that analysis of small samples of surface material with subsequent physical and chemical analysis of the material will provide numerical indicators of the condition of the housing.

3.2 Condition Indicators

3.2.1 Sampling Methods

Several methods have been developed [2] to remove samples of polymeric material from insulator surfaces. Thin silvers of material are sliced from the insulator surface using a small plane that removes slivers of between 0.25 and 0.5 mm in thickness, width about 10 mm and length not more than about 30 mm. Alternatively traces of the main polymer are removed from the insulator surface by swabbing the EPDM surface with a cotton swab soaked in a suitable solvent. After brief swabbing of the area of insulator of interest, the solvent-soaked swab with minute traces of polymer dissolved in the solvent is returned to a suitable air-tight container from which the solvent is later collected and concentrated for subsequent analysis. In addition special analytical procedures have been developed to analyse the amount of filler in the loose chalky material on the insulator surface. Initially in laboratory experiments, the material was scrapped from the insulator surface. However when the technique was extended to outdoor insulators is was found that wind gusts made the collection of loose material difficult. An improvement in the efficacy of collection of chalky material was affected by collecting the material on the surface of abrasive pads that were rubbed lightly on the insulator surface.

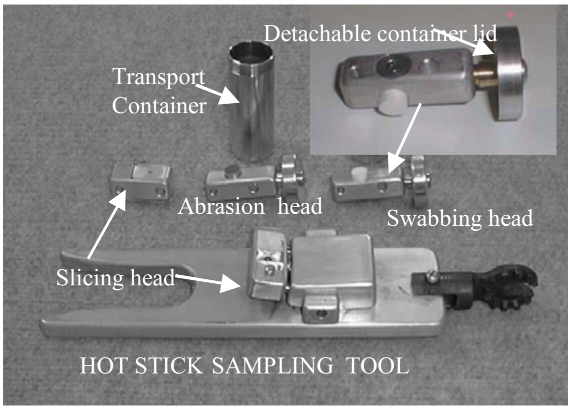

Figure 2. Hot stick tool and fittings for taking samples of shed material

It was not possible, however, to take samples from high voltage lines without de-energising the line. This was seen as a serious limitation to the application of the technique since it has been found [2] that the most degraded parts of insulators tend to be in the high stress regions close to the high voltage ends of insulators. A live line tool was, therefore, developed for taking samples of material from energised insulators. The main components of the live line tool are shown in Figure 2. A pivoted bracket is attached to the main body of the tool. Three types of sampling heads may be clipped to the bracket and secured in position by force due to a permanent magnet. The slicing head is effectively a very small plane that is designed to remove slivers from the insulator surface and capture the slivers in the body of the tool. The swabbing head incorporates a cotton pad that is pre-soaked with solvent. Swabbing heads are stored within a container when not in use are returned to the container after swabbing. The abrasion head is similar to the swabbing head except that the swab is replaced by an abrasion pad. Prior to sampling, and with a sampling head in position on the pivoted bracket, the bracket is moved to a charged position in which a spring is prevented from returning the bracket to its initial position against the main body of the tool by a latch.

Figure 3 275kV insulator sampling

Figure 3 shows the tool in use on a 275 kV insulator. The main body of the tool is inserted along one side of a shed and the bracket with the sampling head attached moves across the other side of the shed. The presence of the shed releases a mechanical latch causing the sampling tool to press against the surface of the shed. Circular movement of the remote end of the hot stick by the operator then causes shed material to be removed by the sampling tool. It has been found that variations of this tool are required for insulators of different designs and a new tool in which the operator exerts a linear pulling force rather than a circular motion has been found to be very effective

3.2.2 Analysis of Material Samples

The sliver surface is examined using SEM to observe the degree of surface cracking of the type shown in Figure 4. A useful numerical indicator of degree of degradation of EPDM is obtained by cleaving the sample sliver of polymer in a plane normal to the surface and making microscopic examination of the cleaved surfaces to obtain a measurement of depth of the degraded surface polymer. A typical result is shown in Figure 5 for a silicone-EPDM blended material. The dark lines in this figure indicate heterogeneous material and suspected de-mixing. X-ray Photoelectron Spectroscopy (XPS) has been found useful in determining the elemental composition of the insulator surface. The indicators have also been obtained from Fourier Transform Infra-red FTIR spectroscopy on polymer weather shed material by ratio-ing peaks in the FTIR emission spectra [1]. The indicators include an oxidation index, a chalking index, and the ester to ketone ratio [3, 4]. The oxidation index is determined as the ratio of spectral peak heights associated with carbonyl (C=O) degradation products (1735 to 1745 cm^{-1}) to hydrocarbon (C-H) at 1460 .cm^{-1}. The numerical indicators give insight into different aspects of EPDM insulation degradation. The oxidation index determines the amount of oxidation. The chalking index quantifies the relative amounts of polymer and filler. The ester to ketone peaks which occur as sub-peaks in the carbnoyl peak have also been ratioed to give a numerical indicator that ratio provides information about the cause of EPDM degradation. It has been suggested [2] that that the limits of the life of the insulating material may occur when:

a. The ratio of the ester carbonyl peak to ketone carbonyl peak determined from the FTIR spectrum is below 0.6.

b. The oxidation index from FTIR is above 0.4.

c. The value of isolated tertiary carbon is equal to or below 0.5.

d. Levels of surface aluminium from XPS are above 7%.

e. The degradation layer is thicker than 20 μm and the width of surface cracks exceeds 7μm.

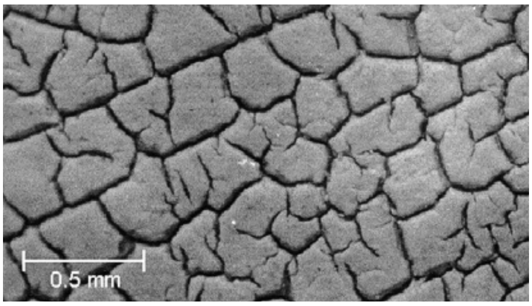

Figure 4 Extensive surface cracking of EPDM insulators from manufacturer C. Top View

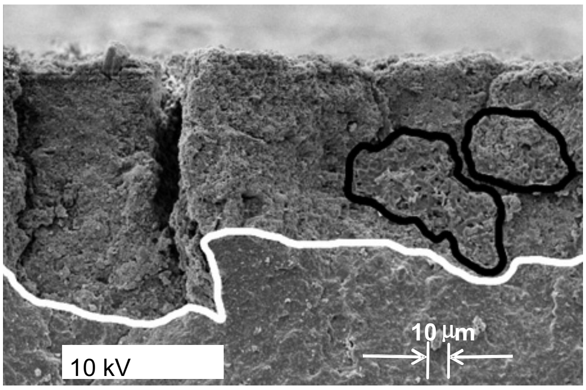

Figure 5 SEM view of the cleave surface of a "White line"- Boundary between degraded and sound

End of life criteria have been difficult to formulate for silicone rubber which is a more complex material than EPDM. However, recent work by Lui et al [5] on the analysis of a badly degraded silicone rubber insulator that was so degraded that some sheds had lost most of the polymer and consisted mainly of the filler gives some indication of the values of indicators at the end of life. Thermogravimetric Analysis (TGA) indicated that there were two major weight losses of from material samples during the TGA heating period, the first due to loss of water from the aluminium trihydride filler and the second decomposition of the polymer. TGA there provides a technique for monitoring the loss of polymer from samples. XPS analysis performed on surface samples of the insulator showed that the worse conditions found were:

1. Total silica was 32 % of total silicone.

2. Atomic concentration ratio C/ Si was 1.71 (whereas for pure PDMS this value was 2)

3. The O/Si ratio increased to 3.5 (compared to 1 in PDMS).

It was suggested that the decrease in weight loss as indicated by TGA and the quantification of silica content from XPS may be the best indicators of silicone rubber insulator life. Acceptable limits will be somewhat lower than the values above. Other indicators based on the measurement of rate of increase of low molecular weight silicone oil on precisely-polluted surfaces have also been investigated recently.

3.3 Application to High Voltage Networks

3.3.1 MV Networks

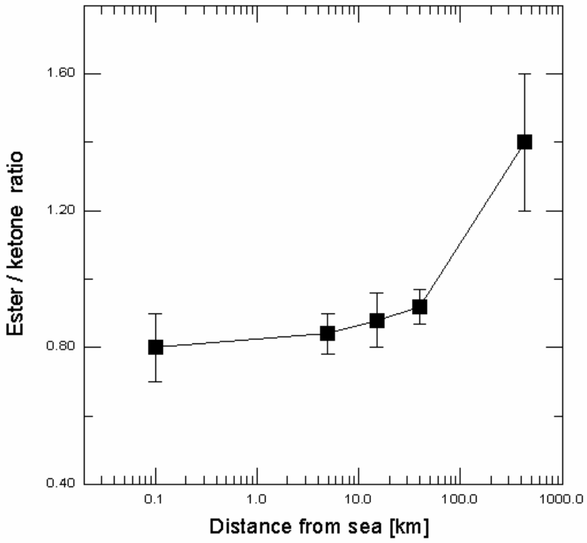

Figure 6. Ester toketone ratio for insulators as a function of distance from sea. (Manufacturer A)

In medium voltage (MV) (less than 66 kV) electricity networks most currently installed insulators are EPDM with a smaller proportion of EPDM/silicone rubber blends. The performance of polymer insulators in tropical climates is, however, not well known. An investigation into condition assessment of EPDM insulators in north-east Australia commenced in 1996. Six participating utilities supplied almost fifty insulators produced by seven manufacturers. The insulators came from locations characterised by different climatic conditions. These included the desert-like climate of inland Australia with daily temperatures of up to 45°C, low rainfall (600 mm/year) and low humidity (30%) and the humid tropical climate of coastal regions with abundant rain (up to 2000 mm/year), high humidity (80%) and temperatures up to 30°C. Australia also has one of the highest levels of ultraviolet exposure in the world. The total annual dose of ultraviolet radiation is more than double than that experienced in Europe [6] Indicators were determined for insulators from three manufacturers. Sheds of insulators from manufacturers *A* and *C* were made from a blend of EPDM and silicone rubber. Sheds of insulators from manufacturer *B* were made from EPDM. Three different types of location were recognised: sea, coast and inland. The sea side locations refer to areas in close proximity to the sea – not more than 200 metres and with direct exposure to salt spray. The coastal locations are more than 200 metres but less than 100 km from the sea. The inland locations are more than 100 km from the sea. Up to six insulators per location were analysed. The extent of the degradation of the insulators from manufacturer *C* was reflected in high levels of oxidation index (>1.5) and chalking index (up to 4). The depth of the surface degradation layer was approximately 100 µm and some of the surface cracks were deeper than 50 µm. The depth of the surface degradation layer of insulators from manufacturers *A* and *B* did not exceed 30 µm. The heterogeneous nature of the degraded surface layer of insulators produced by manufacturer *C* indicated that poor mixing between EPDM and silicone rubber may have taken place, see Figure 4. It was found that the ester to ketone ratio was significantly higher (>1) for inland insulators (Roma, Toowoomba) than for insulators at the sea or in coastal locations (<1), see Figure 6.

The oxidation index for the sea side insulators of manufacturer *A* was greater than for the coastal and inland insulators of the identical manufacturer. The only exception was an insulator at in Goodna that was installed close to the Brisbane river in an area suffering from frequent fogs in the cooler months. Both, salt spray at the sea, and fogs in the river area caused extensive dry-band arcing which damaged insulator surface and resulted in the high values of oxidation index. The oxidation index for the sea-side insulators of manufacturer *B* was much smaller than those of manufacturer *A* even though the insulators of both manufacturers were installed on the same pole. However, insulators of manufacturer *B* showed more extensive surface damage than insulators of manufacturer *A*. The latter point is confirmed by the thickness of surface degradation layer which is approximately 10 µm for insulators of manufacturer *A* and 20 µ m for insulators of manufacturer *B*. Insulators from manufacturer *C* performed worst. They had uniform white chalking on all surfaces and showed extensive surface cracking. It has been hypothesised that solar ultraviolet radiation can cause photo-oxidation of polymers leading to the formation of ester-type degradation products. When meteorological data from the regions were compared, it was found that the inland location (Roma) has 150 clear and 70 cloudy days a year. The coastal location (Beenleigh) has 80 clear and 120 cloudy days a year. As clouds act as a partial screen for solar ultraviolet radiation and both the inland and coastal locations are at approximately the same latitude, the inland insulators received higher doses of ultraviolet radiation and this resulted in higher proportion of ester-type oxidation products.

It has also been shown that thermal oxidation of polymers similar to EPDM can favour ketone oxidation products [7]. In coastal areas, high humidity and salt spray may lead to increased dry-band arcing with subsequent thermal oxidation of the polymer and thus decrease in the ester to ketone ratio. A similar phenomenon has been observed in results of tests from a 275 kV EPDM insulator at a coastal location of similar latitude to Roma or Beenleigh. The ketone to ester ratio was greater at the HV end than at the ground end. This might indicate more dry-band arcing in the high field region near the HV conductor. Annual rainfall might also have played a role in the phenomenon observed in Figure 6. The inland location, Roma, has a lower average annual rainfall (600 mm/year) than the coastal locations, Beenleigh (1000 mm/year). Water soluble oxidation products might, therefore, have been washed away by rain.

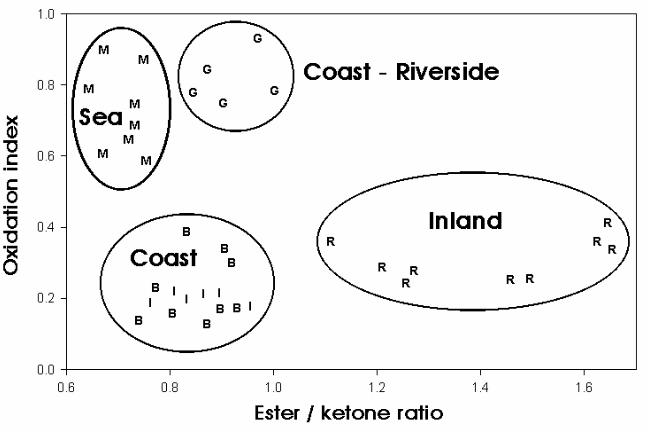

Figure 7 Scatter plot relating the oxidation to the ester toketone ratio for insulators from manufacturer A.

B-Beenleigh, 15 Km from sea, 6 Insulators

G-Goodna, 40 Km from sea, 1 Insulator

I-Ingham, 5 Km from sea, 1 Insulator

M-Miami, 0.1 Km from sea, 3 Insulators

R-Roma, 425 Km from sea, 2Insulators

Effectiveness of the condition is demonstrated in Figure 7, where a two-dimensional scatter plot relating the oxidation index to the ester to ketone ratio for insulator samples from manufacturer *A* is shown. Several distinct groups in the data can be identified. The sea-side insulators from Miami and the coastal insulators from a foggy area in Goodna have high values of the oxidation index due to dry-band arcing, though the coastal insulators have slightly higher ester to ketone ratio due to more extensive UV damage. Inland insulators from Roma with prevailing sunny weather and intense UV radiation have the highest values of the ester to ketone ratio. Coastal insulators from Beenleigh and Ingham form an overlapping group with low values of the oxidation index and the ester to ketone ratio.

3.3.2 High Voltage Insulators at End of Life

During the 1980s a 132kV line was erected in a coastal location (over 1 km but less than 20km from the sea) in South East Queensland. At that time cantilever post insulators having weather sheds manufactured from EPDM were used. The insulators used came from two different manufacturers. The most common type consisted of 16 individual EPDM weather sheds approximately 230mm in diameter fitted on a glass-fibre reinforced resin core, sealed with silicone grease and clamped between two galvanised end fittings. The other consisted of 22 sheds of 210mm diameter. After 10-12 years service a small number were removed due to longitudinal splits in the rubber in the core adjacent to the HV end. Visual examination revealed that significant surface changes had occurred. This included extensive chalking of all polymer surfaces and the development of a rough surface in place of the original smooth surface. The longitudinal splits in the polymer covering the core at the high voltage end had exposed the glass fibre core to the ingress of water and dust. The rubber in this area had a “wrinkled” appearance due to ageing of the EPDM.

The longitudinal splitting of the core near the high voltage end indicated a loss of elasticity of the EPDM. This is probably a result of cross-linking during oxidation which makes the material more rigid. There was also some evidence from chemical analysis of the oxidation products recovered by swabbing the surface that there had been splitting or scission of the polymer chains during oxidation. This is further evidence of extensive thermal oxidation of the EPDM.

The apparent extensive surface “chalking” observed was quantified using diffuse reflectance FTIR. The analysis of selected samples by X-ray Photoelectron Spectroscopy (XPS) confirmed that the atomic composition of aluminium on the surface was between 8 and 10%. When new specimens of EPDM insulator material are examined by XPS, no aluminium was seen on the surface. Scanning electron microscopy (SEM) of the surface revealed a layer of degradation of at least 30µm as well as wide spread surface cracking. Towards the bottom of some of the broadest cracks stretching of elastomer can be observed. This is consistent with loss of elasticity perhaps caused by oxidative crosslinking of the polymer as mentioned above. It is believed that this small scale cracking eventually led to the complete splitting of the EPDM in the core of some insulators.

4 LIFE CYCLE MANAGEMENT OF POPULATIONS OF COMPOSITE INSULATORS

The provision of a series of field-aged insulators by the local utilities has permitted the development of ‘end of life’ criteria in terms of numerical condition indicators for EPDM insulators and formulation of tentative criteria for SIR insulators. If a quick assessment of a number of specific EPDM insulators is required, a single chemical test - surface swab followed by FTIR emission spectroscopy - can indicate insulators that may be “at risk”. Such insulators can then be studied further by both chemical analysis and SEM, and a more reliable indication of condition obtained. Utilities are then in a better position to make decisions about the reliability of the insulators and selective replacement can be made prior to serious failures occurring.

EPDM Insulators from a line indicating high levels of oxidation but a high ester to ketone ratio suggest that although the insulators may be heavily degraded, the combination of the insulators surface condition and pollution severity may be such that significant surface discharging does not occur. The techniques presented provide valuable information for managing both types of failures. The combined measures of the oxidation index and the ester to ketone ratio are promising because they appear to provide indication of both the degree of deterioration and the presence or absence of electrical discharge activity. For example insulators from a line indicating low ester to ketone ratio and high oxidation would indicate that these insulators are degraded and have experienced high levels of surface discharge activity. This in itself could indicate that the combination of pollution severity and material condition is such that there is an increased risk of pollution flashover. By considering the environment, and the importance of the line a decision could be made whether further surveillance such as leakage current monitoring is required. The indication that high levels of surface discharging have occurred may also indicate that erosion type defects are more likely to develop. This could trigger a program of visual inspections or assessment using some of the more advanced techniques such as infrared scanning, or electric field measurements. Insulators that show a low ester to ketone ratio but have a low oxidation index indicate that arcing has occurred, but this has not yet produced significant deterioration. It is suggested that although these insulators may still be in good condition, they may be in an environment where they are likely to deteriorate and should be monitored.

The usefulness of the CM method described in this paper lies in the fact that it can be used to sample the condition of the insulation material from time to time to determine the numerical indicators of the condition of insulators that are part of a larger population. In the initial sampling it should not be necessary to sample large numbers of insulators but rather the samples should be restricted to areas where environmental conditions are severe. If sampling indicates that there only small changes in the indicators over time then it may not be necessary to make other types of inspections that require line patrols. If the indicators of shed condition do, however, indicate that there has been substantial degradation in the properties of the shed material then it will be necessary to make detailed assessments of the insulators by techniques that have been developed to locate defects. It will be a simple matter in sampling to identify particular types of insulators likely to experience early failures and to put in place programs of replacement at an early stage. To enable sampling programs to be effectively implemented electricity companies will need to keep records of where insulators of particular types and manufacturer are installed: this is currently not done for any but the highest voltage types.

5 CONCLUSIONS

Composite insulators are widely used in electricity networks but their lifetimes are less than that of previous generations of insulators. This may lead to failures of overhead lines that can cause loss of supply which it has been demonstrated can be expensive for utilities and very expensive for the community over the life of the asset (such as overhead lines) in which insulators are used. A new type of technique for monitoring the sheds of composite insulators has been reviewed and it has been shown that it is possible to take very small samples of insulator shed material "live line" and to analyse the samples by a number of technique that provide numerical indicators of insulation condition. These techniques are well developed for EPDM but are still being developed for SIR. The techniques have been applied to high voltage networks throughout Queensland.

MANAGING THE INTANGIBLE ASSET

R. B. Ward

Faculty of Engineering, University of Hew South Wales, Sydney, New South Wales

Abstract: About fifty years ago a superintendent of apprentices taught his very junior people that management involves the use of four resources: men, machines, materials and methods [1]. (More recently this author added "money" to those four, but that is another story.) All four are assets and require maintenance, one way or another, and while much has been written about maintaining machines, and, indeed, methods, there seems to be little about maintaining people. The paper following from this abstract shows why "people-maintenance" is needed, examines some of the difficulties (such as the wide range of levels in an engineering organisation), shows the risks in doing, or not doing, this form of asset management, suggests how the asset may be condition-monitored and what standards may be used, and points out the cost of good people-maintenance (and the cost of not maintaining the people asset).

Key Words: management, people

1 INTRODUCTION

The "intangible asset" in the title is people, who are, actually, of course, quite tangible in the sense they exist and can be seen and touched. However, even though that's recognised as being obvious there's a definite impression that people aren't as "tangibly real" as other physical assets such as land, buildings, machinery and similar asset items.

Before progressing to a discussion on why people should be "maintained" we need to state why this is of interest and concern to engineers. That's evident from the list of assets mentioned in the above summary, men, machines, materials and methods. The first three are certainly "physical", the fourth encompasses all types of spoken and written instructions, covered in today's language by the term "intellectual property", perhaps not as "physically-real' as the others (unless existing as documents), but still of value, hence an asset. So if people are one of the assets engineers use and maintain, we submit that they, like the others, should be maintained. People need maintenance just as the other assets do.

So, to the connection between engineers and people. Engineers are familiar with the use of all four of those items, most familiar with the maintenance of machines, materials and methods, all of which need engineering work to overcome wear and tear of machine parts, selection of improved materials, and adjustment and correction of methods as these require updating. Engineers seem to be least familiar with using men, or, to be more general, with people, yet people are a significant asset in any business, even one in which machines and automation have taken over the physically demanding aspects of work. The reason for this appears to be the general task-orientation of most engineers, implied by Samson [2] and indicated by the results of this author's experiments, using management case studies with senior engineering students. With rare exceptions the students primary concentration was on technical factors, then on management issues, and only very occasionally commented on what was presented between the characters.

2 WHAT CAN WE FIND ABOUT PEOPLE-MAINTENANCE?

Maintenance in a purely engineering context is, of course, principally about repair of machines and related equipment with some development in addition, and we might expect maintenance of people similarly to be about repair of wear and tear, but only partly, it should also be about development and support. All contain difficulties; as an illustration of development problems, in a novelised version of a case study sequence this author has presented discussion of what's facing managers in a factory, and one character described the situation, intended to develop those involved, as a test to destruction. The other, the person with an engineering background, pointed out that such a test should not be performed in service, only under laboratory conditions.

Making that statement on the content of maintenance leads into seeking literature support for what the management gurus may have given us on people-maintenance. Consider, first: why "maintain" people? For the organisation's benefit? Or to help the individual person? Or both? That last alternative is the most sensible, provided it truly covers both, and we might expect some reference to this topic to appear in the many texts on management, for surely people-maintenance is part of the general management function. However, search through a considerable range of books, on many aspects of management, has shown this topic is not just remarkably thin but effectively non-existent. Yes, much has been written on how to manage people, but the motive behind such explanations and directions comes out as being for the benefit of the organisation, or for its management, not for any benefit of the actual people being managed.

As an example, going back nearly fifty years, there's a prime example of that omission in Herzberg's presentation of motivation and hygiene factors, both of which contribute to motivating people [3]. The first are positive factors which, *if present*, will *motivate* the individual, result in high performance and cause the individual to experience job satisfaction, examples being the work itself (doing something one likes), responsibility, achievement, recognition, personal growth. A very simple example of the recognition factor is being addressed by name by someone way up the management structure from oneself; which gives even the most cynical person something of a lift. The second, hygiene, or *dis-satisfaction avoidance,* factors, are the opposite, if these are *lacking* they *de-motivate* the person, but providing them will *not* provide a source of motivation. They must be present, adequately, or dis-satisfaction will arise. Examples of these are salary (in the sense of adequacy or improvement), relationships with those above and below, satisfactory work conditions, status in the organisation, security. The most curious item in this is that more money does not motivate people; a seemingly unlikely concept, but it came out of Herzberg's published research, if adequate it only avoids dis-satisfaction.

So that's what he found, what he recommended managers should apply. But why? The reasoning was simply to motivate workers to work better, not for their own benefit but (as already remarked above) for the benefit of the employing organisation. But what about the positive motivation factors contributing to job satisfaction? Surely that benefits the worker? True, but the reason for improving job satisfaction, in this context, is to have the worker work better, for the organisation's benefit.

As another example, take Reason's work on human error [4], which covers the various forms of error, much of what causes them, and (to some extent, and with other writers) how errors can be prevented from occurring. Simply, forms of people-maintenance can be applied to reduce error occurrence. And why should errors be prevented from occurring? Because they're bad for the employing organisation.

A final example: an Australian management text [5] has a whole chapter on Human Resources Management, covering selection, recruitment, selection, training, etc. There's discussion of specialisation of work and the writers point out that this movement tends to make work less interesting, then recommend the use of "Job Enrichment" as a way to overcome employees becoming automatons. However, the reason for so doing is more to improve company results than to perform people-maintenance. Echoing Herzberg.

This author has therefore been able only to conclude there's little, if anything, in the management literature on people-maintenance, so the author's thought direction turned towards observed examples in which nothing was done to support people in the sense of maintaining their abilities, or something wrong was done to cause harm in some manner, and to suggest from these what could, indeed should, have been done. Like anyone with experience as an academic this author shudders at the use of anecdotal evidence but assures the reader these are real examples, from the industrial experience of several engineers and managers. None are fictional.

3 WHY IS PEOPLE-MAINTENANCE NEEDED?

Before progressing to those examples we need to look at the reason for management going to the trouble of exercising people-maintenance.

The most obvious reason relates to the health of the employed people. People get sick and insist on carrying on because "they're indispensible". People work excessively long hours because they want to get the job done. People defer taking annual leave because "there's something needs to be finished", and sometimes continue to defer so that there's a series of "somethings" which roll on one after another.

As well as disturbing the individual's life all those activities (or lack of action) have counter-acting factors in a well-managed firm. Department heads are known to shoo sick people back home, partly for their own sake and partly to protect the rest of the office. Department heads have been known to curtail long weekday hours, and weekend work, not only to limit costs but because people need at least a short break after a certain number of days with the back to the wall and the nose to the grindstone. Department heads have also been known to insist on annual leave being taken for the same reason, people need a longer break after months at work, and many firms have limits to how long a person can put off taking annual leave.

This author has had experience with the result of both no weekend break and taking annual leave. The first was a need to work through three weekends to finish a project on time, he admits at the end of the last weekend he had completely lost track of the days of the week, and slept for well over twelve hours when the work was completed. The annual leave example was much happier, a machine failure occurred while he was absent on leave, the department went through two weeks of agony trying to solve the problem but could only keep the system staggering along. When he returned, fresh from two weeks relaxation, he was able to point to the offending component after a couple of hours thought, but through the years since he has admitted to "cheating", seeing the answer easily by not being bothered by the dreadful two weeks experienced by others.

Keeping employees physically healthy is important because having a person absent costs something, easy to determine when a production person is missing and another on overtime or casual rates replaces, perhaps hard to measure in the case of staff people, but it's a finite amount. What may be termed mental health is much harder to see, it's related to having people satisfied, even preferably happy, in their jobs, which may require management playing confidence tricks on some persons.

On-the-job mental health, related to job satisfaction, which is also related to the development aspect of people-maintenance, is much harder to explain. In an organisation some people have no wish to move up through the ranks (this author has known some), but those who do so wish may find not everyone can move upwards through the hierarchy because there's a numbers limit at every level. So, for those who have some form of upwards-seeking drive means must be found to satisfy that if they're to be retained. Extra education may serve, miscellaneous extra duties, peripheral tasks and projects may be found in reasonably large firms but are usually hard to find in smaller companies.

So, now to the observed and reported examples.

4 EXAMPLES OF POOR PEOPLE-MAINTENANCE

The case of N brings to mind the aphorism about the destination of the road which is said to be paved with good intentions. At the time of his leaving the employer N had been there nearly twenty years after graduation, had moved through several departments, all of which had passed him on to another with reports generally of the "he's all right, but -- - " faint praise nature, none wishing to keep him. He was finally moved into the engineering department, which covered a mixture of maintenance and development, and after a certain amount of fumbling over where he should fit he was put in charge of maintenance at the principal site. During one very wet weekend equipment in part of a production system was flooded, causing lost output, N was notified, didn't act promptly, and on the Monday said quite openly: "It's not my responsibility," referring, of course, to getting the repairs done expeditiously. He was quietly but firmly dismissed.

One may wonder how someone with his background could have said that, considering he had been given, and had accepted, the task of overseeing maintenance of the site. The only answer seems to be a lack, through the twenty-or-so years, of his learning that supervisors, as lower-level-managers, have responsibility for, and are accountable for, effective results in the work to which they are assigned, which attitude could have been caused by the concentration of power held by the more senior managers under whom he worked.

There's a completely different situation in the case of R, who was in charge of maintenance in a small chemical firm through several years, during which R had become almost a personal friend of the Production Director, one of the firm's owners. The curious feature of this situation was R was neither an engineer nor a tradesman but had a more-or-less 'handyman' background. He had been with the firm since very early days, had seen much of the process development, was familiar with the relatively primitive technology used there, was able to perform any elementary maintenance jobs himself, and had access to some outside contractors for specialised work. And, of course, he was friendly with one of the two owners.

The time came when the firm took on a more advanced technical system, decided it was time to employ a professional engineer, went through the usual procedures, and appointed one. Although R showed no overt antagonism towards the engineer his resentment was evident to outsiders, and increased when a qualified tradesman fitter was added to the 'Engineering Department', all understandable from a human behaviour viewpoint because R must have felt 'put down' by the changes; he had moved from being the one solely in charge to being at the bottom of the pecking order.

With the undoubted benefit of hindsight it's evident that management's people-maintenance of R took a wrong turn years earlier, by advancing him in position without ensuring he was gaining appropriate skills to match his position. Or by keeping him at a level appropriate to his knowledge-base, which of course included his extensive background of the early plant development. Either way would have been difficult, but the result of the situation was fairly inevitable, in time the fitter and the engineer both left, leaving R in charge again.

There are similarities between the above and the case of H, but also some differences. H had been employed as electrician in a medium-size firm, in a small engineering department headed by a professional engineer. A time came when the engineer had left, and H was promoted (probably by a "by default" process) to the one in charge of engineering. Some years later the firm was swallowed by a larger competitor, with H remaining in charge of engineering at what was now the secondary site of the overall fairly large firm, but he was not made responsible to the engineer at the primary site. Then the firm appointed another engineer who would manage maintenance and projects at both sites, meaning H would report to him, all very well, but complicated by the engineer having worked in the earlier small firm, over ten years earlier and before the amalgamation, in a position more or less level with H's original position There was no overt friction between them, but H appeared to resent having to follow more formal procedures his new manager required.

During a maintenance shutdown H supervised replacing the packed gland on a large-diameter shaft with a mechanical seal, and in the first assembly one of the two carbon components broke. The parts were stripped and a second carbon was fitted: it also broke. The third assembly also broke a carbon, the last spare available, so the packed gland was replaced. H immediately handed in his resignation, could not be persuaded to withdraw it (persuasion from his manager and many friends on the site), and he left. A few years later his manager met him and found he was much more relaxed, stress-free, and enjoying work as an electrician in a local bus depot.

The similarity between the R and H cases is in the advancement of an unsuitable person in an organisation to a level without ensuring the person has the necessary features. The principal difference is the first was resolved in favour of the person (though inappropriately), the second was resolved with short-term discomfort but for the long-term benefit of both the person and the organisation.

Another different example comes from B's history with a very large firm, in which B provided a specialised service to production plants in several states for many years. He was highly respected for the extent of his knowledge and his ability to provide answers for problems, and he was well liked as a person. There was only one problem: he had no successor. Several attempts had been made to provide one by appointing a junior person with appropriate education (in the same specialised area) as his assistant but the associations only lasted a few months after which each assistant left. There appeared, in this, to be nothing like the situation in which the emperor (or king, or baron) who fears the crown prince (or other person) will stage a palace coup and depose him - - - a state of affairs which occurs as often in industry and commerce as in medieval, or even some modern, royalty - - - the problem was simply that B was so truly competent in his speciality he couldn't hand over work items for another to execute, he was the epitome of "hands-on".

The *word* (a form of communication stronger than gossip) which went around the production plants was that B was a nice fellow but impossible to work with, the short-term assistants said enough to make that understood. Obviously, B had no idea of why an assistant should be trained to provide succession or how an assistant could be trained, and also seemed unable to realise a well-trained assistant would make B's life easier. His inability to accept the reasons for training and developing another indicated poor people-maintenance on his part, and the way in which the company (personified by the general manager above him) tolerated his behaviour indicated equally poor people-maintenance within the organisation.

The word 'gossip', used above, relates to the case in which A was involved. A was a production supervisor in a Sydney company, reasonably competent in that role, but extremely, indeed exceedingly, competent as one who supplied his manager with fragments of information from within the factory. Anyone who has worked in a factory, particularly one which runs a rotating shift system, knows that there's a certain amount of sheer bitchiness (for want of a better word) between people, between shifts, between workers and management, and this grapevine of communication forms a lubricant by venting irritations caused by rotating shifts. (That mixture of metaphors seems to describe well what happens.) The rotating shift system disturbs life in a very real manner and there has to be a way of getting rid of the irritation, so a sensible management may listen to what's noised around in the factory but ignore most of it.

In this case, however, A was encouraged as an open and active information conduit from workforce to management. The information was often used against individuals, as one example he passed on a remark which he overheard, made in confidence from one person to another, and the speaker was given what might be termed verbal chastisement. There is no doubt A was, as a person, maintained very well in the function he performed, but keeping a person in such a role is poor people-maintenance for two reasons: it gave A an exaggerated impression of his value and it reduced the workforce's opinion of the management.

The evidence of poor people-maintenance in J's case showed by how he was managed and how he managed those under him. Both were exposed after he requested an additional professional engineer for the project he was leading as employee of a major firm, and in response the company's human resource office hired an engineer as a casual-contractor through an agency. Without, it seems, in retrospect, asking sufficient questions. With a very few weeks the casual employee had performed very little work, had observed that others in the project group were also effectively inactive although the project manager was always quite busy with phone calls, seeing other contractors, or out meeting others, and the project manager seemed to place more importance on having so many people around him than on having them all engaged. The casual employee went to the human resources office, reported he wasn't being effectively used and outlined his observations to a senior person, who admitted the office had no knowledge of how members of the project group were being utilised, stated the situation would be checked and necessary action would occur. The casual employee was shifted to other work via the agency. The project group carried on without him.

Summing up on J's case: the section of the firm's management hadn't monitored the behaviour of the project group and therefore weren't able to apply appropriate maintenance, and the manager of the project group may have been aware of what was happening but wasn't controlling its action as he should have.

5 WHAT WENT WRONG?

The above examples, of what has been heard to have gone wrong in managing people, show, more than anything, that the seeds of organisation troubles originate more often from the behaviour of senior people, although the fruits show up lower down. Summing up, we have:

N: his unsatisfactory behaviour was noted by department after department, but nothing was done to repair that deficiency, which finally came out by showing a lack of understanding responsibility and accountability.

R: the firm's part owner allowed his friendship to show in the workplace, which at least contributed to R's attitude of "owning" the engineering function.

H: the management promoted H to supervising the site's engineering department because "he happened to be there", not based on his assessed suitability; in his favour we point out he recognised he wasn't suitable when a minor disaster occurred.

B: his work was more than satisfactory and he enjoyed what he was doing, so both he and the management were happy to allow him to continue as a one-person department.

A: his competence as a production supervisor and as an informer cannot be questioned, but for his manager to encourage the latter and use the information raises questions of organisational ethics.

J: there appears to be only two possible reasons for J's behaviour, either he was simply empire-building and wanted to be surrounded by underlings, or he really believed more people were needed for his project.

6 WHAT RESULTS FOLLOWED?

Summing up, now, the results of the above examples of poor people-maintenance:

N: he was dismissed and had to find other work.

R: the firm went through a disturbed period of covert in-fighting then loss of experienced people.

H: he left the firm where he'd worked for nearly twenty years, and found happy employment elsewhere.

B: he carried on in the same manner to retirement; what happened after that is unknown.

A: the management continued to use him, which led to some alienation with the workforce and some staff.

J: the casual employee continued employment elsewhere, J finished the project and was retained.

7 WHAT SHOULD MANAGEMENT HAVE DONE?

Hindsight, as remarked above, can produce wonderful answers, all of little use after the horse has bolted through the stable door, and here's an *oh-so-obvious* review of what should have been done to apply people-maintenance to the persons in the illustrative cases given.

N: a cultural change should have been introduced, to bring in acceptance of responsibility and accountability.

R: the friendship between ranks should not have been apparent, and used, in the workplace.

H: a period of understudying a senior person should have been provided, if his position were to be confirmed.

B: management should have insisted that B would accept, and work with, an assistant.

A: the management culture should have been changed to stop the use of gossip as a disciplinary tool.

J: the human resources department should have questioned the request, and monitored the use of staff.

8 WHAT WERE THE COSTS?

The costs of cases such as the above are usually shared by both the person and the firm, and although numbers cannot be quantified the costs can be indicated.

N: Personal: loss of several weeks income, loss of personal confidence. The firm: loss of an experienced person, cost a hiring a replacement (who, actually, was a dead loss).

R: Personal: R lost nothing, indeed, he probably gained by carrying on after the others left (they had costs). The firm: loss of experienced people, cost of hiring replacements.

H: Personal: H lost some income and was unhappy for a few weeks, but actually benefited, long-term. The firm: no cost, existing people were shuffled around to cover the gap left by H leaving.

B: Personal: no apparent cost, but behind the scenes one can conclude he was working harder than needed. The firm: no apparent cost until B retired, then his expertise had to be replaced (result not known).

A: Personal: A continued in his dual position, with no cost to him apart from general dislike by workers. The firm: no apparent cost, but the workforce became recalcitrant and A had to be moved to another site.

J: Personal: not known, but one can only assume human resources did question J's management.

The firm: the project costs *versus* budget are not known, but that firm was inclined to be liberal.

Having stated, above, what can be excavated from decades-old history, what can we summarise? In every case the poor or inadequate people-maintenance caused a cost to someone, sometimes the person who was poorly managed, sometimes others around that person. In most cases there was a cost also to the employing firm; replacing employees takes time and uses the services of people who have other work to do.

9 A FURTHER EXAMPLE

This example has been left to near the end of this paper for several reasons which include it being not from industry and its providing another, different, demonstration of the cost angle.

An academic with a considerable number of years service in a university retired after accumulating an extensive record of publications and supporting scholarships. About a year after retiring one of his children died in an accident and although the faculty knew of that no condolence messages came to the family from anyone in that faculty.

The accreditation of further publications was transferred to another university, about four papers per year, meaning the related funding from Canberra would be received by that university, which also received the private scholarship funding.

A small example, but it illustrates how lack of "doing the right thing", which is what people-maintenance is all about, can impact on an organisation, in this case by loss of funding.

10 SOME EXAMPLES OF GOOD PEOPLE-MAINTENANCE

After the above series of managers who seemed to have no concept of how to maintain their people we can gain relief by reviewing a case or two in which good people-maintenance occurred.

The subject of this case, P, was a junior project engineer in a medium-sized company, still studying for the TAFE certificate, and, recognised in retrospect, given work beyond his age (early twenties) and experience (this was his first job of this type, and he had not had opportunity to understudy someone senior). The senior engineer to whom this junior person responded has told how the junior fell behind with a critical project but for a few months reported satisfactory progress, too embarrassed to admit he was running late and hoping he'd catch up. When the actual, and lingering, progress was discovered the senior succeeded in getting the fabrication step completed very quickly, and had the junior supervise the installation stage to completion over a weekend.

The senior engineer has told this author that he talked the situation over with the junior, who expected to be dismissed. But through the busy weekend the senior had mentally reviewed some of his own stupid acts through the previous twenty-or-so years and all he felt he could ethically do was to deliver a strong lecture on what had been done wrong and 'don't ever do that again' - - - particularly as the junior had put in many weekend hours finishing the work.

This present author was involved in a good people-maintenance experience, in the dark ages over thirty years ago, when a female university engineering student, K, asked for vacation experience work. His first reaction was: "No, that's not possible!" with an immediate afterthought: "Why not?" The student was hired for six weeks, did some useful work, gained on-the-job understanding of some of her learning, learned some of the art of supervising when she had to exercised her voice by screaming at a fitter who wouldn't do what she told him to do, wrote a satisfactory report, and went off to graduation (and marriage).

11 DISCUSSION OF THE GOOD PEOPLE-MAINTENANCE EXAMPLES

Having thoroughly analysed the results etc of poor people-maintenance, some similar comments are needed on the above two examples of good people-maintenance.

The ethical dilemma which appears to have faced the senior engineer in the first example was how to deal with the junior in a manner delivering justice, when he remembered he'd been caught out under similar circumstances as a junior but had been given opportunities to correct what had happened. As with most ethical dilemmas this had no truly right answer, so he acted as he did, hoping the result would be worth his effort.

Concerning the junior, his attitude became much more focussed on his work, still able to share a joke but more intensely purposeful, with further proof that was good people-maintenance showing about two decades later, when the junior, now older of course, was found to be Pacific Area Manager for a large international company. Concerning the firm in which the incident occurred, nothing was lost, and the work was completed on time. The senior engineer experienced the satisfaction of solving the work-related and ethical problems.

In the second example everyone gained, the student got the work experience needed to satisfy the graduation requirements, the firm gained by having an extra supervisor during a maintenance period and by obtaining the information on the reports, and the author gained by the experience, rare in those days, of having a female colleague work with him.

12 CONCLUSION

The points made in the abstract have been covered, though not as precisely as might be stated in a paper of a technical and mathematical nature, so reviewing those points here:

Very little was found in the literature about "people-maintenance".

The case examples showed dire results can follow poor people-maintenance, and from them we may infer that it's at least desirable, and, probably necessary, for the good of individuals and the employing organisation.

The difficulties in applying people-maintenance can be read from Section 8 above, where the individuals range from factory workforce to managers. Correction would have required change at senior management level.

The results of the seven case examples show the consequences of poor people-maintenance, and working back from those consequences the risk of losing employees and related costs can be seen. The other risk factor, the probability of each occurrence, is more difficult to assess, but in each organisation there was a sufficient build-up of factors to make the observed/reported outcome highly probable, if not certain.

The idea of condition-monitoring this form of maintenance is intriguingly attractive, and might require assessing some form of “happiness factor” of the employees, such as has recently been performed by Monash University through the Australian electorates. At this stage no further suggestions can be offered, it’s a topic for more detailed research.

Each of the case-examples showed costs from poor people-maintenance, some of that due to the crisis nature of what happened. If action had occurred to prevent the observed/reported outcomes there would have been some costs (for example, affecting cultural change isn’t cheap) but spread over a period, and the crisis impact would have been avoided.

Finally, the two examples in which a manager tried to apply good people-maintenance showed results which benefited both the individuals and the organisations involved.

Although the number of bad results exceeds the good outcomes in the above examples we conclude that good people-maintenance is desirable and should be applied where possible. Perhaps all that’s needed is for management to consider “what is right” (long term results) rather than “who is right” (which, in management’s mind, is usually the management).

Abstract: Based on the broad-band random vibration experiment on a structure model of clamping support used in transportation, this paper investigates the problems on detecting the time, evaluating the extent and locating the place of the attachment bolt looseness in the structure model. Firstly, wavelet transform was used to analyse the structural acceleration response data, which includes the moment when the bolt looseness occurred. An obvious step leap along the time axis, which shows the time when the bolt looseness occurs, can be clearly observed in the level-1 details of the wavelet decomposition. Secondly, ARX (auto-regression with exogenous inputs) model was constructed from the measured input and output signals, then the statistical indices of the model residual error were defined as the damage characteristic parameter indicating the severity and location of the loose bolts in the clamping support. The experimental study shows that the extracted characteristic parameter in this paper can be more appropriate than measuring the base frequency for monitoring the bolts looseness at early stage.

Key Words: broad-band random vibration experiment, clamping support structure model, attachment bolts, looseness, feature extraction, wavelet transform, ARX model

1 INTRODUCTION

Vibration is one of the main environmental factors which cause the product's malfunction. With the rapid technology development of the powerful power unit and the high-speed transportation utility, the vibration problem is more of concern. To guarantee the structure safety, especially the structure essential load bearing spot, or the vulnerable region which is unable to be directly inspected, the establishment of the damage monitor (examination), the early warning and the right moment service system is helpful to certain degrees in eliminating the hidden danger and avoiding the disastrous accident occurrence [1].

The commonly used local damage examination techniques (non-destructive evaluation (NDE)) have already been applied to the inspection of the structure crack, looseness and so on [2]. But for the structure real-time damage examination, the previous NDE techniques are not adequate. First regarding the large-scale component, it is very difficult to carry on the examination of all parts of the structure. Second, these technologies applied often request certain functions of the structure to stop using, which is very uneconomical. More serious is, once some important spots of the structure are damaged, the damage degree can develop very quickly, which can cause the entire structure to fail if the problem is not detected promptly. Therefore, it is necessary to develop the global based non-destructive evaluation technology [3], which is simple, economy, and does not affect the structure's normal operation.

The globally based non-destructive evaluation technology can be generally divided into two types: dynamics model based damage evaluation methods and signal analysing non-model based damage evaluation methods [4]. At present, there still is controversy in the dynamics model based methods to the practical applications, mainly because the validity of these methods relies on the accuracy of the analytical or the finite element model; but the dynamic performances of the actual complex component are influenced by the non-structural unit, environmental factor as well as boundary conditions; moreover the structure local variation is generally sensitive to the influence of the high order modes, which are difficult to measure accurately. Therefore, it is an important way to use the non-model based method for the structure overall situation monitoring by analysing and processing the structure dynamic response signal. In recent years, the good results are obtained by use of modern signal processing methods such as time series analysis [5], the wavelet transformation [6], and the high order statistical analysis [7] and so on.

To establish the damage monitoring system, the early warning and the on-line service system, there are two core technical issues: one is how to distinguish the occurrence of the structure damage, the extent of damage, and the damage location; the other is the life prognosis of the damaged structure system. This paper discusses the first issue based on the broad-band random vibration experiment on a structure model of clamping support used in transportation. Firstly, wavelet transform was used to analyse the structural acceleration response data, which includes the moment when the bolts looseness occurred. Secondly, ARX (auto-regression with exogenous inputs) model was constructed from the measured input and output signals, then the statistical indices of the model residual error were defined as the damage-sensitive feature indicating the severity and location of the loosening bolts in the clamping support. The experimental analysis shows that the extracted features in this paper are more appropriate than measuring base frequency for monitoring the bolts looseness at the early stage.

2 BROAD-BAND RANDOM VIBRATION EXPERIMENT ON THE STRUCTURE MODEL

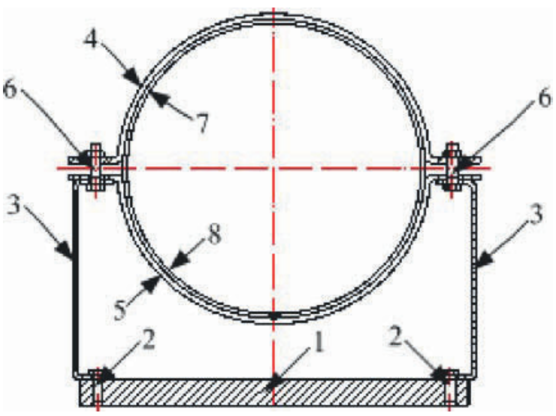

Fig1 Cross section diagram of clamping support

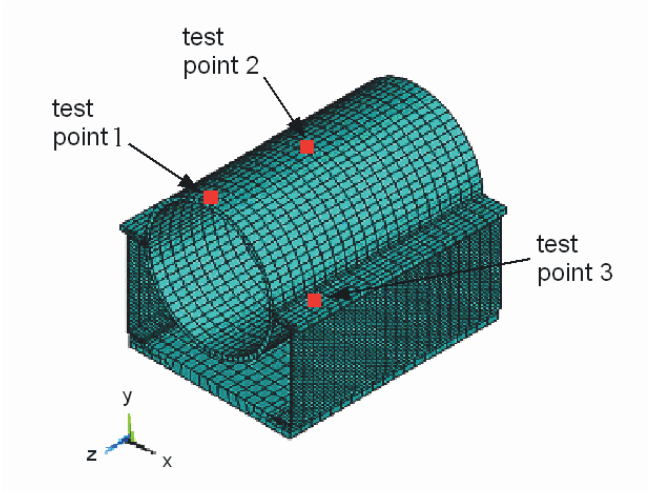

Fig 2 3D sculpt of clamping support and distribution of test points

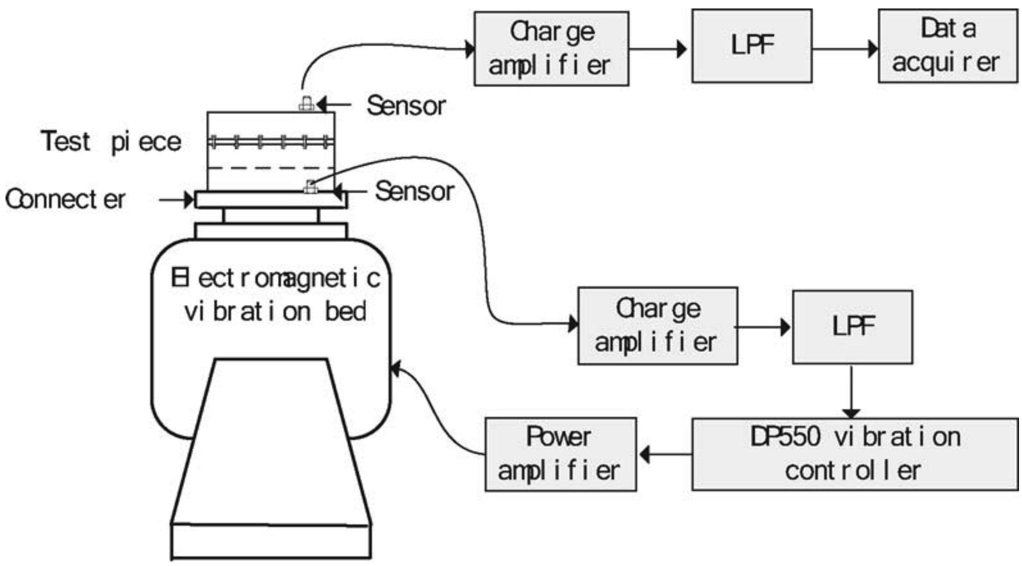

Fig 3 Sketch map of random vibration experiment system

The structure model of the clamping support is composed of a base, 2 blot-braces, a wrapper, 2 half steel-tubes and 24 bolts. The cross section diagram is shown in Fig. 1. On the bottom, the two rectangle blot-braces (No.3) are fixed on the base (No.1) by the 12 bolts (No.2), each side 6; On the top, the blot-braces are fixed with cylindrical wrapper (No.4, No.5) by 12 bolts (No.6), also each side 6. Due to bending pressure, the wrapper restricts the two half steel-tubes (No.7, No.8) inside. The general size of clamping support is: length (Z) 350mm, width (X) 280mm, height (Y) 258.5mm, thickness of blot-brace wall 3mm, thickness of wrapper 4mm, thickness of half steel-tube 3mm. In application, the bolts (No.2) connected with the base are always tightened. So in experiment we tighten and loosen the 12 bolts (No.6), which connected wrapper with blot-brace, to study the different dynamic response of clamping support under vertical broad band random excitation. The 3D sculpts of clamping support and the distribution of test points, at which the responses are taken, are shown in Fig. 2.

Many real vibration environments are stochastic: the uneven road surface causes the road vehicle vibration; the boundary layer turbulent flow causes the flight vehicle vibration. The random vibration experiment system includes two parts: vibration controlling subsystem and data acquisition subsystem. The former controls the vibration of electromagnetic vibration bed and is composed of sensors, charge amplifier, low pass filter (LPF), DP550 vibration controller, and power amplifier. The latter acquires data for analysing from test piece, which is connected with vibration bed platform through a connector. The data acquisition subsystem is composed of sensors, charge amplifiers, low pass filter and data acquirer. The sketch map of random vibration experiment system is shown in Fig. 3. There are four sensors in the experiment, three are placed at test point 1, 2, 3 shown in Fig. 2 and another sensor shown in Fig. 3 is placed on the connector for measuring input signal of the vibration bed.

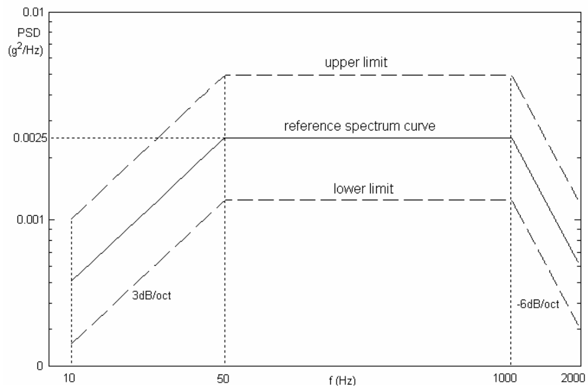

Fig 4 Reference PSD graph

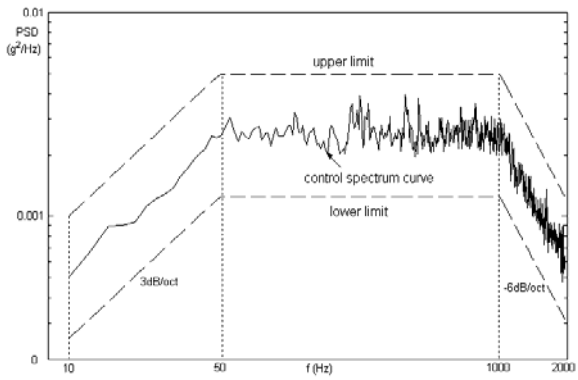

Fig 5 Actual control PSD graph

The random vibration experiment condition generally requires the power spectral density versus frequency curve (the PSD graph). The solid line in Fig. 4 shows the PSD reference spectrum curve which requests the vibration bed produce a straight spectrum in the 50-1000Hz frequency range. The solid line in Fig. 5 shows the actual PSD control spectrum curve. The dashed line in Fig. 4 and 5 shows the spectrum tolerance for upper and lower limits which are set as 3dB and -3dB relative to the amplitude of the reference spectrum. During the experiment, the vibration bed is run in the pre-experimental magnitude -6dB and -3dB for 20 seconds, then 20 seconds in the experimental magnitude 0dB, the sampling frequency is 7680Hz.

In order to simulate bolts looseness of clamping support with different degree, seven kinds of damage cases plus normal state (12 bolts (No.6) which connect wrapper and blot-braces are all tightened) are tested in the experiment. They are: (case1) 2 bolts closest to test point 3 are loosening completely; (case2) 2 bolts diagonal to test point 3 are loosening completely; (case3) 4 bolts at the four corners are loosening completely; (case4) 4 bolts at corners are tightened, the left 8 bolts are loosening completely; (case5) all the 12 bolts are loosening with slight degree; (case6) all the 12 bolts are loosening with medium degree; (case7) all the 12 bolts are loosening with serious degree. The object of this paper is to detect the time, evaluate the extent and locate the place of the attachment bolts looseness in the structure model under vertical broad band random excitation.

3 TIME DETECTION OF BOLTS LOOSENESS OCCURRENCE

Singularities and irregular sudden changes often carry the most important information in signals. In the mechanical structure damage monitoring, it is important to study the irregular components of the structure dynamic response, which imply the breakdown information of the structure. The Fourier transformation is one of the main mathematical tools for analysing singularities, but it provides a description of the overall regularity of signals and can not be well adapted finding the singularity locations of signals along time axis. The wavelet transformation can be seen as a windowing technique with variable-sized regions, which allow the use of longer time intervals for low frequency information and shorter intervals for high frequency information. One major advantage of the wavelet transformation is the ability to perform local analysis, through which the exact time of signal discontinuity can be detected [8].

There are literatures applying wavelet transformation to carry on irregularity detection of structure response signal, thus achieving the goal of structure damage monitoring. Hera [9], by simulation, applied the wavelet-based approach to study acceleration response data of a four-story prototype building structure subjected to simulated stochastic wind loading. He pointed out that the time of structural damage due to suddenly breakage of structural elements can be easily detected by spikes in the wavelet details. The damage region can be determined by the spatial distribution pattern of the observed spikes. In the authors' view, if a system is subject to broadband random excitation, the singularities could also be caused by the excitation process. Therefore, when the structure undergoes not the sudden damage but the cumulative damage in the actual stochastic vibration environment, we often cannot obtain the correct results. Masuda [10] studied the isolation method to separate the singularities due to the excitation and the singularities due to the system's changes through a simple single degree of freedom spring oscillator model, which has limited use in practical application.

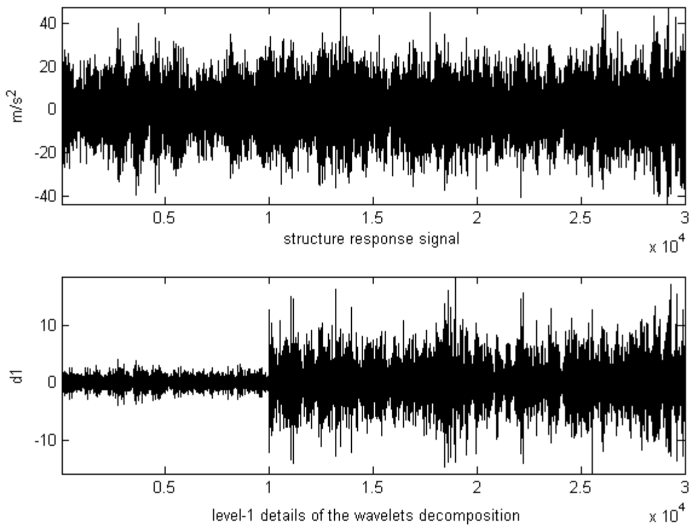

Fig6 Wavelet analysis

For detecting the time of the bolts looseness occurrence, this paper assumes that the bolts looseness is a sudden damage process. Using the Daubechies order 4 wavelets, the acceleration responses of the clamping support was analysed, which contained the occurrence of damage case 7. It is seen from Fig. 6 that, although there is no special change in the acceleration response signal, the obvious step leap can be seen in the first wavelet detail coefficient curve, which demonstrates the time of bolts looseness occurrence. Moreover, when analysing the data segment which did not contain the bolts looseness, regardless of the signal from the normal structure, or from the damaged structure, there is no obvious step leap in the wavelet detail coefficient curve, which is consistent with literature [9].

4 RECOGNITION OF BOLTS LOOSENESS DEGREE AND POSITION

The natural frequency of a structure system is one modal parameter that can be easily measured with high precision in the on-line monitor, therefore monitoring base frequency change is a simple and direct indicator of structure damage occurrence and degree [4]. However, this is not effective for the early small damage, which causes the necessity to seek more sensitive characteristic parameter to damage.

In the broad-band random vibration experiment, because the input energy of the vibration bed is very small, the power spectral density value 0.0025 g^2/Hz in the 50-1000Hz scope, the dynamic characteristics of the clamping support with attachment bolts looseness can be described using the linear model [11]. In this paper, the linear difference equation or the so called auto-regression with exogenous inputs (ARX) model [12] was used to express the system input-output relations.

4.1 Derivation of damage characteristic parameter

Firstly, divide the measured structure input and output signal evenly into M section, suppose the length of each data section is N. In the experimental data analysis of this paper, the actual signal is taken from 2 second to 18 second of experimental magnitude 0dB, and there are 29 data sections with length of each section 4096 points. Then the data normalization process is carried out for each section:

$$x_j(n) = \frac{\hat{x}_j(n) - \mu_{\hat{x}}}{\sigma_{\hat{x}}}, \quad n = 1,2,\ldots,N, \quad j = 1,2,\ldots,M \tag{1}$$

Where $x_j(n)$ is the normalized data section of $\hat{x}_j(n)$, $\mu_{\hat{x}}$ and $\sigma_{\hat{x}}$ are mean and standard difference value of $\hat{x}_j(n)$. The purpose of performing the data normalization is to reduce the influence of the external environment and the working condition changes on the extraction of system damage sensitive parameter.

Secondly, let $u_u(n)$ and $y_u(n)$ denote the input and output data section from the normal state structure after the data normalization, then establish the ARX model:

$$y_u(n) = \sum_{i=1}^{na} \alpha(i) y_u(n-i) + \sum_{j=1}^{nb} \beta(j) u_u(n-j) + e_u(n) \tag{2}$$

Where $\alpha(i)$ and $\beta(j)$ are model parameters, na and nb are model orders. To determine na and nb, the following steps are taken: first give an upper limit of the model orders according to the system physical property and the empirical knowledge, then calculate each candidate orders using the least square parameter estimation method, at last utilize the order decision criterion to determine the actual model orders na and nb. After computation, $ARX(60,60)$ model is used to express the input and the output relations of the normal state structure, and then the residual error $e_u(n)$ is a white noise sequence.

Thirdly, the same principle as above, obtain the input and output signal corresponding to the identical position of the structure with unknown condition (we don't know whether damage occurs). Let $u_d(n)$ and $y_d(n)$ denote the normalized input and output data section from above signal, then use the model parameters $\alpha(i)$ and $\beta(j)$ obtained from equation (2) to express the relations of $u_d(n)$ and $y_d(n)$, and the new residual error sequence $e_d(n)$ can be obtained:

$$e_d(n) = y_d(n) - \sum_{i=1}^{na} \alpha(i) y_d(n-i) - \sum_{j=1}^{nb} \beta(j) u_d(n-j) \tag{3}$$

Because the residual error represents the part that the ARX model cannot construct in the system output, we may believe that, if $u_d(n)$ and $y_d(n)$ comes from the same system with $u_u(n)$ and $y_u(n)$, then $e_d(n)$ can only have a smaller residual error; Otherwise, $e_d(n)$ will have a larger residual error.

Lastly, structure damage characteristic parameter can be defined as:

$$D_F = \sigma(e_d) / \mathrm{mean}(\sigma(e_u)) \tag{4}$$

Where $\sigma(e_u)$ and $\sigma(e_d)$ are standard differences of the residual error sequence $e_u(n)$ and $e_d(n)$, $\mathrm{mean}(\sigma(e_u))$ represents the mean value of $\sigma(e_u)$ corresponding to M sections from the measured input and output signal of structure in normal state.

Therefore, take the input-output signal from the structure of known normal state as the reference, through the damage characteristic parameter computation for each data section from the structure of unknown condition, damage characteristic parameter sequence $\{D_F(j),\ j = 1,2,\ldots,M\}$ can be obtained. Through the statistical analysis to the sequence, influence of non-linear factors such as the time varying characteristics of input can be decreased and robustness of damage diagnosis can be enhanced.

4.2 Recognition of bolts looseness degree

In this paper, the response signals of the clamping support measured from the test point 1 are calculated for different bolts loosening cases, which are (case1) 2 bolts loosening; (case3) 4 bolts loosening; (case4) 8 bolts loosening; and (case5, 6, 7) all the 12 bolts loosening with different degrees. The following table shows the computation results and the measured base frequencies of the clamping support with different damage cases:

Table 1: Mean and standard difference value of $\{D_F\}$ and base frequency

	case 1	case 3	case 4	case 5	case 6	case 7
Mean of $\{D_F\}$	2.8018	3.5678	4.8453	13.7342	19.4744	43.6092
Standard difference of $\{D_F\}$	0.3587	0.6612	1.2133	2.5648	3.4694	8.44
Base frequency (Hz)	217.5	213.8	206.3	185.3	167.8	132.7

Note: Measured base frequency of the clamping with normal state is 217.5 Hz

It can be clearly seen from above table that: as the bolts looseness degree or damage degree increases, the mean value of sequence $\{D_F\}$ presents an increasing tendency, therefore the mean value of $\{D_F\}$ can be taken as the characteristic parameter indicating the extent of damage. The standard difference of $\{D_F\}$ can be seen as an indicator of the credible degree of the sequence data and as a basis for comparing two groups of sequences.

It can also be seen from above table that: for the damage case 1, case 3, case 4, the corresponding base frequency change does not exceed 5%, especially for the damage case 1, when there are only two bolts loosening, the base frequency of the structure is same with that of normal state.

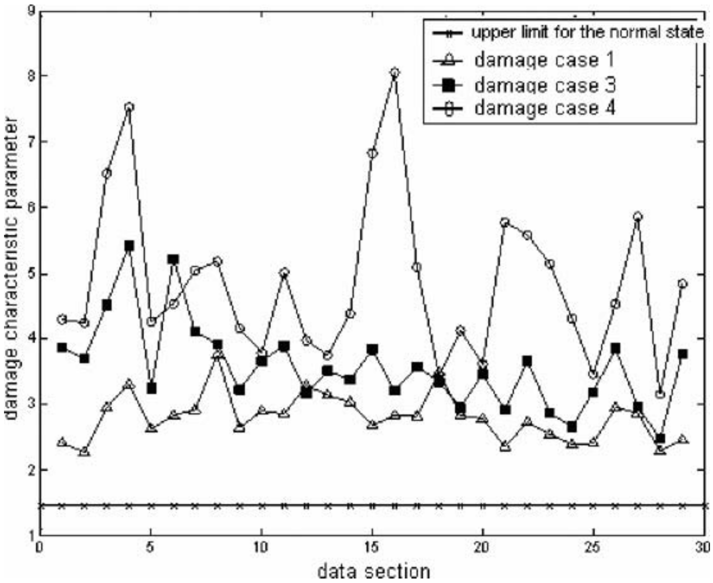

Fig 7detail of the $\{D_F\}$ sequences corresponding to the damage case 1, 3 and 4

The detail of the $\{D_F\}$ sequences corresponding to the damage case 1, 3 and 4 is shown in Fig. 7, from which we can see that even the sequence value for case 1 are obviously higher than the upper limit for the normal state. Supposes the sequence to obey the normal distribution, then we can calculate that the probability of $\{D_F\}_{case3} > \{D_F\}_{case1}$ is 84.57%, and the probability of $\{D_F\}_{case4} > \{D_F\}_{case3}$ is 82.24%, therefore three kinds of various degrees of bolts looseness conditions can be separated.

The above results are obtained from test point 1, and similar results are obtained from test point 2.

4.3 Recognition of bolts looseness position

In order to carry on the work of bolts looseness position recognition, the response signals obtained from the test point 1 and 3 are calculated for damage case 1 and 2, which have 2 bolts loosening with different position. The results are shown in the following table:

Table 2: Mean and standard difference value of $\{D_F\}$ for case 1 and 2

	Test point 1		Test point 3	
	case 1	case 2	case 1	case 2
Mean of $\{D_F\}$	2.8018	3.0348	4.1856	1.9729
Standard difference of $\{D_F\}$	0.3587	0.5334	0.5238	0.4331

It can be seen from above table that: because test point 1 is arranged on the top of the clamping support, the calculated structure damage characteristic parameter is insensitive to the variation of loosening bolts positions; however, because test point 3 is arranged near the attachment bolts, when the 2 loosening bolts is that nearest to the test point 3 (damage case 1), the mean value of $\{D_F\}$ is obvious higher than that of damage case 2, in which the 2 loosening bolts is far away from the measuring point 3. Therefore, if more sensors are laid beside each attachment bolt, the loosening bolts position may by roughly determined by the relative value of damage characteristic parameters calculated from each measuring point.

5 CONCLUSIONS

(1) Compared with the Fourier transformation, the wavelet transformation has the ability to perform local analysis, through which the exact time of signal discontinuity can be detected. Experiment analysis shows that an obvious step leap along the time axis, which shows the time when the bolt looseness occurs, can be clearly observed in the level-1 details of the wavelet decomposition.

(2) ARX model is constructed from the measured input and output signals, and the statistical indices of the model residual error were defined as the damage characteristic parameter. Based on damage case 1, 3, 4, 5, 6 and 7, the damage characteristic parameter rightly indicates the bolts looseness degree of the clamping support structure model. Based on damage case 1, 3 and 4, the damage characteristic parameter is more sensitive than measuring base frequency change for monitoring the bolts looseness at the early stage.

(3) Based on the analysis of damage case 1 and 2, we can envisage that if more sensors are laid beside each attachment bolt, the loosening bolts position may be roughly determined by the relative value of damage characteristic parameters calculated from each measuring point.

APPLICATION OF PROBABILISTIC SAFETY ASSESSMENT TO PARAMETERS OF OPERATIONAL LIMITS AND CONDITIONS OF THE OPAL RESEARCH REACTOR

Bastin, S.J., and Perera, J.

Australian Nuclear Science and Technology Organisation, New Illawarra Road Lucas Heights, NSW 2234 Australia.

Abstract: This paper gives a brief explanation of Probabilistic Safety Assessment (PSA), the meaning and application of Operational Limits and Conditions (OL&Cs) for facilities and describes the application of PSA to the derivation of OL&C parameters such as Completion Times. ANSTO's Research Reactor OPAL is used as a case study but the authors conclude that the methodology, based on NUREG/CR-6141, could equally be applied to major hazard facilities.

The PSA indicates that the OPAL reactor meets the regulatory safety limits and safety objectives. The very low risk is achieved by important design characteristics such as the two independent and diverse shutdown systems, minimal dependence on support systems for the safety functions, the absence of in-core experiments, and the redundancy in cooling modes.

Completion times are derived for safety systems and some sub-systems by balancing the incremental risk of single outages of those systems, and also by balancing the incremental risks associated with the expected number of outages of those systems and subsystems while ensuring that the incremental risks are tolerable.

This methodology can give an estimate of the total incremental risk of allowable outages of safety systems and subsystems taking into account the expected number of outages of those systems each year. An assessment of the tolerability of that additional risk can be made.

Key Words: Probabilistic Safety Assessment, Operational Limits, OPAL, Dependence, Tolerability.

1 INTRODUCTION

Understanding and managing the risks of operations is a critical aspect of asset management and a legal requirement on owners and managers of plant. To assure and demonstrate the safety of complex or hazardous plant, it is important to undertake Probabilistic Safety Assessmenti (PSA) in addition to the Deterministic Safety Analysis (DSA). PSA can provide additional insights into the strengths and possible weaknesses of a plant design, and can give indicative estimates of the risk associated with the plant. The application of PSA was once confined to nuclear power reactors but is becoming more common for all nuclear facilities, and has also been applied, at least in some limited forms, to complex and major hazard plant, especially in petrochemicals, and oil and gas production [ii, iii, iv, v].

PSA is a valuable tool for the quantification of risks, the identification of possible plant responses to initiating events, and the identification and ranking of features that govern the risk.

Yet following commencement of operations of a plant, the risks are often altered from that modelled in the PSA. This can happen in the following ways:

a) When failures in some component of safety systems occur, some leeway is often sought by the operating organisation to correct the fault while still in operations.

b) Over time, some of the assumptions made in the development of the PSA can change. For example, the test frequency of some systems, subsystems or components may change for practical operational reasons.

c) More accurate data on equipment and human reliability may become available in the operational phase.

d) Plant modifications in the operational phase may require changes to the PSA models.

The approach to resolving these issues in the nuclear industry has been (i) to use the PSA to assist in the derivation of acceptable amount of "leeway", (ii) to use the PSA to help choose appropriate test intervals and (iii) to keep the PSA as a "living" document that is used to assess the altered risk of proposed changes, and is then updated to reflect the changes once implemented.

This paper discusses some of the techniques used, using the OPALvi research reactor as a case study, and proposes that there may be applications for non-nuclear plant in the growing field of Engineering Asset Management.

2 OBJECTIVES OF THE OPAL PSA

The OPAL reactor is an open pool type, that is, a reactor where the core sits in a deep pool of water that provides cooling of the core, and shields people and equipment from the harmful radiation. The metallic pool liner sits in a high integrity reinforced concrete block. The OPAL reactor will provide facilities for irradiating targets for the production of radiopharmaceuticals, and silicon and for experiments, as well as providing high quality neutron beams for specialised research.

The reactor vendors, INVAP SE, provided a PSA for licensing purposes for the OPAL research reactor [vii]. This PSA underwent significant review by ANSTO and supported the application for an operating licence to the Australian Radiation Protection and Nuclear Safety Agency (ARPANSA).

In addition to the general objectives of PSA (mentioned above), the main objective of the OPAL reactor PSA is to support the deterministic safety analysis in demonstrating the safety of the plant and demonstrating compliance with probabilistic safety limits and objectives. Moreover, since this PSA was developed in parallel with the basic engineering phase of the OPAL reactor, the preliminary results were used as input to the design process, thus permitting improvements to be made to the design.

The OPAL PSA is considered Level I, with some Level III considerations. Level I PSA examines the risks of breaching the primary barrier for radioactive material *eg* melting fuel, or damaging the fuel cladding. Level II PSA examines the risk of release of radioactive material to the environment, while Level III PSA examines the risk of radiological consequence to people. Probabilistic objectives and limits for doses to members of the public are set by ARPANSA.

In non-nuclear applications, analogous primary measures of risk need to be identified, and in many cases, the three level concept may be applied although the distinction between Level II and Level III may not always be warranted. For example, in a facility which processes and stores hazardous chemicals, the Level I measure may be the "breach frequency" of the storage and process vessels and pipework. The Level II PSA may analyse the possible chemical and physical interactions in a breach, leading to the frequency of releases of different magnitudes to the environment. The Level III measures will be the frequency and severity of exposures of those released chemicals to employees, contractors and members of the public.

3 ANALYSIS METHOD

This section describes the PSA methodology using the OPAL PSA as a case study.

3.1 PSA Approach

PSA involves combining event tree analysis and fault tree analysis to model the propagation of accident sequences beginning with Initiating Events (IEs) and subsequent failures of defence systems. The likelihood of different groups of outcomes (referred to as end states), are then quantitatively analysed using probabilistic calculations. Event tree analysis forms the backbone of this process. Each IE has a corresponding event tree in which the applicable defence systems, are modelled as the nodes of the event tree. Fault trees are used to model the IEs and also the probability of failure of each of the defence systems. The initiating events and the end states are both calculated as frequencies (usually per year).

3.2 Identification and Selection of Initiating Events

The identification and selection of IEs always poses a question as to the completeness of the PSA, and no method can guarantee completeness, although use of one or more standard methods gives reasonable assurance. A systematic method, known as Source and Event Analysis (SEA[viii]) was used for the OPAL PSA. This method is consistent with NUREG/CR-2300 [ix] and the approach given in IAEA-TECDOC-517 [x]. The SEA method is a multi-step, bottom-up approach that involves identification of the sources of radioactive material, the barriers that separate these sources from the public and/or plant personnel and the primary failure mechanisms of these barriers. From these mechanisms, IEs can be postulated. Those events which make a negligible contribution to the overall risk, for example, because the inventory of radioactive material is too small to pose a risk are screened out according to internationally recognised guidelines [xi].

3.3 PSA Models and Data

Many sophisticated tools for the quantification of risks arising from the operation of nuclear reactors and other complex installations are now available. SAPHIRE [xii] is a package used to quantify Level I PSA (*ie* to estimate the frequency of the major undesired event – core damage) and was used for the OPAL study. Industry-specific tools and software must be used to assist in the modelling of dispersion and consequence. For the OPAL study, such modelling was carried out using PC Cosyma (developed by the UK National Radiological Protection Board under a European Commission contract).

Once the IEs are identified, the following steps are typically undertaken in PSA:

a) Each IE is analysed and the possible accident sequences derived from it are mapped against the possible defences (mainly safety systems) that would be required along those sequences.

b) A System Fault Tree (FT) is developed for each of the required defences, using the system success criterion, and relevant drawings and the Operational Limits and Conditions.

c) An Event Tree (ET) is developed for each IE, with the corresponding nodes of the tree corresponding to a defence system. Sequences which have no physical meaning are removed.

d) The ETs and FTs are programmed into a PSA software package. In the OPAL PSA, the SAPHIRE [xii] package was used. The PSA model is then checked and the qualitative results examined. The model is then quantified. In the OPAL PSA, equipment failure rate data used was mostly from the IAEA databases [xiii,xiv].

e) The frequencies of the main plant damage states are determined by the sum of the frequencies of sequences that lead to those damage states. For the OPAL PSA, core damage is the main plant damage state of interest and the results focussed on that, although other release sequences were identified.

f) Importance measures are estimated to give an indication of how significant each basic event is to the overall core damage frequency (CDF). Importance measures are an indication of sensitivity. In the OPAL PSA, it was also of interest to look for "cliff-edge" effects – that is, situations where a small change in basic event data can cause a significant increase in the overall CDF.

g) The probability of each basic event has some associated uncertainty which is represented by the associated confidence interval on the data. Having obtained "best estimates" of all of the end state frequencies, it is usually of interest to understand the uncertainty associated with these estimates. This is achieved by "propagating" the uncertainties through the Level I PSA model. The objective is twofold: (1) to understand the limitations of the numerical results and (2) to obtain upper bound estimates of the end state frequencies at specific levels of confidence.

h) In a full level III PSA, the response of containment and the dispersion of associated releases are modelled probabilistically. In the OPAL PSA, such detailed modelling was not warranted. However, to estimate the plant behaviour beyond the scope of the Level I PSA, a set of representative accidents were analysed to determine inventory, containment response, and consequences of such a release. These accident sequences which included those not related to core damage, were those estimated to have annual frequency close to or within the range of ARPANSA risk acceptance criteria for radiological consequence, and bounded other credible accident scenarios of lesser significance. Using conservative retention factors, and conservative assumptions about the containment response, source terms were derived for each of the grouped plant damage states and these source terms were used to estimate the doses a member of the public might receive, making conservative assumptions about the weather conditions, and sheltering etc. The results were then compared against acceptance criteria.

3.4 Dependent Failure Analyses

Actual operating experience with complex plants demonstrates that, although the likelihood of a series of failures is quite small, this likelihood is numerically higher than would be estimated solely from a postulated chain of independent failures. This is because physical and human interactions result in dependent failures that increase the conditional probability of each successive failure in the chain. The treatment of dependencies in the identification and quantification of accident sequences is called "dependent-failure analysis". Since essentially all important accident sequences that can be postulated for nuclear reactor systems involve the postulated failure of multiple components, systems, and containment barriers, dependent-failure analysis is an extremely important aspect of PSA. This will no doubt be true for non-nuclear major hazard plant.

The main focus of this paper is not on dependent failures analysis but it may be warranted to briefly explain how PSA in the nuclear industry traditionally deals with dependencies. A detailed engineering analysis of dependent failures must consider the root causes of component failures and the degree of dependence among component failures with regard to each root cause. This is particularly important for a new reactor, where no operating, maintenance and testing experience exists. There are three types of dependent failures:

a) <u>Functional dependencies between systems</u> are where the success of one system is dependent on the success of another, for example due to reliance on a support system or where there is a shared component or subsystem in two systems. Functional dependencies are treated explicitly in event trees while shared component dependencies are taken account of by the analysis software, providing the shared items are clearly identified by the analyst.

b) Dependencies or common causes between basic events can sometimes be foreseen (*eg* those caused by improper maintenance or incorrect restoration after testing) and these can be modelled specifically where identified. However, it has been recognised that many significant dependencies cannot be foreseen. Traditionally, these common cause failures (CCF) are modelled as a numeric fraction of the basic event failure probability (*eg* the beta factor, or multiple Greek letter methods). Parameters for these models make use of generic data, which are then updated with plant-specific data, where available. For the OPAL PSA, in lieu of the more conventional method, common cause effects were modelled by recognising that ultimately all faults can be attributed to human error [xv]. Because this method is novel, comparisons were made with conventional beta factor and MGL methods and the effective CCF contributions were similar to those that would have arisen from conventional methods.

c) Dynamic human interactions cover the errors that operators could make in responding to an IE. In the OPAL reactor, the actuation of the safety systems is automatic, and no credit was taken for manual actions or recovery actions. It was difficult to anticipate how an operator might respond erroneously in a particular sequence, when no operator response is required in the first 30 minutes, however, where credible operator actions that could jeopardise safety system functions were identified, they were included as basic events in the fault tree models.

3.5 Seismic modelling

Again, seismic modelling is not the main focus of this paper, but it may be useful to understand how PSA in the nuclear industry deals with seismic issues. There are two aspects to seismic analysis in PSA: (1) obtaining measures of the seismic hazard at the site, usually characterised by the zero period peak horizontal ground acceleration (PHGA) at various return periods, and (2) obtaining measures of the fragility of systems and components of the plant which are required in responding to seismically induced IEs [xvi]. The seismic hazard is considered the initiator of several possible accident sequences, such as a loss of coolant accident (LOCA) or loss of flow. The ability of the safety systems to mitigate the consequences of the initiated fault condition depends on the extent to which seismically induced failures of components have degraded the functional capability of those systems. Failure probabilities (conditional on a specific level of ground acceleration) of components are derived from their seismic fragilities.

The seismic hazard for Lucas Heights was estimated by consultants [xvii] in 1999 and refined by a broader group of experts in 2001 [xviii]. Seismic PSA assumes that the designers have adequately taken into account the spectrum of the seismic ground accelerations so that the seismic PSA can focus on one main parameter of the hazard (*ie* the zero period PHGA) at each return period. Fragilities were derived using commonly adopted values for the uncertainty ($\beta_R = 0.25$; $\beta_U = 0.35$) and setting the high confidence low probability of failure (HCLPF) as the mean 10,000 year ground acceleration for seismic category 1 items and systems. This is appropriate, because all seismic category 1 items and systems are designed with high confidence to continue to function under such ground acceleration.

The seismic contribution to the CDF has been analysed in two different scenarios. The first scenario considers the contribution to the CDF for those seismic events whose frequency is up to the 10,000 year earthquake. However, because all safety critical items have been designed to this level of earthquake, the estimated additional CDF from seismic events up to this level is negligible. For this reactor, the CDF contribution from seismic events up to the 10,000 year earthquake is insignificant and so is not discussed further.

The second scenario considers the contribution to the CDF for all the seismic events indicated by the full Hazard Curve for the site (*ie* up to 100,000 year return period).

4 LEVEL I PSA RESULTS

4.1 Numerical results

4.1.1 Core damage frequency

Significant core damage (such as melting or rupturing of the fuel cladding) can lead to a release of fission products to the coolant and ultimately to the containment building. Degradation of containment can release fission products to the environment. In the context of Level I PSA of a nuclear reactor, the prime measure of risk is the CDF, that is, the expected frequency of significant damage to the reactor core. This is obtained by the summation of all the event sequence frequencies that lead to core damage. The CDF is usually divided into the CDF from sequences arising out of internal random failures, internal fire and flooding, external events excluding seismic events, and seismic events.

Table 1 shows the overall CDF with 90% confidence limits, including all identified external events with the full seismic hazard[vii]. It can be seen that the estimated CDF is remarkably low demonstrating the robust design of the OPAL reactor.

Table 1 Overall Core Damage Frequency including internal, external and using the full seismic hazard from reference [vii]	
Mean Core Damage Frequency:	$5.4x10^{-7}$/year
5^{th} Percentile Core Damage Frequency	$3.0x10^{-7}$/year
95th Percentile Core Damage Frequency	$9.1x10^{-7}$/year

The relative contribution to the mean total CDF due to each of the main classes of initiating events is indicated in Figure 1.

It can be seen that the seismically induced loss of offsite power is the greatest contributor to the CDF with (about 48% of CDF) and seismically induced LOCAs the next most significant cause. It should be remembered that this is based on several conservative assumptions: (1) that seismic events above the one in 100 year event are guaranteed to cause loss of offsite power and (2) that no credit is given for operator intervention. In reality, with a LOCA in progress, operators would ensure the LOCA is arrested by clearing any blockage in the siphon effect breaker, forcefully opening a flap valve or shutting the manual isolation valves. Loss of offsite power (non-seismic) and internal (or randomly occurring) LOCAs are the next two most significant classes of initiators.

4.1.2 Comparison with regulatory requirements

The Regulatory Assessment Principles expect for a new nuclear reactor, the applicant to be able to demonstrate that the frequency of significant damage to the nuclear core is less than 10^{-5} per year. Furthermore, dose-based safety objectives specify the expected total frequencies in various bands of dose to members of the public. Of these dose-based safety objectives, the most stringent (*ie* the expected total frequency in the most severe dose category) is 10^{-6} per year [xix]. The values of CDF shown above demonstrate that the Reactor fulfils the most stringent Safety Limits and Objectives, with 95% confidence. Therefore, it can be stated that those accidents with the potential to cause a significant damage to the core, pose a negligible risk to the public in the vicinity of the reactor.

4.2 Design improvements

The OPAL reactor has two independent and diverse reactor protection systems and corresponding shutdown systems. Whilst both are essentially equal in their respective capability to respond to all design basis events, preference is given to the first shutdown system (FSS) because of the greater time required to reset the second shutdown system (SSS). The second reactor protection system (SRPS) was therefore designed with a smaller set of trip parameters than the first protection system (FRPS). In the preliminary stages of the design, the preliminary PSA results showed that loss of heat sink (*ie* loss of the secondary cooling system function) together with failure of the FRPS was a significantly dominant sequence. Whilst this sequence was still predicted to be extremely unlikely, the PSA showed that the design was not well balanced, in that the total internal CDF was dominated by just one sequence. On the basis of the PSA results, a design decision was taken to implement an additional SRPS trip to respond to the loss of heat sink initiator.

5 LEVEL III PSA RESULTS

It is usual that the accident scenarios that contribute the most to the risk of a nuclear reactor are those that involve substantial damage to the reactor core. However, the very robust design of the OPAL reactor, with inherent safety features and a high degree of redundancy, diversity and independence of its safety functions, makes the CDF so low, that they are not considered credible. One of the reasons for this is that the PSA was developed at the same time the basic engineering was developed, and any weak points identified during the system's analyses for the PSA, were passed to the designers to implement improvements [vii]. As a result, for the OPAL reactor the risk representative scenarios do not involve significant core damage. These other accident scenarios relate to target damage or fuel damage outside the core and they were analysed and quantified both in their frequencies and their associated potential doses on the public. The release categories (RC) for the representative release events, even when modelled under extremely conservative assumptions, show that the expected risk contribution of the selected accidents is well within acceptable levels.

It is important to notice also, that the maximum doses do not require any off-site emergency measure (eg sheltering).

6 APPLICATIONS OF PSA

The OPAL reactor PSA in its current form was primarily intended for demonstrating compliance with regulatory objectives. However, it has potential further practical and beneficial uses such as safety assessment of any future modifications of the reactor and risk-informed decision making on reactor operational aspects. An application of the OPAL reactor PSA is to derive risk-based parameters for the Operational Limits and Conditions (OL&Cs) is described below.

6.1 Completion times

When a failure occurs in a system important to safety, the risk is increased above the originally calculated risk (e.g. CDF) until that failed item is restored. By choosing an appropriate value for the time in which restoration is allowed, the increased risk can be kept within agreed acceptable bounds, both for the single event and for the total number of expected such events in one year.

A Completion Time is the allowed time specified in the OL&Cs to achieve a required action following a failure in, or detection of the inoperability of, a safety system. The required action is intended to put the reactor in a safe or safer state *eg* by restoring a failed item, setting a failed instrument to the "tripped" status, or simply shutting down the reactor . If the required action is fulfilled within the completion time, the OL&Cs are deemed to have been complied with. Traditionally, completion times are derived from experience and past practice but the use of PSA permits risk-informed derivation of completion times.

For the OPAL reactor, the NUREG/CR-6141 methodology [xx] was followed as far as was possible. Using the risk increase and risk reduction factors for systems and components, it was possible to determine the effective increased risk of remaining in a state with a system or component inoperable. By comparing that incremental risk with some criteria, a maximum completion time can be determined. This permits a balanced approach to determination of completion times. Knowing how often a system is likely to come into a degraded or inoperable state and comparing the increased annual risk permits derivation of a second measure of the allowable completion time. The actual completion time should not be greater than the minimum of these two measures. The following outlines the method in more detail.

1. The first step is to define criteria for the acceptable additional risk of core damage allowed for a single event ($\boldsymbol{r_c}$), for the additional annual risk associated with the expected number of failures or outages for each system ($\boldsymbol{R_c}$) and for the total expected number of failures in all systems ($\boldsymbol{R_{cT}}$).
2. Next, one must identify the systems, subsystems and components for which completion times are required.
3. For each of the systems, subsystems and components, obtain the Risk Increase Factor, ***RIF***, and Risk Reduction Factor, ***RRF*** from the PSA. The ***RIF*** and ***RRF*** are importance measures of events in the PSA and are typically computed by the PSA software. The ***RIF*** is the factor by which the CDF increases if the event concerned has definitely failed. The ***RRF*** is the factor by which the CDF reduces if the event concerned is definitely successful i.e. not failed. For coherent systems, both the ***RRF*** and ***RIF*** are greater than or equal to 1.
4. Using the baseline CDF, ***R(x)***, the Risk Increase Factor, **RIF**, and Risk Reduction Factor, **RRF**, for the relevant system or component, taking into account any adjustments for the relevant degradation rather than failure of the system, calculate the per unit time additional risk of an outage (**Δ*R***).

$$\Delta R = \left(RIF - \frac{1}{RRF} \right) R(x) \qquad \textbf{(1)}$$

5. Using failure rate data from the PSA or from other relevant data sources, estimate the summed failure rate of components in the system to estimate the outage frequency (***f***).
6. Compute d_1, d_2 and d_{min} as per equations (2), (3) and (4) below where min(x, y) is the minimum of x and y.

$$d_1 = \frac{r_c}{\Delta R} \qquad (2)$$

$$d_2 = \frac{R_c}{\Delta R f} \qquad (3)$$

$$d_{\min} = \min(d_1, d_2) \qquad (4)$$

7. Calculate the sum of the additional annual risk for each system $\boldsymbol{R_T} = \Sigma \boldsymbol{R_c}$ and if this exceeds $\boldsymbol{R_{cT}}$ then reapportion the risk and repeat.

6.2 Criteria

For the OPAL Reactor, criteria for the derivation of risk-informed completion times were determined by setting the allowed outage time for the first shutdown system to 0.5 hours. This approach, although somewhat arbitrary, was a way of obtaining a feasible completion time while still keeping the additional risk to a level about an order of magnitude lower than the full CDF.

The results were r_c = 7.94x10^{-8} (dimensionless) and R_c = 6.67x10^{-8} pa. The criterion r_c is the acceptable increased probability of a single event that continues for the full allowed completion time. The criterion R_c is the acceptable increased annual CDF frequency arising from the expected number of outage events assuming each continues for the full allowed completion time.

6.3 Systems, Subsystems and Components

Completion times were required generally for any system that helps prevent core damage (as described in the PSA) or helps mitigate consequences. For some systems, completion times were required for subsystems (rather than components). Risk Increase Factors (RIFs) and Risk Reduction Factors (RRFs) are generally only available for components – not for systems – in the current PSA (the reactor protection systems being the exceptions. However, most systems have a common cause event at the highest level (thus forming a single order cut set for that system). The RIF and RRF for such events should be precisely the RIF for the system. Similarly, the RRF for the CCF event should be a reasonable approximation for the RRF of the system.

For some systems, the completion time for a partially degraded system was required (for example, the reactor protection systems, with one channel of a particular function inoperable). A slightly different but similar approach was adopted but this is beyond the scope of this paper.

As discussed above, a slightly different approach was required for those systems that do not contribute to CDF (but have a mitigative effect if core damage were to occur). It was assumed that failure of these systems coincident with core damage would lead to releases ten times worse than with all such systems functional.

6.4 Results of the Completion Times Analyses

The results of the Completion Time derivation are shown in the table below.

Table 2 Completion times for systems and channels/trains

	Risk-Based Completion Times (hours)			
System	**by single event**	**by annual risk**	**Minimum**	**Proposed**
First Reactor Protection System	11.9	902	11.9	12
Second Reactor Protection System	2.16	288	2.16	2
First Shutdown System	0.50	0.50	0.50	0.5
Second Shutdown System	2.15	1.74	1.74	1.5
Flap Valves	5.49	1158	5.49	5
Emergency Makeup Water System	1376	2408	1376	1200
Standby Power System	1035	538	538	528
Containment Isolation	550	1080	550	528
Containment Energy Removal System	548	33	33	32
FRPS single channel	351	212	212	192
SRPS single channel	200	59.2	59.2	60
Single Flap Valve	9068	1912761	9068	1200
SPS Single Diesel	17925	15132	15132	1200
CI Single Train	8005	95532	8005	1200
CERS Single Train	6449	227	227	216

Note: The values in the "proposed" column above were derived by risk based methods with some rounding down (to nearest hour, day or week) and the reduction of very large values. As the risk criteria were set arbitrarily low, there is significant flexibility in the final values which were finalised taking into account other technical criteria and practical considerations. These values are indicative only and not to be taken as the final decision on completion times.

6.5 Test Intervals

Where generic probabilities of failure on demand were used for items in safety systems, maximum test intervals were derived by applying the unrevealed/test interval model to the probability of failure. The adoption of such test intervals would ensure that the safety systems will have the required reliability consistent with the data used for the PSA.

To calculate the test intervals, for single components and single channels the following formula was used:

$$p = \frac{\lambda\tau}{2} \qquad \textbf{(5)}$$

This makes use of the small failure rate / small test interval assumption. The equation is then solved for the test interval, τ.

$$\tau = \frac{2p}{\lambda} \qquad \textbf{(6)}$$

From the above data and equations, test intervals were found for all the relevant components.

For the First Reactor Protection System (FRPS) and Second Reactor Protection System (SRPS), because the PSA assumed a single probability of failure on demand for the system (or relevant system function), the test interval was calculated at a single channel level, assuming that a channel failure is dominated by failure of the sensor/transmitter.

$$p = 3 \cdot \left(\frac{\lambda\tau}{2}\right)^2 \text{, thus} \quad \tau = \frac{2}{\lambda} \cdot \sqrt{\frac{p}{3}} \qquad \textbf{(7)}$$

However, since any set of three instruments on a trip parameter would have all three instruments tested at the same time, the instantaneous unreliabilities of each channel are synchronised, and the average of the product of any two leads to a slightly different denominator as follows:

$$p = 3 \cdot \left(\frac{\lambda^2\tau^2}{3}\right) = (\lambda\tau)^2 \text{, thus} \quad \tau = \frac{\sqrt{p}}{\lambda} \qquad \textbf{(8)}$$

Note: For each of the FRPS and SRPS it was also conservatively assumed that only one input signal parameter (with 3 channels in 2oo3 voting configuration) is capable of the detection of a fault sequence, although in practice for many sequences more than one parameter will be capable of detecting and responding.

For the Diesel Generators, although there are three diesels, this system model was simplified to consist of two symmetrical trains. The system probability of failure on demand was derived in the PSA so the test interval was derived as follows assuming synchronised testing.

$$p = \left(\frac{\lambda^2\tau^2}{3}\right) \text{, thus} \quad \tau = \frac{\sqrt{3.p}}{\lambda} \qquad \textbf{(9)}$$

6.6 Results of Test Intervals Analyses

The results of the Test Interval Analyses are shown below.

Table 1 Test/inspection or surveillance intervals for systems and components

System	Component	Calculated Test Interval (h)	Proposed Test Interval (h)
First Reactor Protection System	Instruments	29900	13140
Second Reactor Protection System	Instruments	9550	8760

System	Component	Calculated Test Interval (h)	Proposed Test Interval (h)
First Shutdown System	Valve	533	840
	Rod	400	840
	Compressor	12000	168
Second Shutdown System	Ball valve	65100	2400
	Solenoid valve	2400	2400
Flap Valves/Siphon Breakers		870	840
Emergency Makeup Water System	Float valve	870	840
	Ball valve	4000	840
Containment Energy Removal System	Fan A	189	168
	Compressor	2200	
	Fan B	5660	168
	Pump	1330	
	Valve	294	
Containment Isolation System	Valve	12600	2400
	Solenoid valve	2410	2400
	Check valve	980	840
Standby Power System	Diesel generator	3030	840

Note: The values in the proposed column above were derived by risk based methods with some rounding down (to nearest hour, day or week) and the reduction of very large values. These were to be considered along with other technical criteria in the finalisation of the OL&C surveillance times. These values are indicative only and not to be taken as the final decision on test intervals.

7 CONCLUSIONS

A Level I PSA with some Level III considerations was conducted on the OPAL Reactor and shows that the reactor is safe and meets regulatory objectives. The PSA has been used to determine risk-based parameters for Operational Limits and Conditions and will continue as a living PSA for the assessment of modifications and other applications. This application of PSA is now standard for nuclear power plant and is becoming more common in other nuclear facilities such as research reactors. Furthermore, this application of PSA is of significant practical benefit in guiding decision makers on the appropriate values for parameters such as completion times and test intervals and can of benefit in demonstrating to regulatory bodies that these values are appropriate. Since probabilistic safety assessment, in some form or another, is becoming more common in non-nuclear facilities (such as petrochemicals and oil and gas production), it follows that there may be similar applications to operational limits and conditions in such facilities.

IMPROVING MAINTENANCE WORKFLOWS THROUGH THE USE OF ACTIVITY SAMPLING TO IDENTIFY AND REMOVE BARRIERS TO PRODUCTIVITY

Steve Berquist

Fluor Operations & Maintenance, Brisbane, Queensland 4064, Australia.

Abstract: The way we design and implement our maintenance management processes directly impacts the productivity we can achieve from our maintenance workforce. Activity sampling is a method that can be used to directly measure the direct utilisation achieved in the field by the craft labour and more importantly help identify the delays and support activities that are preventing craft from "getting on with the job". This information is used to target specific changes that will remove barriers to improving both wrench time and overall maintenance workforce productivity. Benefits include reduced cost and increased plant uptime. This paper discusses the elements that make up overall craft productivity and describes Australian experience in the application of activity sampling in the heavy industrial maintenance environment in both union and non union workplaces.

Key Words: activity sampling, wrench time, workforce productivity, maintenance workflow

1 INTRODUCTION

One of the accountabilities of maintenance and asset management professionals is the identification of what is the right work to be done in order to achieve the business objectives from the physical assets under management. Once the "what" has been established it then becomes necessary to establish the "how"? This is sometimes expressed as …..doing the right things and then doing those things right. The maintenance workforce is usually one of the larger groups at a plant that are expected to do these things right and attracts considerable supervision and management attention when this is not believed to be the case.

In Australia today, as in may other places in the world, the availability of skilled maintenance personnel is insufficient to match the demand for these resources in the market. Many asset owners, and contract service providers, are finding that their ability to grow their business is being restricted by the availability of skilled personnel, and the ability to leverage their workforce to support increased production output. It was reported by the Reserve Bank of Australia [1] recently that, for the first time in the history of NAB business surveys in Australia, the most popular response to the question of what factors are significantly constraining their output was 'lack of suitable labour' and not 'sales and orders'.

Accompanying this reporting of high levels of labour scarcity is the current strong Australian labour market with unemployment rates down from a peak of nearly 11 per cent in 1993 to an average of just over 5 per cent in 2005. State-wide shortages are reported in the engineering trades including metal fitters, electricians, electrical powerline trades and welders in New South Wales, Victoria, Queensland, Western Australia and others [2]. These are skills that are required in significant numbers to maintain and improve the heavy industrial assets of many businesses in this country.

In addition to a shortage of maintenance and construction personnel to support growth there is the relentless pressure on plant managers to remain in business by operating their assets at a competitive unit cost position in the global market place. Companies who can not reliably produce their product at a competitive unit cost eventually go out of business. The cost of maintenance is usually a significant contributor to the unit cost of production. It typically ranges from less than 3 per cent to more than 8 per cent of sales revenue [3] depending on the industry and much management attention is applied to reducing, or in more enlightened companies optimising, this cost.

Labour makes up a significant component of the cost of maintenance and this paper describes an approach to assisting maintenance workforces increase their productivity and thereby accomplish either the same quanitity of the "right" work for less labour cost or alternatively achieve more work for the same labour cost. Another benefit to businesses, often far exceeding the labour cost benefit of improved maintenance productivity, is the increased revenue due to less plant down time to achieve a given work scope. This is especially important during plant shutdowns or turnarounds when major sections of a plants productive capacity are taken off-line for several weeks or months. Significant revenue benefits can be achieved if the duration of the shutdown can be reduced, with revenues in the millions of dollars per day not uncommon. Conversley significant contractual penalties can be incurred if planned shutdown durations are exceeded. Finally, if labour is in scarce supply then it becomes even more of an imperative to maximise the work that is achieved from the workforce that one already has.

2 CRAFT PRODUCTIVITY

There are three basic elements that together define overall workforce craft productivity. These are

a) Direct Utilisation: the percent of time that craftspeople are performing direct work i.e. wrench time

b) Direct Productivity: the actual units of work completed per unit time expressed as a percentage of a defined standard for that work

c) Rework: the percentage of work performed that must be redone to correct errors

When these three elements are combined together craft productivity becomes an overall measure of the amount of labour required to perform direct work compared to that required to perform the same direct work without any losses in efficiency or effectiveness. It is the amount of work that actually gets done per paid hour.

$$= \quad \times \quad \times (\quad - \quad)$$

where: DU = direct utilisation DP = direct productivity RW = rework

Each of the three elements defined above will be examined in more detail below.

2.1 Direct Utilisation

Direct utilisation is the ratio of actual direct activity measured to the target direct activity for our workforce. It indicates how our actual direct activity compares to our desired direct activity. Fluor sets 50 per cent as the direct activity target for a maintenance workforce.

The formula to calculate direct utilisation is below.

$$= \frac{\quad}{\quad}$$

Direct activity is the percentage of time that a maintenance technician spends on activities that are directly advancing the execution of a maintenance task. This is often referred to as “wrench time”, loosely illustrating that the technician actually has a “wrench” in hand performing direct activity advancing the job towards completion i.e. welding, grinding, painting, bolting, measuring, fitting, rigging etc. Conversely, indirect activities are those things that are not directly advancing the job. If these activities could be reduced or eliminated, more time would be spent by the maintenance technician “on the job”. Some examples of indirect activities are travel to and from the job, waiting for instructions, waiting for permits, waiting for materials, getting materials from the store, planning the job before starting to work, taking rest breaks and meal breaks.

While not all types of indirect activities are undesirable it is important to acknowledge that this category of activity exists. When measures are taken to reduce the amount of time in the day a technician spends on indirect activity it will create the opportunity for more direct activity and hence for more work to be accomplished.

Fluor, in Australia, finds organisations that have not implemented best practices for maintenance planning and scheduling typically have direct activity in the 20 per cent to 30 per cent range. World class performance can result in direct activity of 50 per cent or more.

A measured direct activity (wrench time) of 30 percent equals 60 per cent direct utilisation i.e. the maintenance work processes on site are resulting in people working at only 60% of the Fluor target for direct activity i.e

$$= \frac{\quad}{\quad}$$

2.2 Direct Productivity

This is the percentage of time actually taken to perform a task versus the standard time established for that task. Standard times are established for tasks based on the time an average skilled technician will take to do the job working at normal pace using a prescribed method without breaks. Standards are more likely to have been established by planners for frequently recurring maintenance tasks than for other types of work. Where standards do not exist it is possible to simply use the estimated time assigned by the planner for the task as a benchmark for direct productivity calculations.

The Gulf Coast of Texas is a well know benchmark used by construction industry estimators for comparing labour productivity in other locations to that experienced from workers on the Gulf Coast. Once the productivity factor is known, labour estimates can be then be factored for other locations of the world.

2.3 Rework

This is the percentage of craft labour that is required to perform a task a second time because of errors with the performance of the task the first time. Rework has many causes and is usually a topic of heated debate at all levels in the maintenance organisation. Few organisations measure and record rework.

It is possible to use a computerised maintenance management system to check for occurrences of repeat maintenance intervention on equipment within a defined time period (often one month is selected) from the last work order being completed. This can be used as a rework metric as follows

$$= \frac{Total\ Hours\ of\ Repeat\ Maintenance\ Intervention\ Work}{Total\ Maintenance\ Hours\ Worked}$$

The target for rework is zero. The measurement of rework generates focus on this problem and will immediately result in the desire to categorise the causes for this loss. Causes include faulty materials, poor procedures, lack of training, lack of time, rushing the job, inadequate supervision or incorrect work scope. Once the causes are understood corrective actions can be taken.

3 DRIVERS OF CRAFT PRODUCTIVITY

Craft productivity is a lagging indicator of the effectiveness of the maintenance management processes implemented at a plant. Where plant management has developed and implemented effective integrated work processes, together with providing effective training, supervision, motivation and support to the workforce, craft productivity will be significantly higher than where these factors are absent. Examples of processes that have a significant impact on craft productivity include

- planning
- scheduling
- permit to work
- materials management
- contractor management
- shift handover
- site logistics
- job safety
- technical support

The challenge to craft productivity improvement is to first measure what the current level of productivity is and then to identify what current barriers exist preventing productivity from increasing. In Fluor's experience, the craft workforce understands what the barriers are that hinder them from "getting on with the job". If asked they will tell you. Most barriers are sources of frustration to the workforce and they will gladly point out what should be changed! It is management's responsibility to listen and take those actions necessary to address barriers in a prioritised manner.

4 ACTIVITY SAMPLING

Activity sampling is the process of measuring an activity of a population by the acquisition of sufficient random samples to make a statistically valid conclusion about that activity for the entire population. Activity sampling, often called work sampling, is a recognised industrial engineering process and has been used by Fluor for over 20 years to measure the labour productivity of its construction workforces and for more than 15 years for maintenance workforces.

The activity sampling process is one where an observer makes a snapshot observation of a person or group of people, records the observation immediately and briskly moves on until the next observation is made. Observations are made by walking a pre-determined route around the plant. Each observation should take no longer than a few seconds to capture. The workers being observed are not subject to continuous surveillance, so are more accepting of this style of observation than if they were placed under constant observation.

Activity sampling is a practical alternative to the continuous observation method, sometimes known as time and motion studies, where a person's activity is observed continuously over a period of time. The continuous observation of a person is usually unwelcome in most workplaces in Australasia and will quickly lead to objections from the workforce and an immediate change in their normal behaviour. Industrial action is a strong possibility in many Australian workplaces if a workforce is subjected to a continuous observation process. An exception to this is direct observation performed as part of a safe work observation process where the objective is to improve people's safety at work.

4.1 Categorisation of Work

The three major categories of work used in work sampling of a maintenance workforce are Direct Activity, Support Activity and Delays. These are defined as follows:

a) Direct Activity: Performing those elements of a task that directly advance its completion. Examples include:

- Working with tool in hand
- Measuring up prior to cutting
- Using a test instrument
- Directing a crane lift
- Operating a forklift
- Erecting a scaffold

b) Support Activity: Performing those elements of a task that indirectly advance its completion. Examples include:

- Travel to get/with equipment
- Travel to get/with materials
- Planning on the job
- General travel
- Checking/receiving a work permit
- Daily tool box meeting

c) Delays: Periods of lost time that prevent Direct or Support work. Examples include:

- Waiting for a work mate
- Waiting for a vehicle
- Waiting for materials
- Waiting for instructions
- Waiting for a permit
- Taking a smoke break

The immediate work area is defined as being with 3 to 4 metres of the task. Most activity occurring in the immediate work area is considered direct unless it is a delay. For example moving with materials in the immediate work area is a direct activity, whereas moving with materials outside the work area is a support activity and it could be questioned why the journey was necessary.

Support activity and delays are losses that reduce direct activity in the field. These losses can be considered as one or other of following:

- Inherent Losses: These are the minimum requirements of time related to travel and logistics assuming pre-planning and preparations for work is complete and without errors e.g. the need to travel from the workshop out to the job site at the start of the day or the need to travel to and from the lunch room.
- Planning Losses: These are all other time requirements beyond direct utilisation and inherent losses e.g. the need to return to the store from the job site to get spare parts that were not identified on the job plan as being required or the need to wait until another crew moves out of the way before starting on a new job.

Inherent losses will occur even with the best planning and these activities can never be eliminated, only minimised. Planning losses are activities that are possible to eliminate given better planning. The aim of the maintenance activity sampling study is to increase craft productivity by reduction of the inherent and the planning losses.

4.2 Statistical Basis of Activity Sampling

The statistical basis of activity sampling requires sampling performed in an unbiased way. Randomisation is used to eliminate bias. Examples of the factors to be randomised include; starting time for each sampling activity, direction of movement along each sampling route and the location for starting the sampling along each route. Because the very act of taking an observation can change the behaviour of the population being sampled it is important to take enough samples over a number of days to ensure the final results are truly representative of the population's actual direct activity.

Using the assumption that a population's direct activity follows a normal distribution, the formula used to solve for the minimum number of required sample observations is [4]:

$$n = \frac{z^2 p^\wedge (1 - p^\wedge)}{E^2}$$

where: n = number of sample observations required

z = standardised normal random variable corresponding to the level of confidence in result i.e. z = 1.96 for a 95% confidence level in our result.

$p^\wedge$ = an estimate of the populations proportion i.e. estimate of the direct activity expected

E = one half of the total precision range (error) acceptable i.e. E = +/- 0.025 for a 5% error

The variable $\hat{p}$ is usually estimated prior to sampling at a value of 0.5 i.e. 50 percent direct activity.

Utilising the values suggested above, a total of n = 1537 observations must be made of either the total workforce, a plant area or a workgroup, in order to be 95 percent confident that the direct activity sampled does in fact correspond to that of the workforce population being sampled with a precision range (error) of 5% i.e. +/-2.5% .

If the actual direct activity $\hat{p}$ for the workforce is found to fall above or below 0.5 during the course of the sampling period, the minimum value for n can be adjusted by iteratively calculating its value as the workforce $\hat{p}$ is sampled.

4.3 Route Design

The design of the routes used for activity sampling of a maintenance workforce requires consideration of the following factors

- The sites overall layout. The larger the site (horizontal and vertical) the more routes will be required.
- The expected location of maintenance workers around the site – plant areas, office buildings, workshops, stores and break areas. The routes combined need to cover 90 percent to 110 percent of the workforce each time the plant is walked. Some people may miss being observed, others may be observed twice.
- The presence of hazards on site and the ability for observers to remain safe while on their route. Some areas may need to be excluded from a route e.g. electrical switch rooms, confined spaces etc.
- The number of observers available to assign. The fewer observers then the fewer routes are possible.
- The location of, and activity on, main thoroughfares and roads. May require splitting across several routes.
- Each route to take a similar time to cover

4.4 Route Schedules

The schedule for covering the plant is developed based on the following

- The shift work pattern to be sampled i.e. day work only, 24 hour shift, weekdays only etc.
- The start and finish time for the shifts being covered.
- Random starting times for each round of routes. All routes walked together starting at the same time.
- The timing of the allowed breaks taken by the workforce i.e. tea breaks and lunchtime.
- The direction the route will be walked i.e. forwards or reverse direction
- The start position along the route that the route will be walked from. Route can be started from a mid point, start or finish location.
- The time taken to walk the route. The longer it takes the fewer routes can be scheduled per day.

The aim is to have sufficient routes walked per day to collect the required number of observations over shortest number of days commensurate with covering the shift patterns of the workforce being studied. For example it might be required to cover every day of the week and every hour of the day between 7am and 7pm when studying a maintenance workforce that works days only but has coverage on site every day of the week. If there are a significant number of maintenance people working night shift then it may be an objective of the study to sample nightshift work also.

Once the routes have been designed and the schedule established it is necessary to then prepare both the workforce and the observer team for the work sampling to commence.

5 CRITICAL PREPARATION FOR SUCCESSFUL ACTIVITY SAMPLING

There is significant preparatory work required in order to ensure activity sampling can be performed successfully in a heavy industrial workplace. The key activities required to ensure success are discussed briefly below.

5.1 Management Commitment and Alignment

Unless the plants site management are committed to improving craft productivity and clearly understand how the activity sampling process will contribute to that goal, the probability of success will be reduced. It is management that will be required to release personnel to participate in the activity sampling team and to support the team through assisting to eliminate barriers that can arise during the course of the activity sampling process. Common barriers are those associated with releasing personnel from normal duties and implementing visual identification to enable various work groups to be accurately identified by the observers.

5.2 Communication

It is critical that the workforce being sampled is engaged and supportive of the sampling process. Fluor's experience is that Australian workforces are generally accepting of most initiatives genuinely aimed at improving their workplace experience. This includes anything that will make it easier for them to "get on with the job". The identification and elimination of barriers to getting work done is usually welcomed and the workforce views the activity sampling exercise as an opportunity to validate with management their previously expressed views and ideas for improving the workplace.

Fluor communicates the activity sampling process to the workforce either through a presentation direct to the workforce or to representatives of the workforce. The presentation explains the benefits the workforce can typically expect from implementing solutions to its findings. Concerns that the workforce commonly have are reduced through the following means.

- Request workforce representation on the observation team.
- Advice that supervisors are not included in the observation team.
- Advice that people's names are not recorded and also that the job observed is not recorded.
- Advice that full training is provided to all observers.
- Make all observation record sheets available to the workforce to review at any time. Invite them to look immediately after making an observation in the field especially during the first few observation rounds.
- Advice that a closeout presentation will be provided to the workforce and their input sought in improvement planning.
- Advice that the opportunity exists to identify to management current barriers to improving productivity e.g. tools, vehicles, workshops, stores etc.

5.3 Observer Team

The observer team must be fully trained in order to ensure that accurate observations are made and that there is no inherent bias in the observation process. It is the responsibility of the activity sampling team leader to identify and correct individual observers who are making suspect observations. The observer training must include the following:

- An understanding of the three elements of craft productivity.
- The ability to identify and categorise members of each of the workgroups included in the study
- The ability to identify direct activity from the various categories of delay activities and support activities.
- The ability to question people respectfully in order to correctly categorise the activity first observed.
- The ability to identify the reason why delay or support activities observed are occurring.
- Knowledge of each route that is to be walked.
- A test to confirm that each student has been successfully trained.
- Field practice, to confirm to the leader that each team member is ready to deploy.

The observers may operate in the field either singly or in pairs depending on numbers available. More than two people is not advisable as it makes the observers too conspicuous and therefore enables people to change their behaviour when the observers approach. The advantage of working in pairs is that observer safety is enhanced out in the plant and that discussion on observations and reasons for the activities observed can be held. It also helps maintain observer motivation and allows observers to swap partners occasionally.

5.4 Diagnostics

It is critical that observers are able to not just correctly categorise and record the work activity observed but to also attempt to determine the cause of the activity that was observed, where it is not readily obvious. By asking the people what caused the need to travel to the store or what resulted in the delay while they wait for a colleague to return from the workshop with a tool, it becomes possible to begin to identify where the work processes used on site are failing to support craft productivity. If all that results from an activity sampling study are values for percent direct activity and percentages of delay and support activities, much of the value of the exercise is lost. Activity sampling of a maintenance workforce should provide actionable information that will help drive improvement in craft productivity, not simply state what the current wrench time is.

6 AUSTRALIAN EXPERIENCE APPLYING ACTIVITY SAMPLING

The authors company, Fluor, has successfully implemented labour activity sampling of maintenance workforces in three states of Australia during the past year – Western Australia, Victoria and Queensland. These workplaces include workforces employed under the following industrial instruments; Australian Workplace Agreements (non union collective agreement), Enterprise Bargaining Agreements (union collective agreement) and Individual Contracts of Employment (common law contract).

As stated earlier in this paper the key to acceptance of the workforce in each case to the application of the activity sampling methodology has been the genuine commitment of management to improving the workplace experience of maintainers through the elimination of those frustrating barriers and delays experienced by people every day. When the workforce understand and accept that the process is not about headcount reduction but rather about improving the maintenance workflow process they are usually willing to accept it and contribute as members of the activity sampling team.

In the authors experience the workforce sees the activity sampling process as providing them opportunities to be heard by management and to prove through the collection of hard data that the problems they have been complaining about for years are real issues that management should address. This objective aligns with management's objective to improve craft productivity enabling more direct work to be accomplished (maintenance work and/or improvement work) by the workforce. Business benefits include reducing the maintenance backlog, reducing the amount of overtime required, reducing the requirement for contractor labour, improved equipment reliability through improved preventive maintenance program compliance and the ability to release craft from the tools to work on improvement projects e.g. RCFA team participation, review of PM's, review of BOM's etc.

At all times it is necessary to acknowledge to both the workforce being asked to undergo the observation of their work activity and to their supervision, that the activity sampling process is somewhat of an intrusion into their privacy, that their patience and tolerance of having people somewhat "interrogate" them over what they are doing is appreciated and that the observations will come to an end shortly. The supervisors are often more concerned than the maintenance workforce because the results may reflect unfavourably upon their supervisory performance.

Fluor's experience in Australia includes successful introduction of labour activity sampling to our client's own in-house craft employees, Fluor's own craft employees and other contractor's employees. Both permanent (full-time) and casual (temporary hire) employees have been successfully engaged. Regardless of employer, it is important to include all craft in the communication process.

7 SOME AUSTRALIAN MAINTENANCE RESULTS

Table 1 contains examples of results of labour activity sampling of maintenance from three Australian worksites

Table 1

Summary results from three Australian workplaces

Site	Industry	State	Direct activity %	Support activity %	Delays %
1	Mining/Mineral Processing	Western Australia	33.9	31.8	34.3
2	Power	Victoria	27.6	32.1	40.3
3	Mineral Processing	Queensland	25.5	40.1	34.4

These results are typical of sites where best practice maintenance work processes have not been implemented. It is clear that the direct activity measured is significantly lower than the target of 50 per cent. The opportunity exists in all these sites to reduce time spent by the craft workforces on delay and support activities and increase time spent in direct activity. Figure 1 below illustrates this potential.

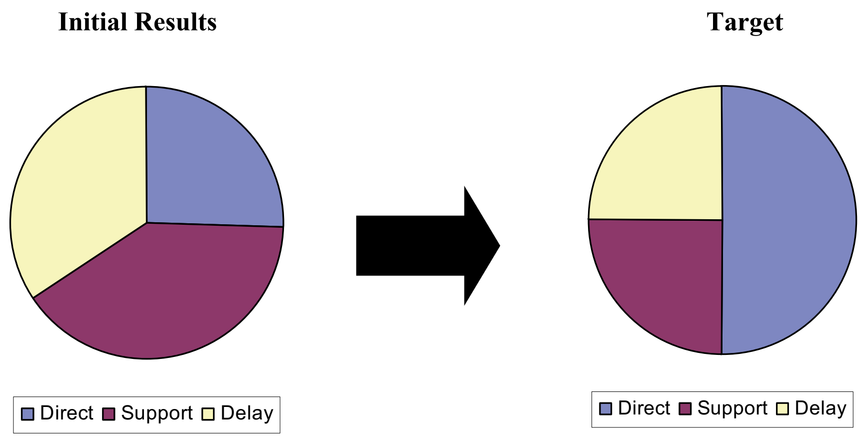

Figure 1: Typical activity sampling results and comparison to best practice targets.

As an example, if the direct activity of site 3 can be increased from 25.5 per cent to the target of 50 per cent, that workforce could achieve double the maintenance workload that it previously was capable of. This improvement would only occur following changes successfully implemented to address the causes of the excessive delay and support activities measured.

Figure 2 below shows the major causes of the delays and support activities measured at one of the three Australian sites listed in Table 1.

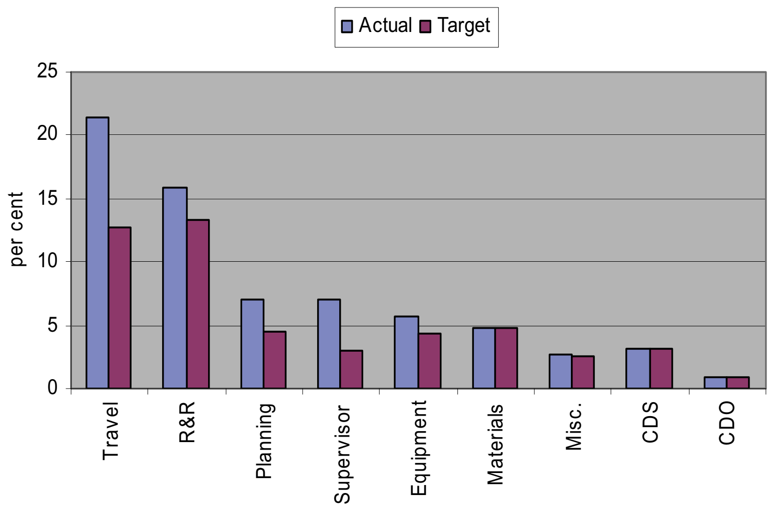

Figure 2: Graph of major reasons for losses in direct activity for an example Australian maintenance site.

The graph shows that the biggest opportunities at this site lie with reducing the time spent on general travel around the site, in this case from 21.4 per cent down to 12.7 percent. The second largest opportunity lies in reducing the time spent on supervisory related delays from 7 per cent down to 3 per cent. Planning is the third area of opportunity for this site where craft spend time on planning related activities that should have been performed by others.

It is the task of the activity sampling team to identify the gaps between measured activities and best practice targets for each activity. Fluor uses its experience from over 20 years of performing activity sampling on both maintenance and construction sites to establish achievable targets that can be met through the application of best practices in each loss category.

Other forms of analysis performed that provide additional insight into the causes of losses in direct activity are the review of results by any of the following; shift, day, hour, crew, route, plant area, contractor or trade. When subsequent studies are performed it is also possible to compare results by time of year to assess the impact of climatic conditions on direct activity.

7.1 Improvement Planning

Improvement planning is the next step following on from the establishment of the current situation by conducting an activity sampling study. Improvement planning is most effective when the craft workforce is included in the planning process. Maintenance best practices in each of the key loss categories must be identified and utilised by the improvement planning team in the redesign and planning for implementation of changed work practices in order to significantly improve direct activity to sustainable target levels.

7.2 Implementation

Sustainable improvement only occurs after changes are made to the work processes in place at the time of the initial activity sampling study. There may be an initial improvement in direct activity simply through drawing the workforce's attention to the fact that the current wrench time is low and what some of the major causes of losses are. For example, there may be an initial improvement in some areas such as early stop and late start to work around scheduled breaks. Unless there are changes to things such as the way work is allocated to individuals or the way craft are briefed by supervision any initial improvement will soon be lost.

Table 2 shows an example of the improvements made by an Australia craft workforce through the design, planning and implementation of a wide range of maintenance best practices. The results are shown for three cycles of activity sampling studies over a period of 12 months.

Table 2

Summary results from three cycles of maintenance labour activity sampling over a 12 month period

	June 2004	April 2005	July 2005
Direct activity %	33.4	36.4	41.4
Support activity %	30.8	29.6	29.2
Delays %	35.8	34.0	29.4

8 CONCLUSION

Activity sampling of maintenance work is an effective method for establishing the level of craft direct utilisation or wrench time. Direct utilisation is one of the three elements of overall craft productivity, the others being direct productivity and rework.

Activity sampling has been successfully applied by Fluor in maintenance workplaces in heavy industries around the world including three states in Australia. It has been acceptable to both union and non union craft employees when communicated well and when supported by management's commitment to remove the barriers and frustration that get in the way of craft simply getting on with the job.

Improvement in direct utilisation will occur when the gaps between best practice and current practice are identified in a number of maintenance areas identified from the activity sampling as the main causes of loss in direct productivity. The craft workforce must be included in the improvement planning process.

Abstract: More often in the world, in many applications, composite materials replace traditionally applied materials like steel, aluminium alloys etc. Especially they have an application when the product must be light and should have specific mechanical and dynamic features, important for the sake of place of application and type of work. One of this application is the mast of high-performance sail boat. Applied materials in process of its production are expensive, and technology and process engineering are complicated and time-consuming. Mast, for the sake of characteristic kind of work and because it is very important constructional element, should have very big reliability. Other important thing is ability to early defect detection of reinforcement structure at the stage of production and then in the middle of operational use. This ability has large influence on safety of deck crew. One of the most often and invisible defect is enlarging of holes around rivets and bolts fasten mounting elements of rigging caused by strong dynamic overloads. In this paper Authors made an attempt to finding this kind of defects by vibroacoustic techniques and try to determine proper symptoms. Authors postulate that change of hole diameter should change dynamic response (transmittance) of a system on dynamic coercion.

Keywords: carbon fibre composite mast, dynamic response, coherence function.

1 INTRODUCTION

In the contemporary world in many different areas composite materials replace those traditionally used: steel, aluminium, etc. It happens especially when the product should possess small mass together with particular mechanic and dynamic characteristics, important because of its position and character of work. One of such applications is the mast of a sport sailing boat. The materials it is produced of (e.g. carbon and Kevlar fibres) are expensive, while technologies of production applied tend to be complex and time-consuming, and consequently expensive as well.

The life-span of the modern rigging of racing yachts, which is designed with minimum safety factors, is necessarily limited. The technology of rigging fastening itself results in local brakes of reinforcing fibers, or the basic supporting structure, in spite of variety of reinforcing and stiffening solutions applied; all these results in important construction difficulties. Enlarging mast's openings are one of the principal, invisible damages, followed by delamination around bolts and pivots of fittings. The first structural degradation of the composite (e.g. delamination) happens already during its mechanical processing. It influences further development of the composite's delamination, finally resulting in lost of its mechanical characteristics, happening even earlier that it would be forecasted taking the analyses of tolerable stress. Initially, it is only a phenomenon of local dimension but in consequence it results in weakening the whole structure of the construction. Nowadays both monitoring and detecting damages of the composite, as well as identifying its state is carried out applying non-destructive methods, mainly roentgen graphic and ultrasonic ones, and only recently some tests using vibroacoustic diagnosing have been done.

The vibroacoustic method has the advantage of allowing localization of any discontinuities existing inside of the material (it is clearly visible in the pictures of samples: darker spots between openings). The roentgen graphic method is limited only to the immediate surroundings of openings and edges. However, it is much more accurate (to achieve approximately similar resolution in ultrasonic scanning, it would have to take a very long time: assuming a step of 0.1mm scanning of one sample would take about 75 hours (let's note that the resolution of film is higher anyway).

The fact that correct diagnosing is possible using both methods doesn't change the truth that these are only laboratory methods that can not be applied directly to an object. Therefore, the aim of the Authors' studies was to answer the question whether it is possible to find a simple vibroacoustic symptom sensible to the increase of discontinuity of the composite structure.

2 BRIEF THEORETICAL EXPLANATION

The vibration analysis of composite masts of non-circular section has been treated by authors [5,6]. The analysis clearly show, as it has been expected, that even with the small amplitudes the non-linear effects of the system can be detected.

However, in spite of all the work done in this area of studies, there is still no mathematic (digital or analytical) model available, accurate enough as to let the analysis of form variation of vibrations accompanying propagation of a small structural damage. On the other hand, we know that the initial stages of damages are so soft in terms of energy that in practice we are not able to observe any change in general vibration level. In these circumstances the only thong to do is to make use of he fact that the proportion of damage changes the non-linear disturbances in a system. In [6] the authors applying the analysis of non-linear differential equations have shown that slightly non-linear disturbances can be observed in spectral characteristics of the system even though the medium value of spectrum (general vibration level) does not change. The persisting problem consists of searching for measures that would be sensible to this type of disturbances. One of them is the function of common coherence (the condition is that the system of analysis should be of appropriate accuracy). Let us consider a simple model shown in the picture 1.

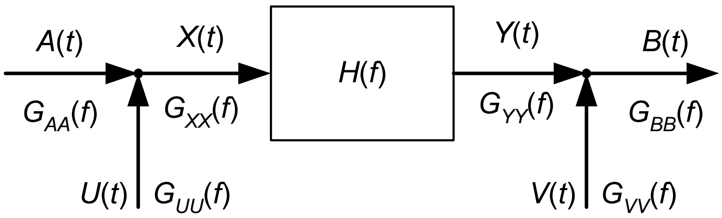

Figure 1. Model of the analyzed system.

When the input $U(t)$ and output $V(t)$ disturbances equal 0, the transmittance values are deduced from the generally known relationships

$$H_1(f) = \frac{G_{AB}(f)}{G_{AA}(f)} \qquad (1)$$

$$H_2(f) = \frac{G_{BB}(f)}{G_{BA}(f)} \qquad (2)$$

here:

$G_{AA}(f) = \left(G_{AA\,\mathrm{RMS}}(f)\right)^2$	averaging power spectrum of the input signal,
$G_{BB}(f) = \left(G_{BB\,\mathrm{RMS}}(f)\right)^2$	averaging power spectrum of the response signal,
$G_{AB}(f)$	averaging mutual spectrum of the signal at the system's input and output (the spectrum correlated with $G_{BA}(f)$),
$G_{BA}(f)$	averaging mutual spectrum of the signal at the system's input and output (the spectrum correlated with $G_{AB}(f)$).
$G_{UU}(f)$	averaging power spectrum of the input disturbance,
$G_{VV}(f)$	averaging power spectrum of the output disturbance,
$G_{XX}(f)$	averaging power spectrum of the non-disturbed input signal,
$G_{YY}(f)$	averaging power spectrum of the non-disturbed output signal.

They meet the condition without disturbances:

$$H_1(f) = H_2(f) \qquad (3)$$

and function of ordinary coherence equal 1:

$$\gamma_{AB}{}^{2}(f)=\frac{H_1(f)}{H_2(f)}=1 \tag{4}$$

When disturbances appear both at the input and output, the relationship ( ) can be brought to the following form:

$$\gamma_{AB}{}^{2}(f)=\frac{\gamma_{XY}{}^{2}(f)}{1+G_{UU}(f)/G_{AA}(f)+G_{VV}(f)/G_{BB}(f)+G_{UU}(f)/G_{AA}\cdot G_{VV}(f)/(f)G_{BB}(f)} \tag{5}$$

On many occasions we can assume that a non-linear system works in the same way a linear one does, when both kinds of disturbances are present, so we can bring the formula to the following form [4]:

$$\gamma_{AB}{}^{2}(f)=\frac{\gamma_{XY}{}^{2}(f)}{1+\Delta(f)}=\frac{H_1(f)}{H_2(f)}\cdot\frac{1}{1+\Delta(f)} \tag{6}$$

where $\Delta(f)$ is the correction coefficient of coherence function on account of slightly non-linear disturbances. If we assume in diagnostic applications that each state comes accompanied by different disturbance, the coefficient $\Delta(f)$ becomes a natural state parameter, and subsequently, according to the relationships (1) and (2) both transmittances (H_1 and H_2) can be such a parameter in certain frequency bands. We decided to check experimentally whether the same effect can be observed for the propagation of damage in a composite mast.

3 EXPERIMENTAL RESEARCH

Let us follow the experiment aiming at finding a way of reproducing diameter of the opening in form of vibration signal. Although it is a laboratory experiment, translating its results into a real object is relatively simple.

The measurement set used in the test (Figure 2) consisted of the following elements (all produced by Brüel&Kjaer):

- a impact hammer B&K8202 equipped with force sensor B&K8200 – used for impulse forcing of vibrations of the studied mast together with input measuring,
- piezoelectric accelerometer B&K4284 – sensor used for measuring a response for impulse input,
- preamplifier B&K2692 „Nexus" – a device adjusting the signal level to the parameters of analyzer's input,
- dual channel analyzer B&K2034 – principal element of the system, used for recording and analyzing measurement signals.

Figure 2. Elements of the measurement set.

It was assumed that positions of the vibrations sensor and the impact point of hammer should be located on the opposite ends of the studied element. The preliminary tests were done for samples of composite masts, each about 1.1 m long, with centrally situated openings (symmetrically at both sides of the mast). Positions of the accelerometer and the impact point of hammer (distance about 1 m) relative to the openings are shown in the figure 3.

The preliminary tests consisted in searching for symptoms that could point to changes of diameter of the openings in the sample of composite mast. Four measurement series for various states were made:

- for the undamaged sample,
- for the sample with an opening ø10mm approximately in the middle of the beam, on its side marked by the axis *y*,
- for the sample with two openings ø10mm approximately in the middle of the beam, on its sides marked by the axis *y* and *v*,
- for the sample with two openings ø14mm approximately in the middle of the beam, on its side marked by the axis *y* and *v*.

side marked by the axis y and v.

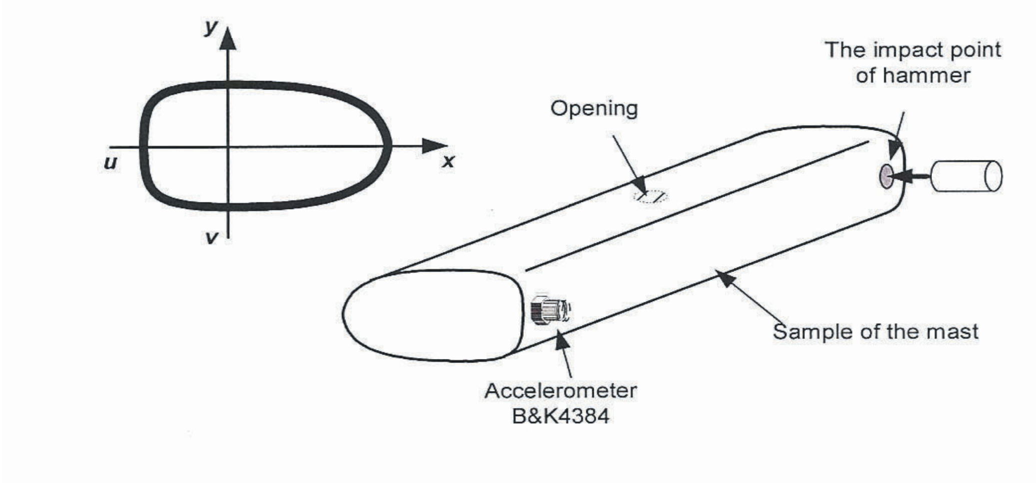

Figure 3. Positions of the accelerometer and the impact point of hammer.

Preliminary measurements and analysis of the results were carried out for several positions of the accelerometer (*u, y, v*) and the impact point of hammer (*y, u*) for three frequency ranges:

- 1600 Hz (resolution 2 Hz),
- 3200 Hz (resolution 4 Hz),
- 6400 Hz (resolution 8 Hz).

For further analyzing the frequency range of 3200 Hz was chosen, combined with positioning the vibration sensor and the impact point of hammer in axis y and u. Using the given characteristic of the coherence function which permits to define linearity or non-linearity of the system's response, the following frequency ranges were singled out in the analyzed functions:

- dominating response of linear part of the system (up to 900 Hz),
- appearing response of non-liner part of the system (above 900 Hz).

The figure 4 shows way of fixing the accelerometer to the tested samples.

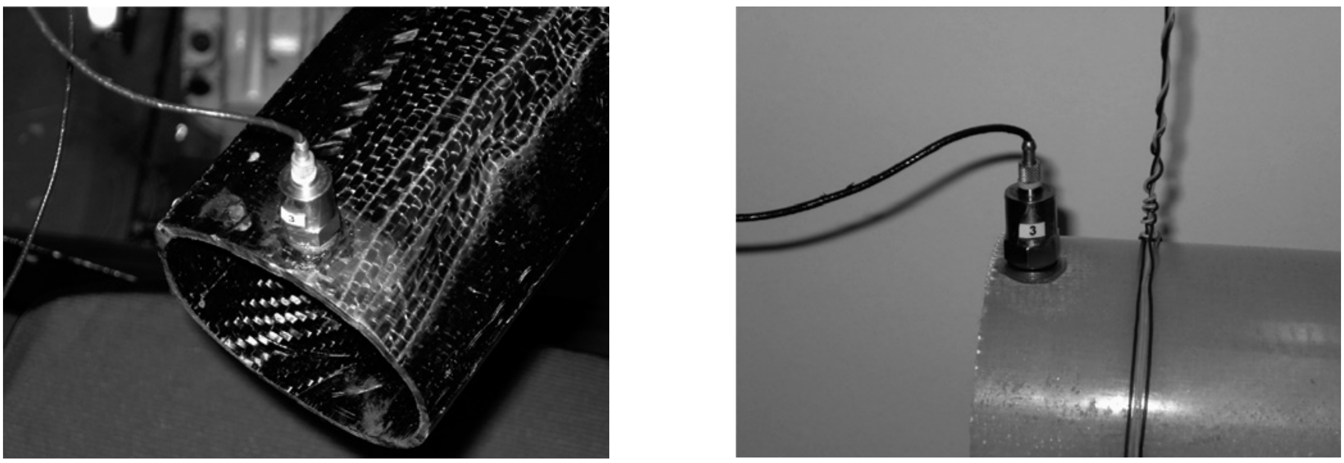

Figure 4. Fixing of the vibrations acceleration sensors.

4 ANALYSIS OF THE RESULTS

It seems obvious that for such a type of construction, strongly anizotropic, symptoms of the induced changes (damages) should be searched in the range of non-linear response of the system. In our case the following functions were registered within the capacity of the analyzer B&K2034:

- averaging spectrum of RMS values of input (force of impact of percussion hammer) G_{AA} RMS (f),
- averaging spectrum of RMS values of the system responses (vibrations acceleration at opposite side of the sample) G_{BB} RMS (f),
- frequency response of the system, admitting disturbances of the input signal $H_1(f)$
- frequency response of the system, admitting disturbances of the input signal $H_2(f)$
- coherence function between the input signal and the output signal $\gamma^2_{AB}(f)$.

All the functions serve in general for analyzing non-linear systems (or linear responses of non-linear systems). Some examples of the results of analysis are shown in the figure 5.

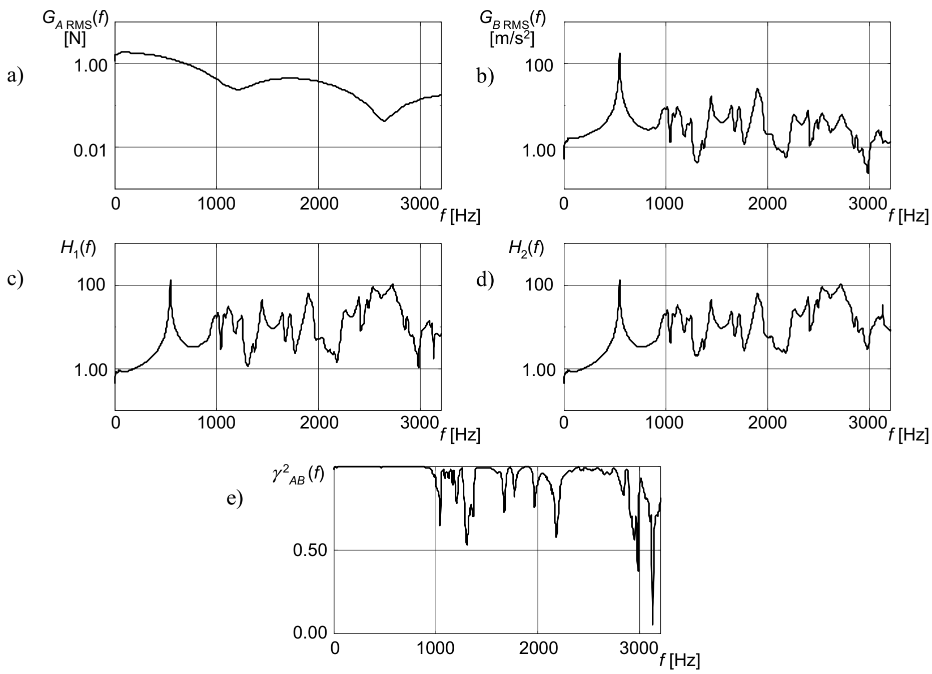

Figure 5. Visualization of measurement results (an example): a) averaging RMS spectrum of input, b) averaging RMS spectrum of responses of the system, c) frequency response of the system H_1,d) frequency response of the system H_2, e) coherence function γ^2_{AB}.

As in the tested system there are no signal disturbances at input and output of the system, the transmitantion H_1 should equal the transmitantion H_2. Therefore an ideal case should consist of a system, where coherence function between a signal originated in the source and the output signal is equal. It can be observed that value of the coherence function shown in the figure 5e is smaller than one within considerable frequency range. We should then consider reasons of such a situation. With no exterior disturbances, lack of feedbacks between the recorded signals and relatively high accuracy of measurement, the only reason seems to be non-linearity of the tested element [2, 3].

The figure 6 shows the ordinary coherence function between the input (the impulse of force coming from the hammer) and the system response (signal recorded using the accelerometer) for subsequent trials, while the figure 7 shows changes of transmitantion (system amplification factor) H_1.

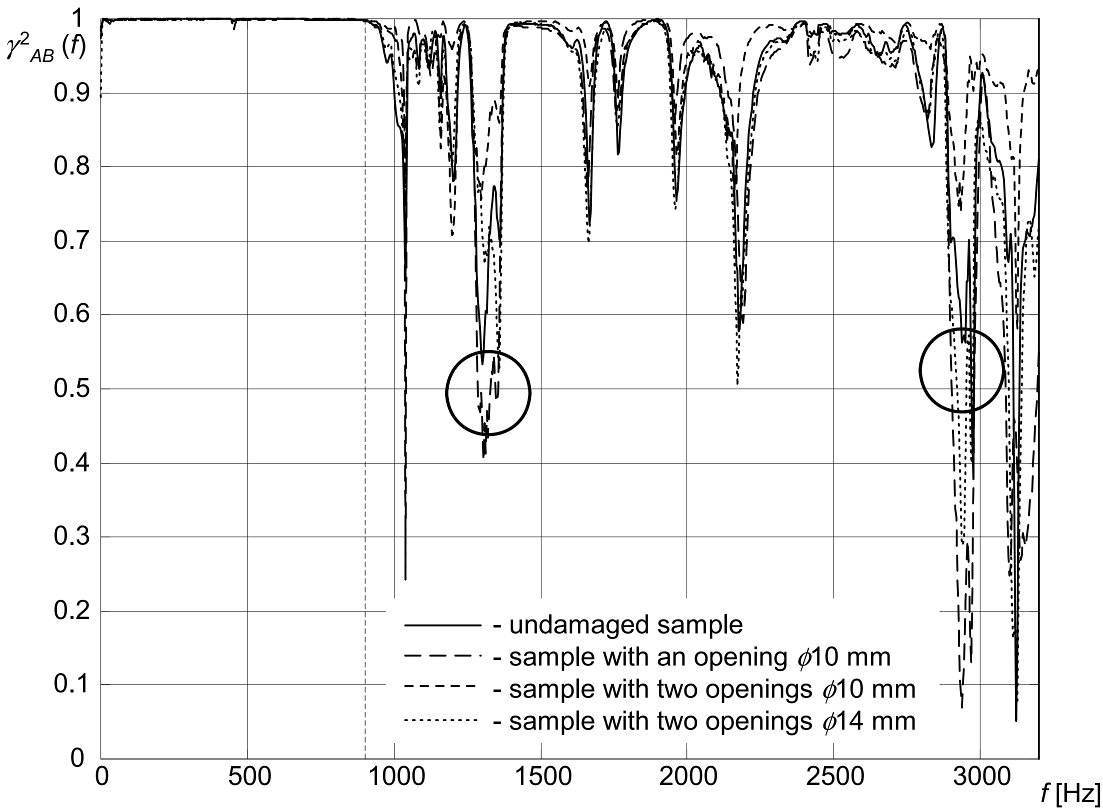

Figure 6. Values of coherence function compared for the tested samples.

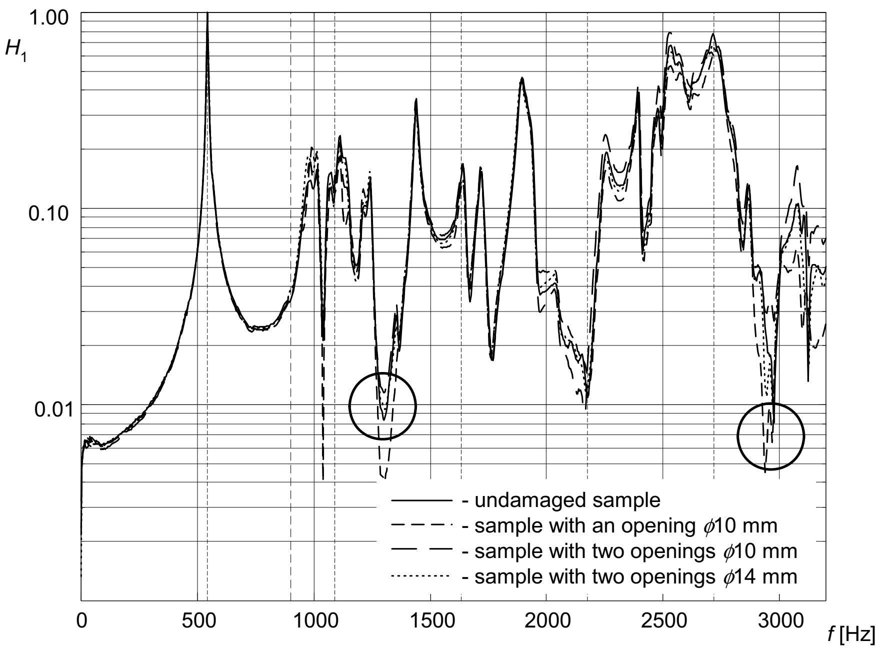

Figure 7. Values of amplification factor (transmitantion module) H_1 calculated for the tested samples.

Analyzing the results of measurements it can be said that structural disturbance of tested material (diameter of opening) gives a repeatable and intelligible picture both for the coherence function and for the amplification factors (transmitantion module).

In the main part of the research subsequent measurement series were made for different diameter openings centrally located on both sides of the mast's profile. The tests were done for openings of diameters of 4, 6, 8, 10 and 12 mm.

The measurements and analysis were carried out in the same way as in the preliminary tests. The figure 8 shows changes of value of the amplification factor (transmitantion module of the system) H_2 in frequency function for different diameters of openings drilled in the sample.

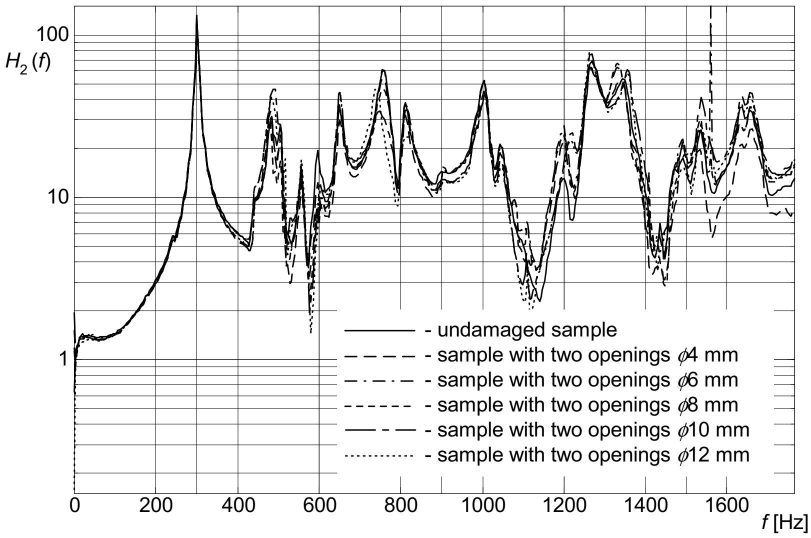

Figure 8. Changing value of the amplification factor (transmitantion module) of the system) H_2 in frequency function for different diameters of openings drilled in the mast.

Figure 9 shows values of the amplification factor (transmitantion module) of the system) H_2 in frequency function for different opening diameters in a chosen frequency band (around non-linear resonance frequency).

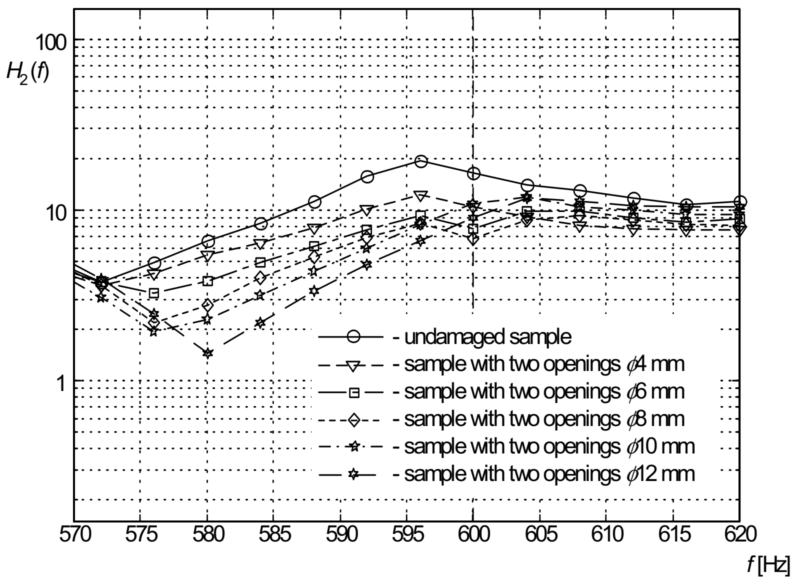

Figure 9. Changing value of the amplification factor (transmitantion module) of the system) H_2 in frequency function for different diameters of openings drilled in the mast (within the diagnostic band).

5 CONCLUSIONS

If we analyze amplification factor of the system in a chosen frequency band, we can observe a monotonic change of value (for several subsequent frequencies), depending on changes of the opening diameters. The figure 10 shows changes of value of amplification factor in function of changes of diameters of the openings in the mast (for selected frequencies).

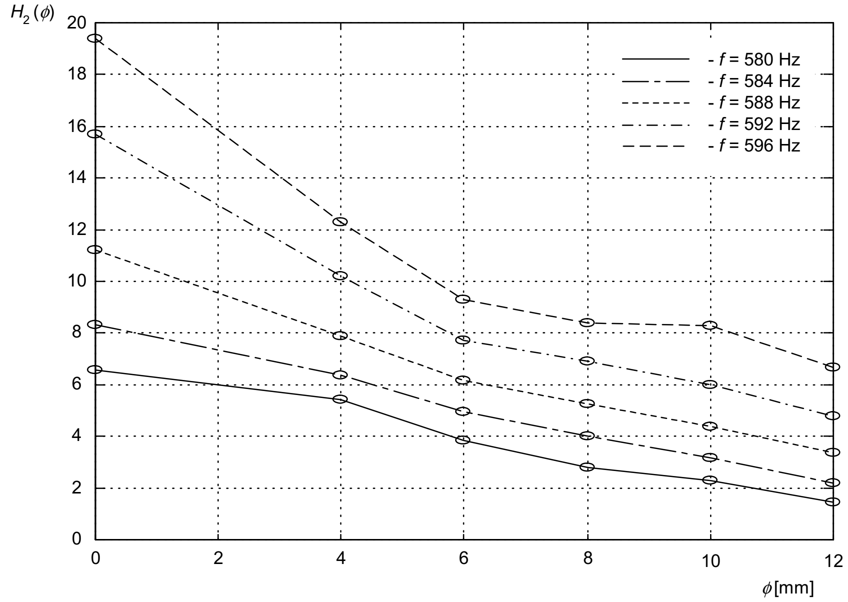

Figure 10. Changing value of amplification factor in function of changes of diameters of the openings in the mast for selected frequencies.

The research has proved that there is a possibility of detecting changes (openings enlarging or/ and changing their form, etc.) in profiles of carbon-epoxide masts. The analysis suggests a possible simple way of defining quality changes. In order to attempt defining the changes in quantitative terms, a broad active diagnostic experiment is necessary, testing a big number of differentiated samples. The frequency range of analysis depends on principal parameters of mast (geometrical dimensions, material characteristics, etc.). The results also show that vibroacoustic methods can be possibly used for evaluating of state of the composite masts in points of fixing construction joints. The main advantage of the applied research method seems to be possibility of submitting a mast to tests without dismantling it, which can significantly lower the diagnosing costs.

THE INFLUENCE OF CRACK PROPAGATION OF THE BENDED BEAM ON PROPAGATION PERFORMACE OF VIBRATION ENERGY

Grzegorz Klekot and Zbigniew Starczewski

Faculty of Automobiles and Heavy Machinery Engineering, Warsaw University of Technology, Narbutta 84, 02-524 Warszawa, Poland.

Abstract: Possibilities of using the vibroacoustic diagnostic methods for monitoring condition of concrete pre-stressed structures have been researched by the Laboratory of Vibroacoustics, Faculty of Automobiles and Heavy Machinery Engineering. An active experiment was carried out in order to examine the relations between loading (up to damage) of a concrete beam and its vibrations. The research methodology has given an opportunity to assess the possible use of descriptors reflecting propagation of vibration energy for evaluating the stage of failure development or the level of crack propagation. The concept of these descriptors (measures) is based on variable in time energy of processes, proportional to the square of instantaneous value of amplitude. As another assumption of this simple equation is that the defined measures are inversly proportional to the force of impact, it results easy to process the descriptors on the basis of synchronically recorded time signals. The preliminary results have shown that the proposed method can be considered as a supplementary way of detecting damages at an early state of propagation. At the current, preliminary stage of research it can be said that the location of both the impact point and the accelerometer, as well as direction of measured vibrations of the object have proved to be important for diagnostic utility of detectors.

Key Words: Fault monitoring, Vibrations, Concrete structure

1 INTRODUCTION

The materials commonly used in construction are mostly characterized by anisotropy of their strength qualities: unquestionably higher compressive stress is acceptable than tensile, tangential or torsional stress. However, there is a group of several elements submitted to bending, working under a complex stress (floor beams, bridge and overbridge spans, etc.) where load is transmitted mostly by the steel profiles and ferroconcrete structures. Everyday the prestressed concrete becomes more frequently used, means concrete submitted to stressing by flexible distortion of steel bars placed within the concrete mass.

The supporting structures of bridges and overbridges undergo, as any technical objects, exploitation wearing processes. The vehicles circulating in Poland often carry excessive loads which results in speeding up wearing processes of the roads. According to forecasts, in coming years either replacement or major repairs of many bridges will be necessary, as well as building new ones. Thus studies leading to formulation of some efficient methods for evaluating and forecasting technical conditions of these objects are needed.

The Vibroacoustic Laboratory of Institute of Machine Design Fundamentals, Warsaw University of Technology, has inaugurated studies on applying the vibroacoustical diagnosis in evaluation of technical conditions of prestressed concrete structures. Up to date several experiments have been carried out, consisting of controlled overloading some concrete beams working under bending forces until their destruction. The details of the experiments are presented in [1, 2]. The research carried out within the framework of the COST programme are focused on developing vibroacoustic diagnostic methods to be applied to the prestressed concrete structures.

The methodology consists of registering acceleration time courses of impact–forced vibrations of a beam, the beam being both side supported and loaded by the static centrally applied force. This made possible to apply the measures of propagation of vibroacoustic energy developed by the Author and check their potential in evaluating level of damage development. The paper presents some results obtained using the data collected in course of the pilot experiment. The conclusions confirm the direction of further studies to be carried out.

2 THE MEASURE OF EFFICIENCY OF VIBRATION PROPAGATION

In the engineering reasoning real constructions are usually modeled in a simplified way. The dynamic models of one or few degrees of freedom are often considered a satisfactory base for pondering on construction or practical qualities of machines and devices. However, difficulties appear when the non-linear component emerges, which is unfortunately the way technical state of objects changes [3]. Consequently, diagnostic application of the measures based on description of movement of a one degree of freedom system is quite limited. There are different research centres developing methods of forecasting and evaluating the object technical state and trying to make them both efficient and well-anchored in physical bases of analyzed phenomena.

The relationship between the technical state of a mechanic system and the energy dissipated during performance of its functional tasks has been observed [4]. It seems sensible then to search for energetic descriptors to be possibly used in diagnostics of technical objects. So we come to the idea of defining a measure matching a simplicity of expression with an universal quality, and reflecting at the same time the vibroacoustic effect of an input of determined energy [5].

It is commonly known that the average square value of amplitude of a signal variable in time is proportional to the energy of the process characterized by the signal. We can thus examine the following relationship:

$$U \sim \frac{1}{T}\int_0^T \left(x(t)\right)^2 dt \qquad (1)$$

where ***x(t)*** represents the variation course of amplitude of the examined physical quantity in time, while **U** is energy, and ***T*** observation time.

Let us try to use the above statement in our pondering on the vibroacoustic processes. Let us also assume that a description of inputs provoking vibroacoustic activity of the technical object is known in form of ***F(t).*** The measure matching the energy of observed process with the input quantity, and called the measure of propagation of vibroacoustic energy seems to be a valid solution:

$$H = \frac{\int_0^T \left(x(t)\right)^2 dt}{\int_0^T \left(F(t)\right)^2 dt} \qquad (2)$$

If we replace ***x(t)*** by the course of acceleration of vibrations physically registered (measured) for an actual point of the technical object ***a(t)*,** and take ***F(t)*** as the course of input force for the vibrations, we will be able to talk about the measure of efficiency of vibration propagation:

$$H_a = \frac{\int_0^T \left(a(t)\right)^2 dt}{\int_0^T \left(F(t)\right)^2 dt} \qquad (3)$$

The above form is particularly useful while examining the results of experimental studies when the object’s vibrations are forced by impulse. As to damped vibrations, it is enough to take the integration time ***T*** to be longer that the time of vibration disappearing, and the lower integration limit established for the moment of impulse input; subsequently the above quotient will explicitly reflect the relationship between the energy of vibration movement and the particular qualities of an actual object.

One of the characteristics of numeric signal processing is operating on discrete values obtained by discretization and quantization of an analogue signal: so the integrating is replaced by the summation.

$$H_a = \frac{\sum_{i=1}^{N} \left(a(i)\right)^2}{\sum_{i=1}^{N} \left(F(i)\right)^2} \qquad (4)$$

In the above relationship the amplitudes of input force ***F(i)*** and vibration acceleration ***a(i)*** correspond with values of i-th time step. Value of measurement can be calculated on the base of a single impulse or a series of impulses; the only condition is a synchronic processing of both physical quantities used to define the measure.

3 PILOT EXPERIMENTAL STUDIES

The objective of pilot studies was to consider validity of use of the vibroacoustic methods for the purpose of diagnostics of concrete construction elements. A concrete beam supported by two supports (as shown below) was centrically loaded with a force of jerkily increasing values until it broke.

For any of the values of effectuated load, the impulse inputs and the vibration answer of the object were synchronically recorded using six accelerometers located as it is shown in the figure 1 (points 2-7). The vibrations of the beam were activated using an impact hammer equipped with a force transducer; the points of impact are marked 1, while the arrows demonstrate the impact directions. Top values of impulses of input reached 3-5kN.

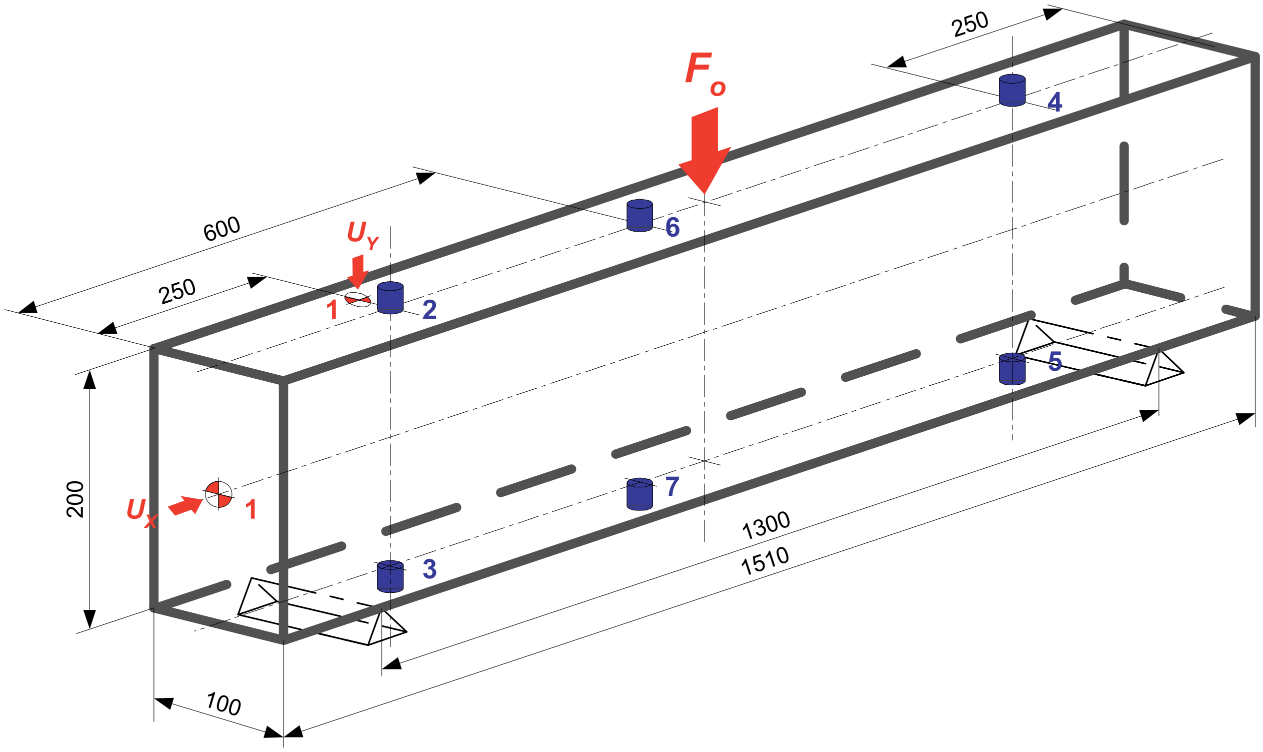

Figure 1. The studied object: location of accelerometers, point of load application and impulse input points.

4 THE RESULTS OF NUMERIC CALCULATIONS

Single numerical values of the measures of efficiency of vibration propagation were calculated according to the relationship (4) as average value coming from a series of 10 subsequent input impulses. The cases of stroke in perpendicular directions were analyzed separately.

The graphs in the figures 2 and 3 show the changes of measures of efficiency of vibration propagation as a function of static load of a beam, obtained by processing the changes of input and the variation courses of acceleration of vibration in fixing points of one of the six accelerators. During the registration of vibration signals of the beam under maximum load, the lead was destroyed, so the graphs illustrating the measure values for vertical strokes have been prepared for static load under 40kN.

The highest numerical values for measures of efficiency of vibration propagation were obtained for the measurement points located near the places of stroke: it seems consistent that structural damping results in lowering of vibration amplitudes in the places situated within a bigger distance from the source. The load input changes to some extent the way the object is supported, and in consequence it explains the maximum without loading and lowering in the function of loading force.

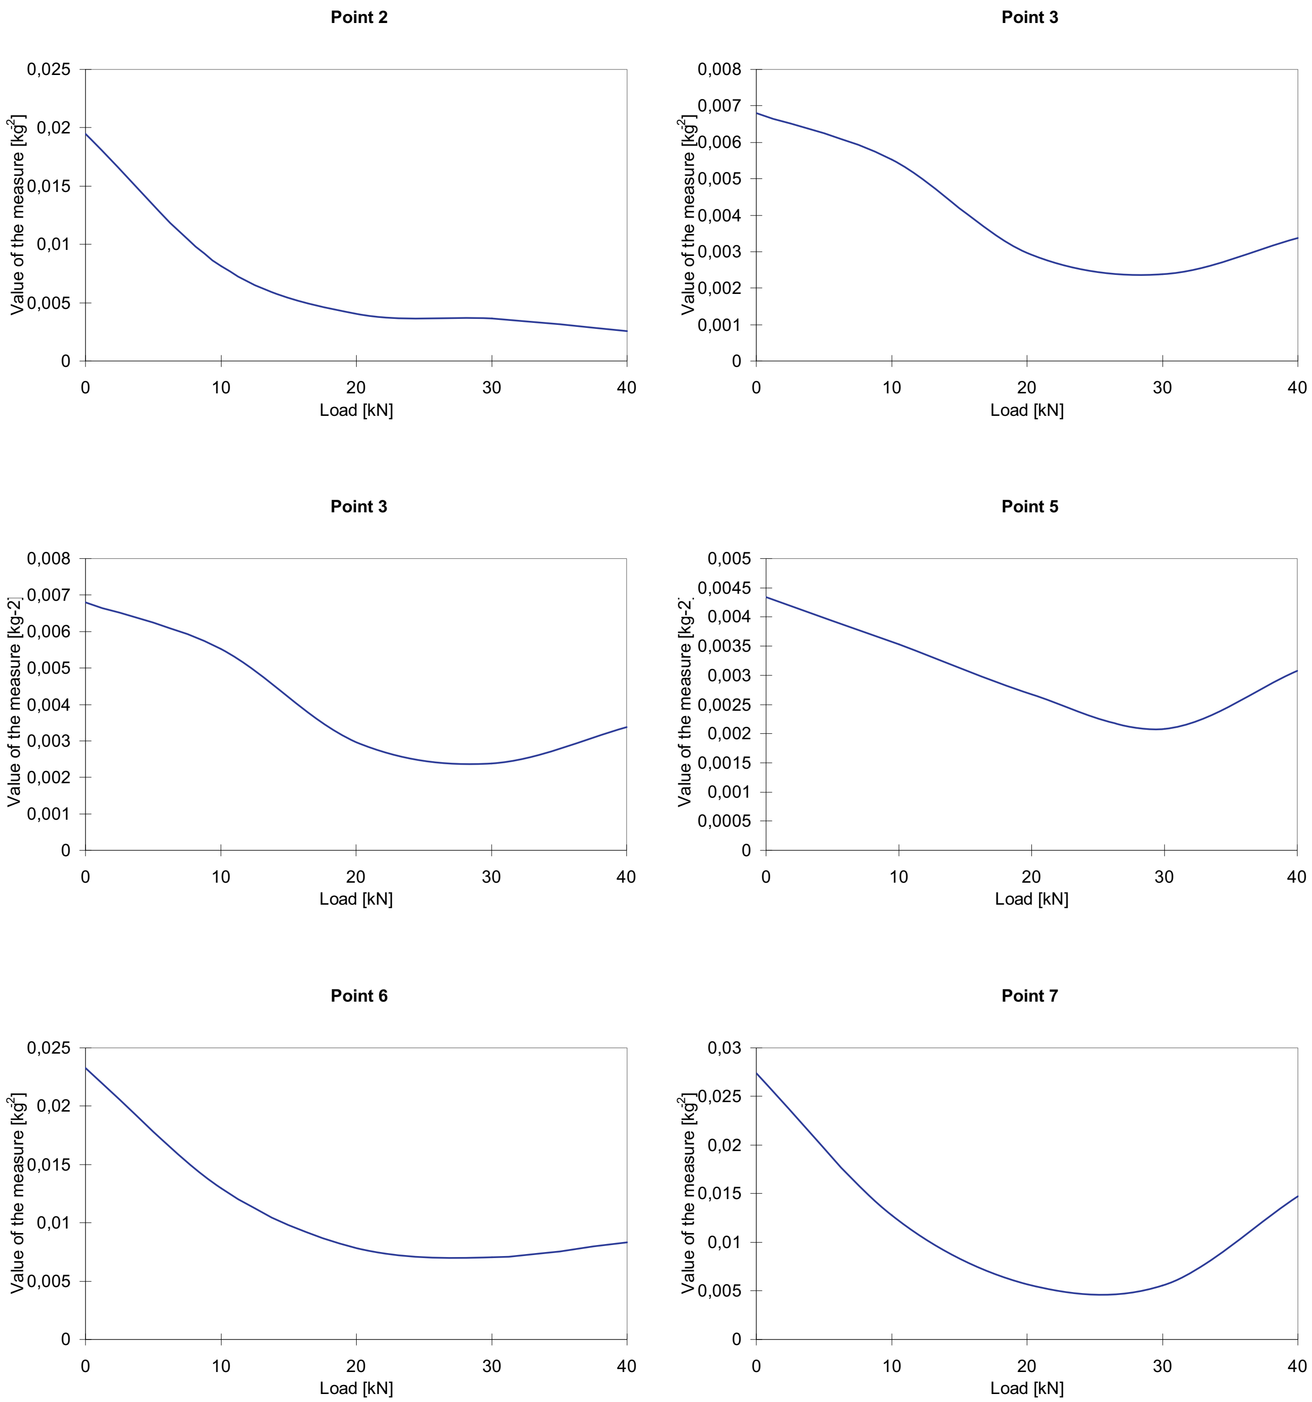

Figure 2. Changes of efficiency of vibration propagation for separate measurement points, vertical input (U_x).

The changes shown in the graphs have a monotonous character only in isolated cases which points to their potential diagnostic utility. On the other hand, there is a lack of an explicit trend in majority of the graphs that suggests a need of deepening the analyze in aspect of this types of application.

Interpreting the graphs and relating them to the object's state become easier if we refer to the information that the first visible cracks (break initiation) were observed under the load of 30kN. In many courses the local extreme corresponding this load can be seen. Quality evaluation makes possible relating the changes of the curve's shape to the initiation of damage.

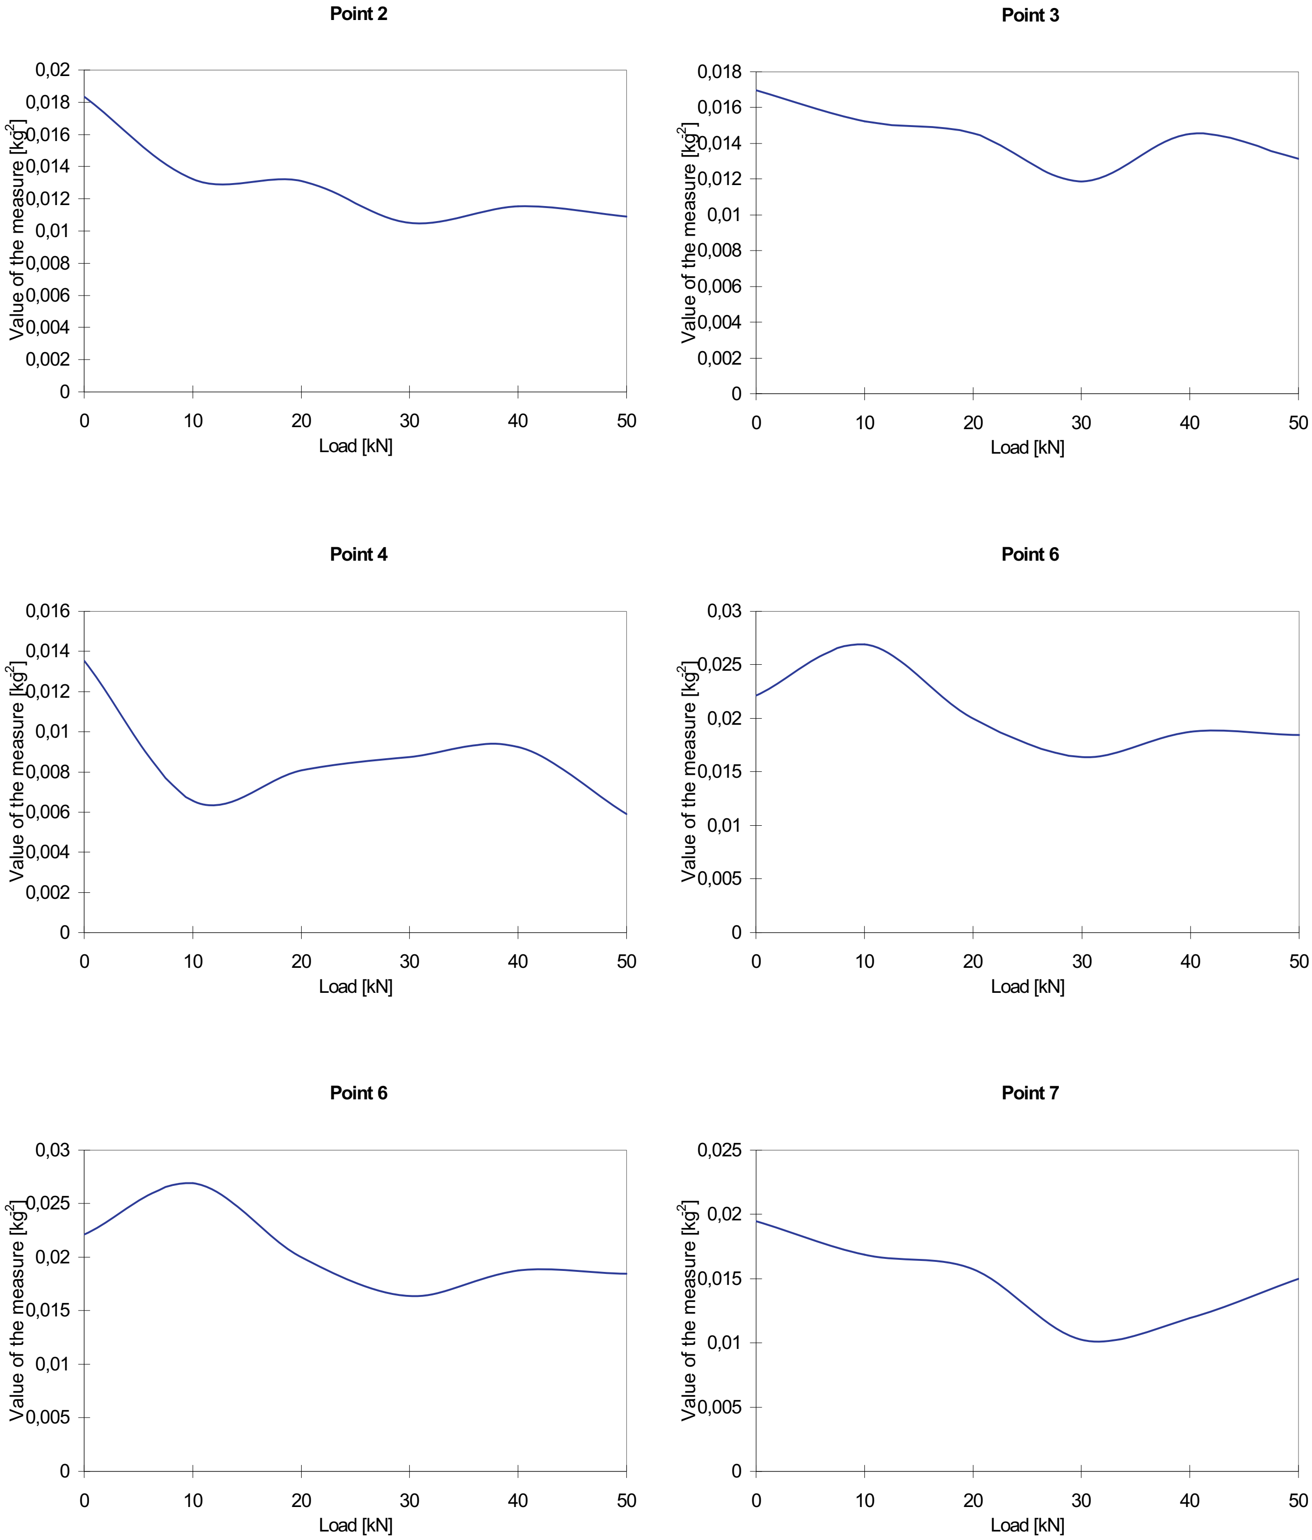

Figure 3. Changes of efficiency of vibration propagation for separate measurement points, horizontal input (U_y).

5 CONCLUSION

The conclusions based on the experiment point to possibility of applying the efficiency measures of vibrations propagation for exploitation diagnostics of concrete structures. However, some additional experimental tests of similar objects seem recommendable, especially of elements made of pre-stressed concrete. Everyday structural beams made of pre-stressed concrete and bended under a load are being more frequently used. Therefore, considering a considerable information value of efficiency measures of vibrations propagations calculated on the base of vibrations induced by horizontally oriented impulses, we would suggest further studies. They would include registration by accelerometers situated at both ends of the beam, processing the motion accordingly with the direction of its induction. Application of bigger number of measurement processors is planned, as well as thickening of changing step of static loading for different qualities of preliminary tension of a stressing element.

All the defects appearing in exploitation process (plastic deformations, cracks, fractures, etc.) change dynamic characteristics of the object, so attempts to apply the already explained measures for evaluating the level of wearing of concrete structures seem justified. Any damage results in modification of the ways of propagation of vibroacoustic energy which necessarily provokes changes of form of the structural vibrations, and consequently, a visible change of numerical value of the measure of propagation of vibrations.

Thanks to virtually free localization of receptors of vibroacoustic signal (accelerometers) and virtually free choice of application point of inducing impulses there should be a possibility of directing the measure towards comparing the properties of actual elements of studied structures, or their fragments. Further selection process can give a chance for crating a tool sensitive to damages of chosen, determinate types.

Abstract: The growing competition in the market demands a better performance from any product in terms of availability, reliability and maintainability. The product is expected to perform well beyond its original life expectancy, which requires efficient prediction tools. How long a component can last, requires life prediction methods such as Accelerated Life Testing and *Virtual Life Testing*. *Virtual life testing* method offers a cost effective and fast option to predict the useful life of mechanical components. In this method, it is important to have reliable models to predict different aspects of the component design performance, one of which is wear. Wear is the result of sliding friction between two contact surfaces, which has been the subject of extensive research and investigations. Due to complex nature of the problem, there is no single wear model, which can be adopted for wear prediction. This paper discusses a systematic approach for modelling of dry sliding wear using time domain models. Models are capable of predicting the wear in transient (running-in) and steady state regimes. The predicted wear volume is translated into dimensional changes in the actual geometry to determine the remaining useful life of a contact. Interpolating data obtained from pin-on-disc wear experiments has been used to form the models. The validity of the modelling approach is verified by comparing the predicted results of wear experiments, using the approach described, with that actually measured.

Key Words: modelling, useful life

1 INTRODUCTION

The evolution of market over the past century has shifted the focus of product development efforts from producer to customer. At the beginning of 19th century the market was known to be "producer oriented", namely anything produced in bulk could be sold. Today the customer plays a driving force in design, development and the quality of the product. With frequent advances in technology, customers need products that meet their changing requirements. The competition forces manufacturers to continuously develop new products, which have higher reliability, enhanced useful life and features to replace the ones in market [1]. Moreover, it is expected that products perform satisfactorily well beyond their original life expectancy, which requires tools for predicting the product behavior during their development [2]. A product has to go through a series of development steps namely: Concept Design, System Design, Detailed Design and Testing before it is released to the market [3]. In order to design a reliable product, the last step holds an important position in the product development cycle and often consumes a significant portion of time [4].

Accelerated Life Testing (ALT) is the current prevailing industry practice at the Testing phase of the product development. This is a process, in which prototypes are subjected to accelerated tests specified in the product's specification, so that failure occurs in a short period of time [5]. Based on ALT results, the reliability of the unit is estimated for its normal operating conditions. ALT not only consumes a considerable time of product development cycle, but also incurs a cost through the prototype units utilised for testing.

To grasp competitive edge, the manufacturers need to limit the amount of physical testing and design iterations thus minimizing the time-to-market incurred ALT. One such direction is "Virtual Life Testing" method for product reliability evaluation. The method uses mathematical models of the product instead of using the physical prototypes. This method offers a cost effective and fast option to predict the life expectancy of mechanical components using powerful computers and software [6]. Sliding wear is one of the important physical characteristics of , which can be modeled and used in VLT.

Sliding wear can be defined as the progressive material loss, which occurs on the contact surfaces of components that experience a relative sliding motion [7]. Wear of mechanical components is one of the major failure modes encountered in sliding contacts. It is a critical factor influencing the service life span of components. The ability to predict the wear and hence the useful life of sliding members is important in redesigning or proposing a replacement schedule for faulty components.

As illustrated in Fig. 1, mechanical wear can be classified in four major modes; Adhesive, Abrasive, Erosive and Fatigue. These wear modes are not mutually exclusive and in most cases they can be transformed into each other depending on the operating conditions. Adhesive wear is the most commonly occurring wear [8].

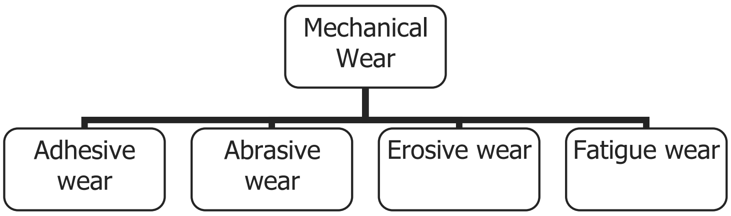

Figure 1: Major wear modes

2 MODELLING OF SLIDING WEAR

There are over 300 wear models documented in literature [9]. The dependence of sliding wear on dynamic factors like; load, speed, temperature, time, contact geometry, surface roughness, oxygen availability, lubricant chemistry, and material surface compositions makes it difficult to have a single comprehensive representation [10]. In spite of the existence of such a large number of wear models, there is still no single wear model that can be used for all situations [11].

In general wear volume loss can be defined as

$$V = f(P, S, \mu, H, t, R) \tag{1}$$

where P, S, μ, H, t, and R represent the applied normal load, relative sliding speed, coefficient of friction, hardness of the softer material, sliding time, and the size of contact respectively. Normally, for wear modeling it is assumed that the wearing action will only occur on the softer of the two sliding surfaces. The two wear models used in this research are Archard's wear model and Yang's wear model, which are described next.

2.1 Archard's wear model

The wear model proposed by Archard has been extensively used for wear coefficient calculations . The wear volume loss, V, for a sliding contact is given as

$$V = K_s \frac{PL}{3H} \tag{2}$$

L and P are sliding distance and normal load applied to wear surfaces respectively. H is the Brinell hardness of the softer wearing material and K_s represents the steady-state wear coefficient. Therefore, for known values of V, P, H and L the standard wear coefficient can be calculated [12].

2.2 Yang's wear model

Most of models treat the wear in steady-state and not considering the transient (running-in) wear. A wear model was recently presented by Yang, which takes into account the initial running-in wear of a contact [13]. The transient wear volume can be calculated from.

$$V_t = A(1 - \exp^{-BL_t}) \tag{3}$$

V_t and L_t represent the transient wear volume loss and the sliding distance accordingly. A and B are constants, whose values are determined by fitting a curve using equation 3 through the experimental values of wear volume loss and sliding distance. Subsequently, making use of equations 2 and 3, the wear coefficient can be computed using equation 4

$$K_s = \frac{3HA}{PL}[1 - \exp^{-BL_t}] \tag{4}$$

The wear coefficient thus calculated will follow an exponential curve, which indicates that the virgin contact surfaces have higher number of asperities wearing as a result of running-in wear. After the running-in stage the wear coefficient follows a steady pattern for the given conditions. Once in the steady state wear region, equation 2 can be used to model the wear [13].

3 LIFE PREDICTION METHDOLOGY FOR SLIDING CONTACT

Traditionally, the conservative safe life of critical mechanical components for (time or usage) was estimated statistically. Although, this method still works well, however the current evolution of diagnostic and prognostic techniques, coupled with the development of advanced computing systems can provide accurate design and prediction tools. Model based prognostic methods have proven to be useful for life expectancy prediction of mechanical components [14]. The life prediction model for the sliding polymer contact in consideration goes through the steps, which are described in the following sub-sections.

3.1 Experimental setup and procedure

Pin-on-disc method is commonly used for determination of the wear coefficient of a sliding contact. The pin is usually the wearing member and has a lower hardness value. However, instead of standard pin-on-disc in the present case the experimental contact geometry was designed to mimic the geometry of the real contact as it appears in the final product. Figure 2 (a) depicts the actual geometry consisting of three sliding contact pairs.

The test setup is demonstrated in Figure 2 (b). Referring to Figure 2 (b) 'Track' is used as the disc and the 'Slider' correspond to pin when it is compared to conventional pin-on-disc method Slider' is mounted on a rotary pneumatic cylinder, which can be revolved in clock and anti-clock wise directions relative to the fixed Track. It consists of three contact pairs. There is a 430 N dead load applied on the Slider as the normal load, which is assumed to be equally distributed across each of the three contact pairs (~143 N). The angular stroke of the Slider is 32.3° as defined by the operating range of the mechanism. Thus the linear sliding distance can be computed for wear volume loss calculations.

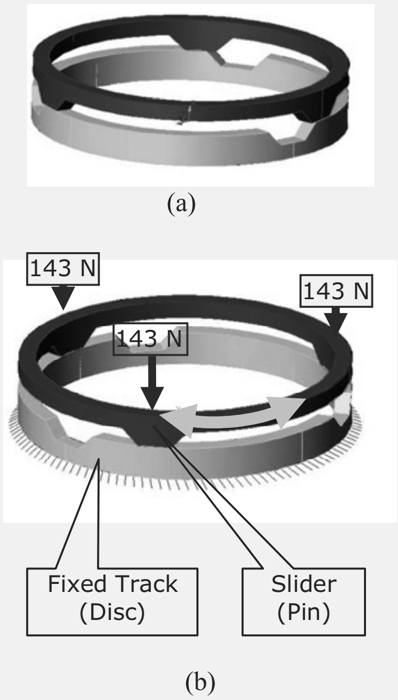

Figure 2 (a) Configuration of actual contact (b) Experiment setup

Slider is made of a 33% glass reinforced, heat stabilised black nylon copolymer resin density 1400 kgm^{-3} and tensile strength 172 MPa) commercially marketed by DuPont as Zytel 72G33HS1L and the sliding Track is made of BK15945% glass reinforced modified polyethylene terephthalate (density 1700 kgm^{-3}, tensile strength 186 MPa and hardness $95HR_M$ ($120HR_R$)) commercially marketed by DuPont as Rynite 545 NC010.

Track is made of relatively harder material than the slider therefore it is assumed that only the slider will be worn in wearing process. Wear volume loss is measured at sliding distances of 25, 50, 75, 100, 125, 225, 325, 425, 525 and 625 metres.

The service life of the mechanism is 35000 cycles comprising folding 32.3° and reverse fold to the original position. The sliding distance of each contact of Slider is 30mm through the fold – reverse fold cycle. The height of Slider contacts has direct influence on the service life of the mechanism described above. Therefore, the purpose of virtual testing is to model and simulate service life of one of the three identical Slider contacts. Since the Slider contact pairs are identical, modeling one is sufficient. In order to have sufficient data points throughout the expected service life of the mechanism it was decided to obtain the data points in 25 m increments (787 folding cycles). When 3935 folding cycles or 125 m linear sliding distance was reached, the measurement frequency was altered to 100 m increments, which is equivalent to 3148 folding cycles.

The sliding speed during testing was set at 6.3 x 10^{-3} ms^{-1} (12.3 $°s^{-1}$). The normal load of 450 N applied as per the mechanism design condition. The ambient temperature during testing was controlled at 22 ± 1 °C.

Figure 3 depicts the general approach that has been adopted for prediction of height decay of the sliding contact pairs [15].

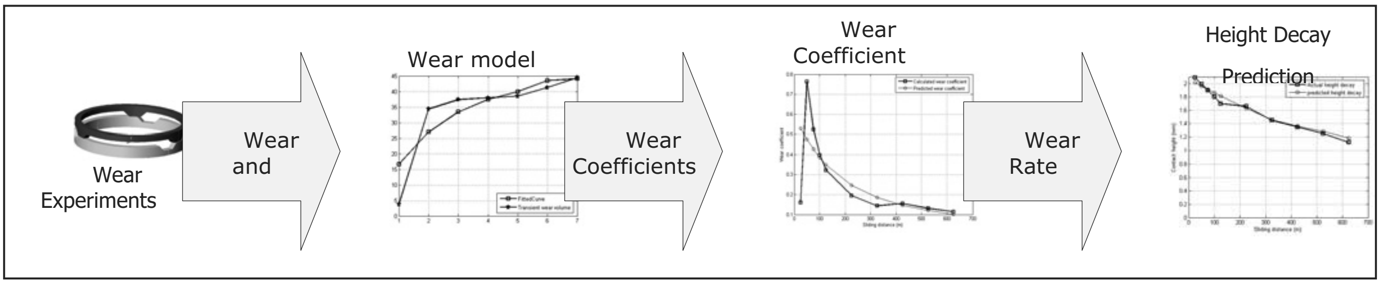

Figure 3: Modular virtual testing approach for dry sliding wear in time domain time

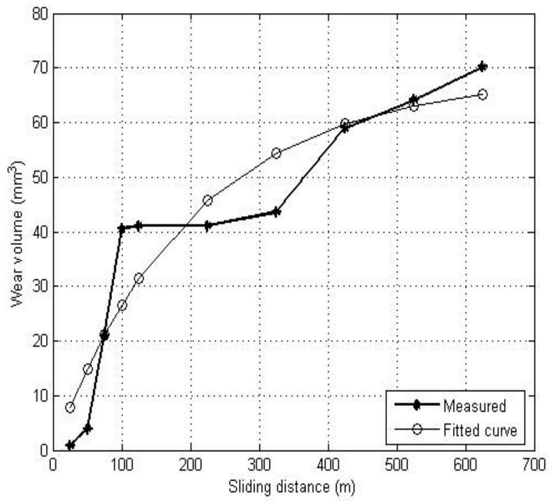
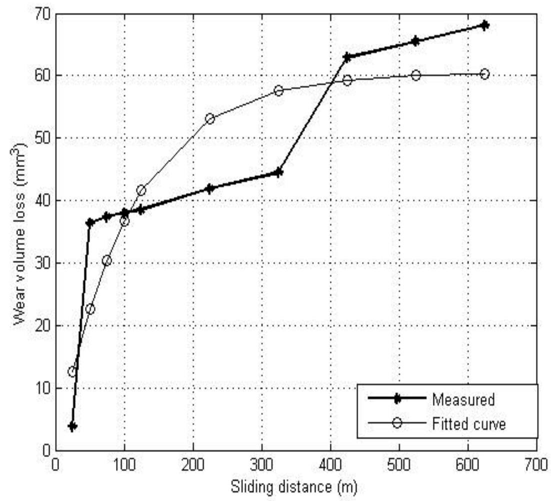
3.2 Calculations of Yang's constants

In order to obtain constants A and B, which are required for calculation of the wear volume loss in Equation 3, two experiments were carried out with two sets of slider and track. Curves were fitted through each set of experimental data. The experimental results of wear volume loss versus sliding distance together with the fitted curve for each of the two experiments are illustrated in Figure 4 (a) and (b).



(a) Experiment 1



(b) Experiment 2

Figure 4: Wear volume versus the sliding distance and the curve fitted around the data

The fitted curves in Figures 4 (a) and (b) show the transient (running-in) wear reaching a steady-state. From each plot it can be observed that the running-in wear extends from sliding distance of 0 to approximately 400 meters. Beyond this distance, the wear tends to reach steady state condition. Due to the limitations of the experimental setup, further verification of steady state regime could not be carried out. The spikes of the experimental curves, above or below the fitted curves may be attributed to the small step size of sliding distance for which the wear volume loss was recorded. Such spikes would be masked out if larger increments were considered. The experiments are carried out over varying sliding distances at a constant speed, thus the wear volume loss results are in time domain.

Table 1

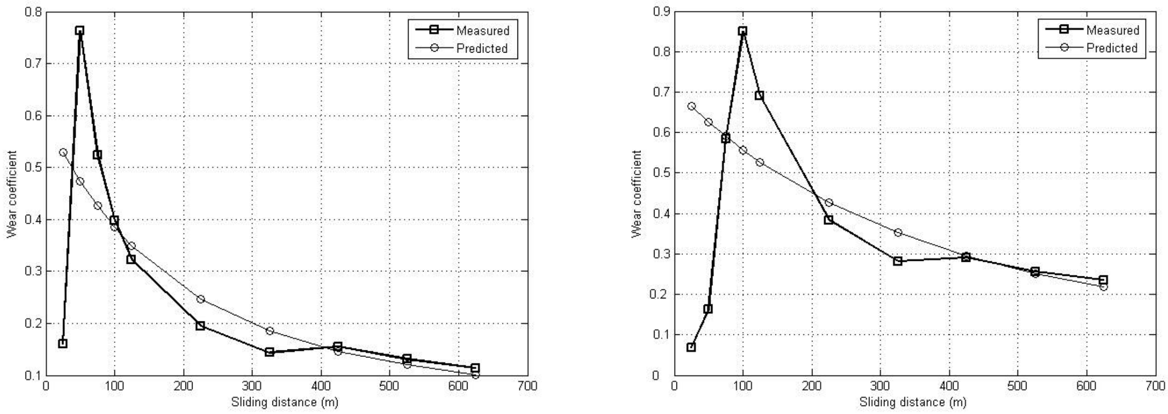
Constants A & B for transient wear of the sliding contact

	A	B
Experiment 1	60.4482	0.0093
Experiment 2	68.1899	0.0049

The values of calculated constants A and B for the two experiments are given in Table 1, which are quite high compared to constants calculated for the model presented by [13] for aluminum composites. This is in agreement with the difference in material properties of metal and polymers. A glass re-enforced polymer composite is much more prone to wear as compared to metals.

3.3 Wear coefficient calculations

Both measured wear volume loss and fitted curve data from previous section were used to calculate the wear coefficient values using equation 4. The graphs of both measured and predicted wear coefficient versus sliding distance for each of the experiments explained in the previous section are shown Figure 5 (a) and (b). Both of the wear coefficient plots resulting from the two experiments indicate a very high initial spike from a low to very high wear coefficient. As can be seen from the Figures 5 (a) and (b), the initial distance increments results in a very small wear coefficient. The reason being, once the initial asperities have released abrasive particles in the contact region, the wear coefficient increases to a high value, which later slowly decays to a low but steady wear coefficient.

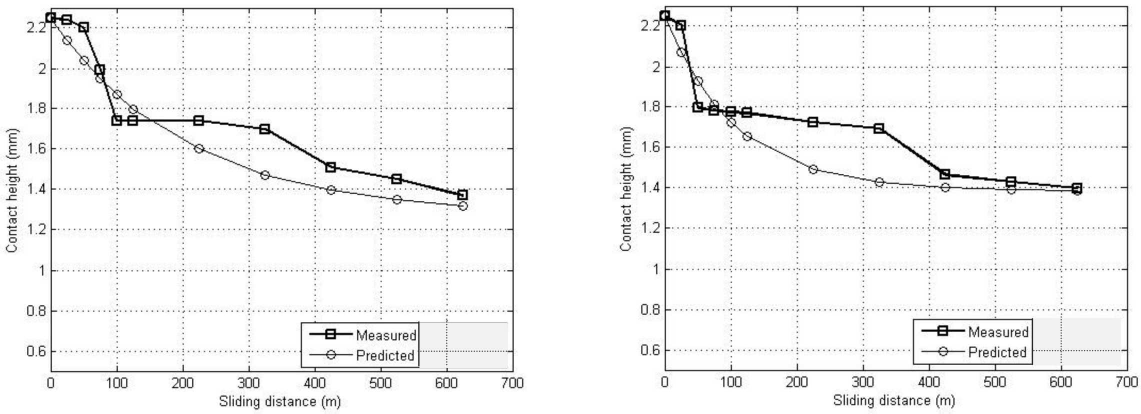


(a) Experiment 1 **(b) Experiment 2**

Figure 5: Experimental and predicted wear coefficients versus sliding distance

.

3.4 Contact height decay



(a) Experiment 1 (b) Experiment 2

Figure 6: Actual and predicted height decay vs sliding distance

Given the geometry of the wearing member, the wear volume loss at each distance increment can be translated into the height loss of the contact. This in turn gives the contact height decay as a function of sliding distance or number of cycles. The decay rate can be compared with performance specification of the product. This information helps designer or maintenance engineer to decide on redesigning or scheduling replacement of the worn component.

Figure 6 (a) and (b) illustrate the measured and predicted height decay of the wearing member versus sliding distance for the two experiments. The measured and predicted curves correlate well, showing the accuracy of modeling approach. The graphs demonstrate rapid height decay at the initial distance increments that is in conformance with the initially high wear coefficient as discussed in section 3.3. The subsequent distance increments demonstrate a gradual decrease in the wear rate till it reaches a steady state condition. The predicted decay curves - are based on the predicted wear volume data from the calculations in section 3.2, showing no decay as steady state is reached. In contrary, the decay should continue beyond the steady state but with a different governing model, which could not be demonstrated due to limitation of the experimental setup as was explained before.

4 CONCLUSIONS

Under dry sliding conditions, the ability of wear models to predict wear conforming to experimental values varies greatly for different polymers and test conditions [14].

During the experiments, it was observed that the actual load on the slider was not uniformly distributed between the three contact pairs, however it was consistent between the two experiments. The varying load between the contacts caused them to wear unevenly, affecting the overall geometry of the Slider. Therefore, it can be the deduced that the individual wear of a contact is influenced by the wear of other contacts. This may prove to be a challenge to understand and simulate this problem in future.

The design of Slider's contact causes the leading edge to wear at a faster rate than the trailing edge. Determining the relationship between geometry and material properties for wear modeling is important, which will be studied in future.. Metrology techniques have been marginal during these experiments due irregular wear caused by mechanism geometry. A standard pin-on-disc configuration offers more options with respect to material loss measurements.

Slider's contact geometry used in these experiments was limited by height to keep it in accordance with the actual design of the end product. Therefore, the height was not enough to carry on the experiment beyond the running-in phase of the model. Moreover, the environmental and loading conditions were set only for this particular product design. Further experiments will be carried out with different geometries, loading conditions and environment variables to establish a more generalized wear model for these materials.

The models and predictive methodology presented by Yang [13, 16] were based on confirmation experiments carried out for aluminum composites only. The sliding distances selected and the corresponding wears found in the current experiments have no comparison with the values in [13] due the difference in the nature of materials. Since, limited literature on polymer wear was found by the authors, therefore it is difficult to benchmark the findings.

The virtual life testing approach depicted in Figure 3, is not completely virtual and there is some experimentation involved in establishing the models. In order to standardize designs and manufacturing equipment to optimize the operating cost, industries tend to design components that could fit in a wide range of products with minimal variation. Once successful wear models have been established corresponding to a particular product and operating conditions, they may be adapted to a range of similar products.

UNDERSTANDING FAILURE RISK IN ELECTRICAL MACHINES

MIKE DAVIS

Machinemonitor Pty Ltd

Abstract: Most operators of business critical electrical machines experience unexpected electrical failure events from time to time. The consequence of these events is typically significant losses resulting from down-time and recovery costs. This paper outlines an approach to establish electrical failure risk in a given machine through understanding machine condition in the context of design characteristics, maintenance and operational histories. Over the last decade extensive data collecting has been undertaken on upwards of 500 high voltage machines to establish risk profiles and a knowledge database. The information gained from the machine modelling has allowed users to make more informative judgments on machine condition, risk and maintenance requirements. Two case studies will be presented one from a Hydro Generating Plant and another from a Minerals Processing Plant to demonstrate how business risk cost can be reduced through modelling and identifying failure risk in electrical machines and targeting maintenance toward mitigating the risk.

Key Words: Business Critical, Down-time, Risk Profile, Hydro Generating, Modelling, Maintenance.

1 INTRODUCTION

A project was developed in 2001 to establish a web based management portal for electrical machines which would permit machine owners to enter machine design operating and condition monitoring data for the purpose of modeling electrical machine failure risk. A common standard methodology was established to asses and analyse machine data for the purpose of establishing and displaying a failure mechanism matrix for individual machines. Once it was understood which failure mechanisms were predominant in a given machine it then became possible to rank machines based on the extent and severity of the identified failure mechanism and what maintenance action would be required to mitigate the failure mechanism(s) and hence risk of failure.

2 THE “RISK MODELING” METHODOLOGY

The six-step high voltage electrical machine risk assessment tool is summarised below. The functionality of this assessment tool takes the machine maintainer through the following simple steps to establish risk profiles on stator and rotor windings for individual high voltage machines. The risk profiling is an on-going life of machine process and will afford the machine owner the opportunity to economically target maintenance to the areas of greatest risk in the monitored machine population.

2.1 Machine Identification

Establish a machine database detailing all technical information on the particular machine. Information collated included;

- Full machine name.
- Manufacturer.
- Machine type i.e. Induction Motor, Synchronous Motor, Steam Turbine Generator or Gas Turbine Generator.
- Speed.
- Voltage
- Output KW or KVA.
- Year of Manufacture.
- Stator Insulation Class, B, F or H.

2.2 Maintenance History

Collate the maintenance history on the machine. This step lists all maintenance activities on the machine with particular focus on major maintenance that may have changed the material content in the machine.

2.3 Operational History

Collate operational data. This following information is required;

- Machine state, In-service, off-line or disassembled.
- Number of starts.
- Operating hours.
- Operating environment i.e. Wet/Contaminated or abrasive environment.
- Events i.e. asynchronous operation, over excitation, stalls, locked rotor etc.

2.4 Design Data

Collate design data. In this collation a thorough review of design data is undertaken with attention being paid to flux and current densities, ground wall stress levels, mechanical assembly and voltage stress distribution. These parameters are then compared against normal engineering design limits. The following data is required,

- Stator insulation – Asphaltic Mica, Mica folium, Polyester/mica splittings, Polyester/mica paper or Epoxy mica paper.
- Winding data including coils, groups, turns and cross-sectional area & stator core dimensions
- Stator winding connection Y orΔ.
- Number of parallels circuits.
- Semi-conductive coating YES/NO.
- Global VPI of stator YES/NO.
- Stator winding type.
- Temperature monitoring YES/NO. Nominal hotspot temperature (stator).

2.5 Data Analysis

Integrate data into machine database. The data collated in steps 2, 3 and 4 is integrated into a machine database to establish the likely predominant failure mechanism(s) that could exist in the machine. These failure mechanisms are presented in descending order of likelihood.

2.6 Verification Testing

Based on the likelihood of a failure mechanism a testing regime is put into place to collect objective data as to the presence and extent of the identified predominant failure mechanism(s). Testing can be selected on the following criteria;

- Usefulness - which test is going to give the most meaningful data to assist in making the risk judgment?
- Risk - which test has the lowest risk for damage to machine?
- Time - which test is the most time efficient test?
- Machine State - which test is best considering the state of the machine?
- Machine History – considering machine history which test is best?

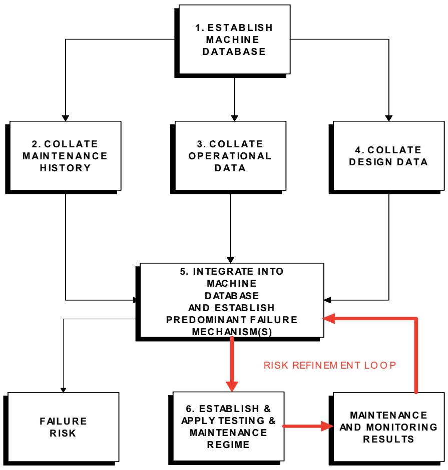

Figure 1 Risk Assessment Process

3 FAILURE MECHANISM AND RISK RANKING

The analysing of machine and test data permits the rank the failure mechanism(s) in the machine stator winding and also ranks overall risk of failure for the machine stator and rotor windings. The failure mechanisms are ranked on predominance through a confidence factor from 0 to 1, 0 meaning there is no evidence of the presence of failure mechanism and 1 meaning the mechanism is definitely present. The process output is illustrated in figure 2.

Risk ranking required development of scores based on severity of the modeled failure mechanism matrix and consideration of the operating environment and design stress raisers in the machine. It became apparent from the entire list of possible electrical failure mechanisms in a machine some develop rapidly whilst others develop slowly in some examples over decades. Elevated risk is typically associated with the presence rapidly developing or advanced failure mechanisms. Risk rankings are expressed in percentage terms and further divided into quartiles.

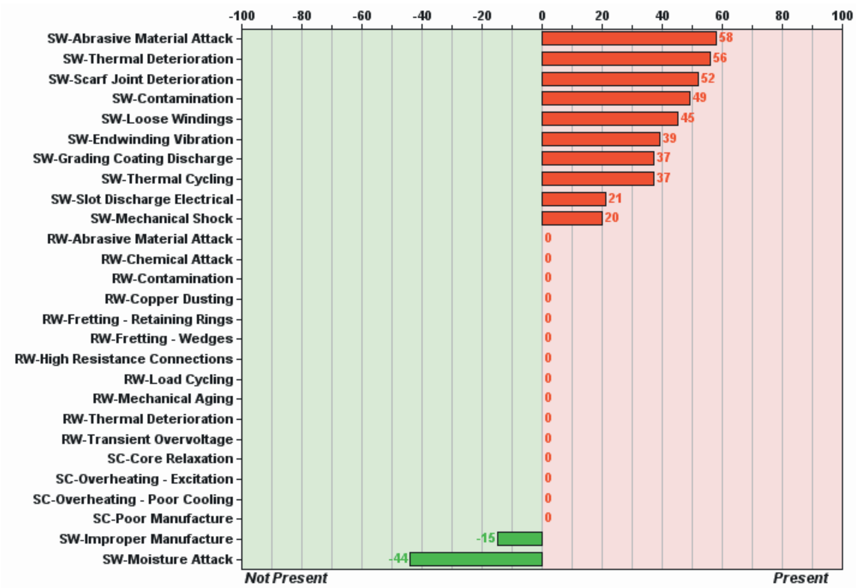

Figure 2 Failure Mechanism Matrix from 50 year old Steam Turbine Generator

4 RISK IMPLICATIONS

Having ranked machines according to risk the next step was to relate a risk ranking to a maintenance action. The relationship between risk ranking and maintenance requirements is tabulated below

Table 1

Risk Implication – Stator Windings

Percentage	Risk Quartile	Risk Implications
1 -50%	1st & 2nd	Associated with reliable machine condition no remedial action required
51-75%	3rd	Low level failure mechanisms present. Plan medium term strategic maintenance
70-90%	4th Level 1	Predominant failure mechanism(s) present. Actively monitor and trend in accordance with specific Inspection Test Plan (ITP)
91-98%	4th Level 2	Susceptibility to unexpected failure. Avoid operational excursions. Plan inspections and maintenance. Check availability of spares.
98% +	4th Level 3	Immediate Maintenance Required

5 ESTABLISHING RISK COST OF ELECTRICAL MACHINES

Operating electrical machines in business critical applications exposes the business to losses associated with unexpected failure. These losses include opportunity cost due to loss of production and equipment recovery cost. Annualised risk cost can be calculated by;

Risk Cost = (η x b) c

Where η = annual probability of failure

b = cost of failure (including downtime and reclamation costs)

c = risk %

6 CASE STUDY ONE – REDUCING BUSINESS RISK COST

A 3.2MW ,11kV, 6 pole wound rotor induction motor operated on milling duty at "the heart" of this cement manufacturing plant for 10 years. No spare was available and down-time cost amounted to $40k per hour. Baseline inspections and risk modeling indicated a 4th quartile level 3 risk at 98% contributed to by loose windings in the stator slots. Modern high voltage machines have a low tolerance to this kind of failure mechanism due to the non flexible nature of epoxy based insulation used in the stator insulation system.

- The risk cost associated with the above condition is expressed as;
- Risk Cost = (η x b) c
- Risk Cost = 0.5(400000.24.60) 0.98
- Risk Cost = $10.944M
- Where
    - η = 0.5 (annual probability of failure on measured condition)
    - b = cost of failure (including downtime and reclamation costs)
    - c = risk %

Maintenance was scheduled on the machine which including removing the machine, transporting to a repair facility and re-wedging the stator. After this maintenance a revised risk model was developed reflecting the maintenance and confirmation testing (Partial Discharge). The revised risk was modeled as Quartile 2 at 42%

- The risk cost associated with the condition after maintenance is expressed as;
- Risk Cost = (η x b) c
- Risk Cost = 0.2(400000.24.60) 0.42
- Risk Cost = $1.209M
- Where
    - η = 0.2 (annual probability of failure on measured condition)
    - b = cost of failure (including downtime and reclamation costs)
    - c = 0.42 %

This experience demonstrated the effect of reduction of business risk cost by simple targeted maintenance. The total reduction in business risk cost for a $100k maintenance investment was in the order of $9.7M.

7 CASE STUDY TWO – TARGETING MAINTENANCE IN A POPULATION OF AGED MACHINES

This hydro generating business operates some seventy generators aged up to 70 years old. In an environment of diminishing maintenance resources and exposure to increasing failure rates there was a requirement to target maintenance toward generators which require attention. The risk modeling process was applied to the entire generator fleet to benchmark machines on risk. Extensive data mining was undertaking in the business to understand the design, maintenance and operating data for each generator. The ranking summary for the machine population is represented below;

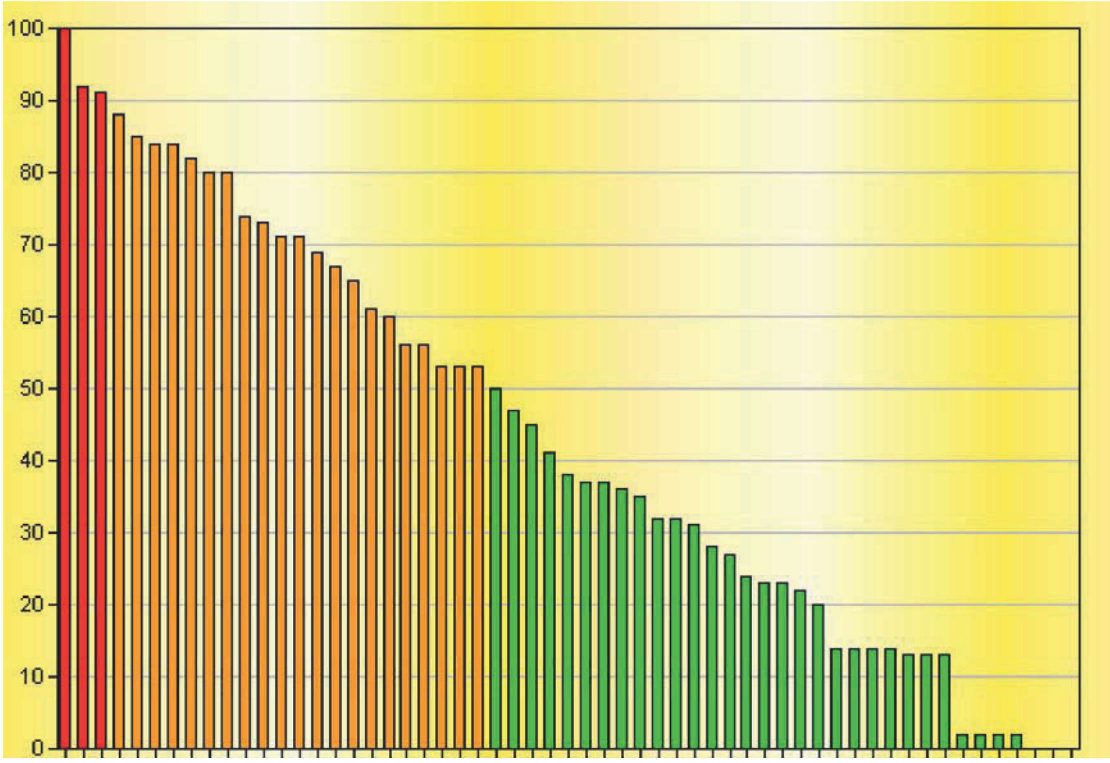

Figure 3 Failure Mechanism Matrix from 50 year old Steam Turbine Generator

As a result of the process one generator was identified as requiring immediate maintenance with an additional two machines requiring maintenance in the short term. In the order of 75% of the machine population returned risk rankings associated with reliable operation.

8 CONCLUSION

Based on the experience of the last five years it has been demonstrated that using common standard approaches for risk modeling across a machine population permits machine owners and maintainers to rank machines based on risk ratings. Furthermore once machines are ranked and the problems driving risk understood significant maintenance and risk cost savings can be achieved through mitigating risk by applying targeted maintenance toward that low percentage of machines with elevated failure risk.

AD-HOC TO BEST-PRACTICE – THE ROADMAP TO ACHIEVING BEST-PRACTICE MANAGEMENT OF CONDITION MONITORING DATA

Adam Van Dyck [a]

[a] *Product Development Centre, CCI Pope Pty Ltd, 29 Rosegum Close Warabrook, NSW, 2304, Australia.*

Abstract: It is widely accepted that predictive maintenance is an essential component of an effective maintenance program. As organisations increase the quantity of predictive maintenance, it becomes increasingly difficult to manage the huge volumes of data generated through the various condition monitoring techniques from potentially many different sources.

There are many shortcomings with the status quo, whereby condition monitoring reports are organised using a manual or electronic filing system. Many organisations struggle to make this information easily available across their organisation. Reports can be difficult to find and searching through these reports is often a time consuming manual process. Collecting the data from various condition monitoring techniques for a particular asset can involve manually searching through many filing systems. Seeing the 'bigger picture' of overall plant health is virtually impossible. While modern Computerised Maintenance Management Systems (CMMS) are more than capable of managing the maintenance program, they are not ideally suited to managing high volumes of condition monitoring data. The absence of a suitable information system is often a barrier in the transition from status quo to best-practice.

Short term benefits are immediately realised when organisations adopt a best-practice approach to condition monitoring data management. An instantly accessible and exhaustive condition monitoring history for each asset is available, enabling the most informed maintenance decisions to be made. Potential problem areas are communicated to the relevant personnel immediately and overall plant health can be easily determined at any point in time. Over the longer term, these organisations are able to extract an extra layer of value from their condition monitoring data management systems. This may include benchmarking the health of similar assets across the organisation as well as identifying both effective and ineffective maintenance practices.

In this paper the author outlines the features and benefits that a best-practice condition monitoring data management system should provide. The people, processes and information systems required for best-practice are discussed in detail. Finally, the author suggests a roadmap that can be followed by those organisations wishing to achieve best-practice data management. Potential challenges that may arise are identified to allow risks to be managed through the implementation process.

Key Words: Predictive Maintenance, Data, Information, System, best-practice, condition monitoring

1 INTRODUCTION

Developing systems and processes to manage condition monitoring data is a significant issue in the overall maintenance program. However, while resources are readily invested in areas such as commissioning CMMS systems and developing maintenance strategies, the issue of condition monitoring data is often left unaddressed. By default the condition monitoring data that flows into the organisation is unmanaged; resulting in significant hidden costs due to time wasted searching for this data and the inability to leverage its full potential.

For the organisations that make the commitment to develop robust condition monitoring data management processes there is a significant prize in terms of time and money saved and increased plant reliability.

2 THE STATUS QUO

2.1 Silos of Data

In many organisations, Condition Management data management is an ad-hoc process. Typically, condition monitoring reports flow into the organisation from various sources, including internal condition monitoring groups, third party contractors, OEM's and on-line systems. Once delivered, these reports become the responsibility of various individuals or departments within the organisation. There is a reliance on the diligence of these individuals to file reports appropriately so that a permanent record is kept and that it is accessible to others within the organisation. This may be done by manually filing a paper report in a filing cabinet or saving a softcopy to a known location on a central fileserver. The end result is often a set of disconnected 'silos' of condition monitoring data across the organisation. Once a report is filed this information is essentially lost to the remainder of the enterprise. It becomes significantly more difficult and time consuming to conduct any higher level enterprise wide analysis of that data. When individuals change jobs or leave the organisation, the manual report filing processes fall over, resulting in further effort to re-establish these processes and the likelihood of an incomplete condition monitoring history for the organisation's assets.

2.2 Inspection-Centric Condition Monitoring Reports

Condition monitoring information is typically delivered to maintenance personnel in an "Inspection Centric" format. That is, it is usually a written report in Microsoft Word, Excel or PDF format that is specific to a single inspection technique, for example, Thermography. A well written condition monitoring report will summarize the problem areas of plant and outline the recommended corrective / preventative actions at the top of the report. This allows the maintenance personnel to flick through the first few pages of the report and action any necessary preventative or corrective maintenance recommendations before filing it. However, often the recommendations in the report are based only on the results of that specific inspection using a particular inspection technique. They may not take into account the holistic health of the component by considering other predictive maintenance data that is available. To do this requires a "Component-Centric" view of the condition monitoring data. That is, For a specific component, maintenance personnel need to see an entire set of current and historical condition monitoring data across all condition monitoring techniques. If the condition monitoring data is delivered and stored in an "Inspection-centric" format such as non-divisible written reports, then maintenance personnel will need to manually find and collate information from appropriate reports, which is a time consuming and potentially error prone process.

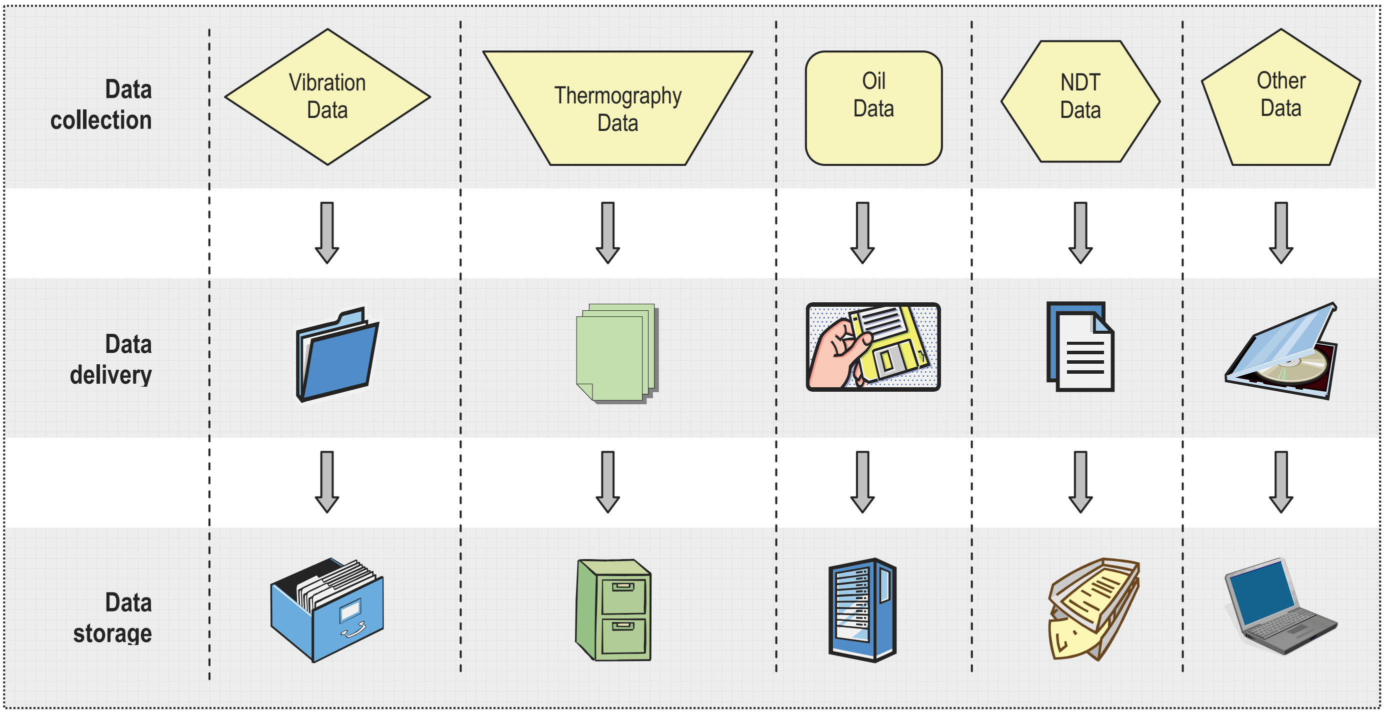

Figure 1: Typical ad-hoc condition monitoring data management results in 'silos' of condition monitoring data. It is difficult to share or collate condition monitoring information across the organisation. Obtaining a holistic view of the current health of all assets can be almost impossible.

2.3 The Limitations of the Status Quo

The ad-hoc storage of "Inspection-centric" condition monitoring reports inhibits an organisation's ability to quickly access and further leverage the condition monitoring data.

Inability to quickly understand current plant condition and identify trouble spots: It becomes difficult for organisations to quickly and easily obtain an overview of the current health of the assets in an area of plant. For example, to understand which assets in the plant are currently in poor or critical condition, a maintenance manager would need to manually collate and analyse all of the relevant recent condition monitoring reports.

Inability to quickly retrieve an exhaustive history of condition monitoring data and trends for a particular component: Often, maintenance personnel will need to review an exhaustive history of the condition monitoring data for a specific component. Take for example a vibration monitoring report that indicates that a particular gearbox may be approaching failure. A decision needs to be made to either allow the gearbox to run or to schedule preventative maintenance. To make the most informed decision the maintenance personnel should review all relevant condition monitoring data for that component. This may include reviewing historical vibration monitoring reports for the suspect gearbox to see if this was the first reported indication of the potential failure or whether the failure indications have been trending upwards over some time. Additionally, relevant oil analysis, thermography and NDT data for the suspect gearbox should also be reviewed for any supporting or contradicting evidence of an impending failure. For organisations that take an ad-hoc approach to storing condition monitoring data, the maintenance personnel will be required to manually find the relevant reports and then collate and analyse this information. In many cases, this work is too difficult and time consuming so the maintenance decision is made based purely on the evidence presented in the most recent condition monitoring report.

Inability to add value to condition monitoring data: Organisations lose the ability to turn condition monitoring data into knowledge through data mining. For example, an emerging trend of poor health of similar assets across the enterprise may identify the need for a maintenance strategy review or even a design review. An ad-hoc approach makes it infeasible to trowel through condition monitoring data across the entire enterprise and to extract the knowledge contained within the data.

3 WHAT IS BEST-PRACTICE CONDITION MONITORING DATA MANAGEMENT?

Best-practice condition monitoring data management is a system of three equally important and inter-dependent components working in synergy.

- The underlying ***information system*** is the repository for the organisation's condition monitoring data. It is driven by *people* using well defined and documented *processes*.
- ***People*** are responsible for the day to day management of the system. They develop and use *processes* to enter and consume data in the *information system*.
- ***Processes*** ensure consistent data entry from all relevant sources of condition monitoring data. The *processes* also ensure that the authorised *people* are properly trained and extract maximum value from the data contained in the *information system*

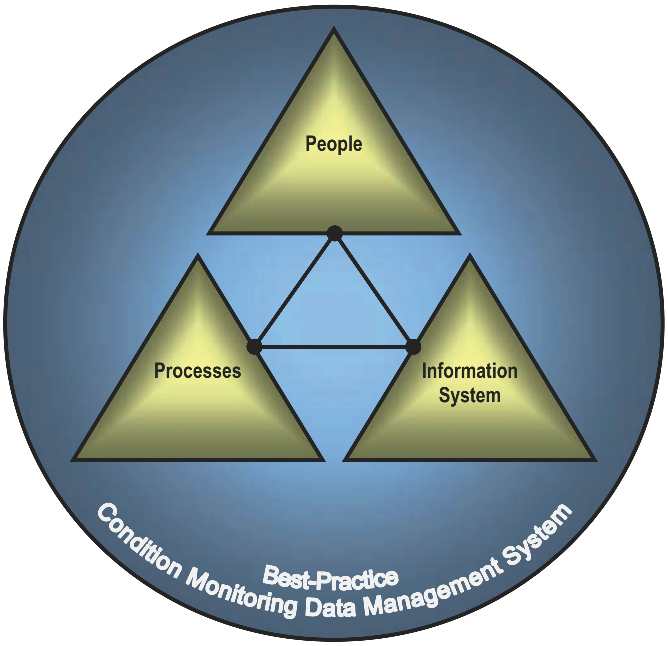

Figure 2: A Best-practice system consists of three equally important and inter-dependent components working in synergy

3.1 Information System

To allow an organisation to realise the true value of condition monitoring data there needs to be a fundamental change to the way that this data is managed. Typically, condition monitoring reports are delivered to the organisation in a non-divisible entity like a Word or PDF document. Instead, the data contained within the reports needs to be "groomed" into a collection of individual records of observed equipment condition, or "Condition Records". Each "Condition Record" is a set of data fields that in most cases gives the maintenance personnel enough information to 1) Understand what test was done and when, on what component and by whom 2) Understand what the interpretation of the observed test results was and 3) Understand what preventative maintenance, if any, is recommended. This is, regardless of the technique used, the results for each individual condition survey should be distilled into a common set of data fields such as

Component Tested, Test Date, Technician, Test Technique, Interpretation of Results and *Maintenance Recommendation(s).* The process of grooming the data ensures data consistency between test techniques and trims the data of all non-essential information. This allows the maintenance personnel to quickly understand the situation without being overwhelmed with unnecessary data. While additional test specific information (a vibration frequency spectrum for example) should be accessible with just a few extra mouse clicks, in most cases it is not required in the day-to-day management of the plant.

The process of grooming the condition monitoring data before it is stored is a key enabling step for achieving best-practice condition monitoring data management. Simultaneously, the underlying storage system for condition monitoring data must be changed from existing ad-hoc systems such as filing cabinets or hard disk storage, to a dedicated (but not necessarily complex) information system. The information system must be capable of storing the groomed condition monitoring data for each asset in the plant. It must also then allow maintenance personnel to query this information, ideally from any location and at any time.

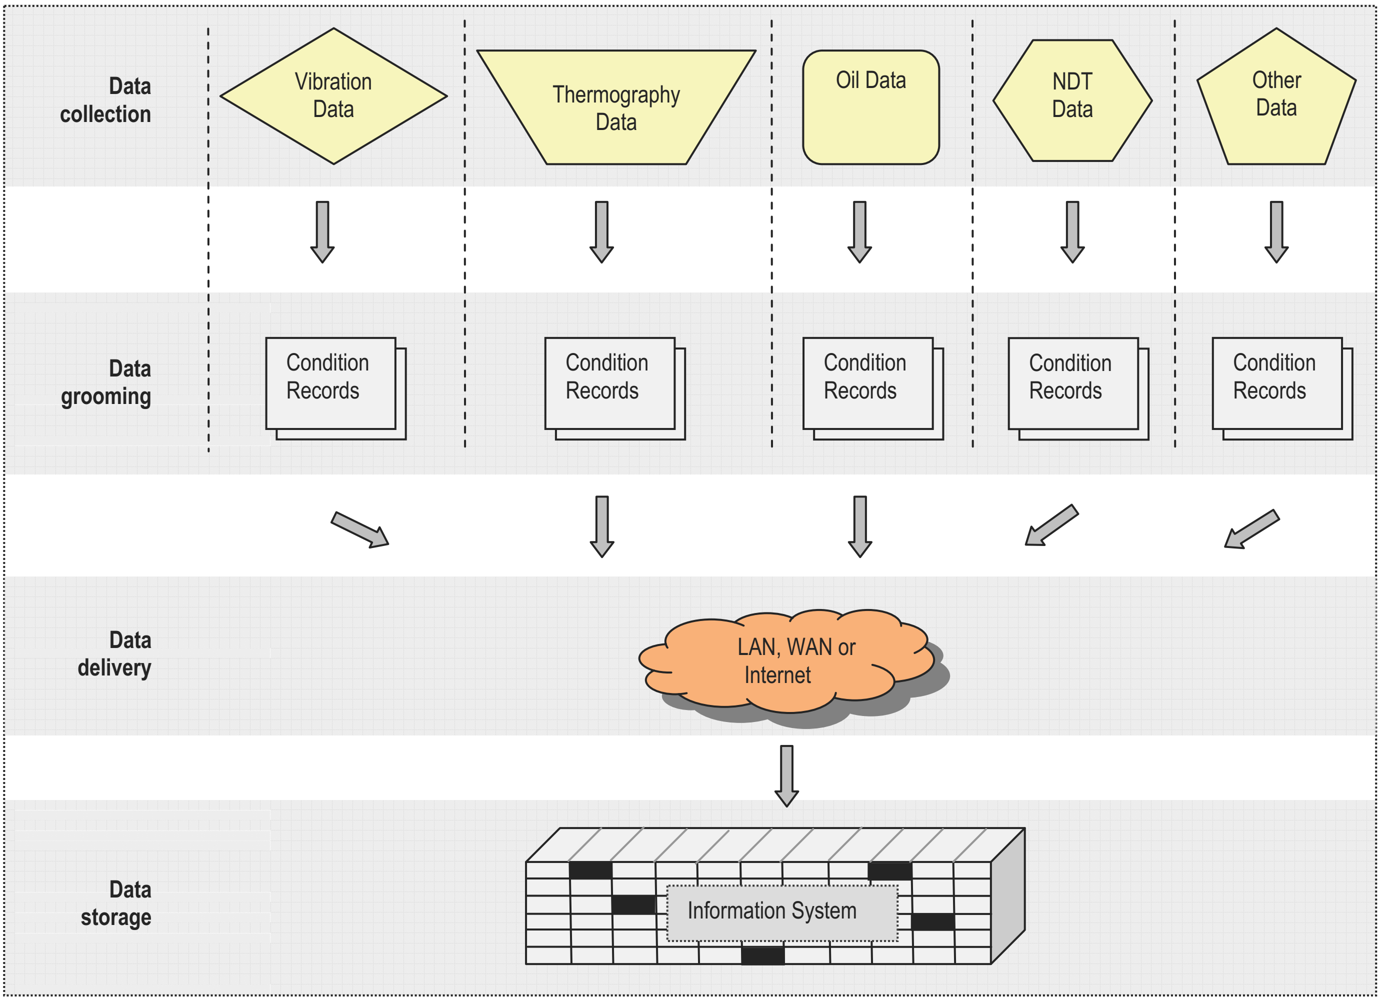

Figure 3: A Best-practice approach to condition monitoring data management requires the data from each technique to be "groomed", that is, broken down into a basic set of common data elements, before being delivered to an information system. This approach enables the data to be easily accessed by everyone in the organisation and also allows for value adding through future data mining.

3.2 People

Making the transition from ad-hoc to best-practice requires the commitment of a number of different groups of people from both inside and outside the organisation. While maintenance personnel will consume the data in the information system on a daily basis, other people such as project managers, expert consultants, external contractors, OEM employees and IT Support staff may all be required to implement the system and to keep it running. All of these people need to understand the potential benefits of a best-practice approach and need to be aligned to the goal of achieving it.

3.3 Processes

A set of well defined process and procedures is required to commission and maintain a best-practice system. Well defined processes will ensure that data integrity and completeness is maintained and that maximum value is leveraged from the collective condition monitoring data. Typical processes might include

- Well documented data formatting and transmission standards to ensure data integrity in the likely case that there is more than one source of condition monitoring data
- Developing training procedures and user manuals to ensure that maintenance personnel extract the most value from the organisation's consolidated condition monitoring data.
- A complete set of IT system management processes to ensure that the underlying information system remains secure, stable and available around the clock.

4 WHAT ARE THE BENEFITS OF BEST-PRACTICE CONDITION MONITORING DATA MANAGEMENT

There are significant direct and indirect benefits for the organisations that achieve best-practice condition monitoring data management.

Silos of data are eliminated: Organisations benefit through instant enterprise-wide access to condition monitoring data. There is only one single, centralized storage location for all data and provided it is an Internet based system, authorized personnel can access the data at any time and from any location. There is minimal effort required to collate condition monitoring data across multiple techniques for a particular asset. Maintenance decisions are more informed and more efficient because all relevant data is considered, rather than just the results of the most recent condition monitoring report for the asset in question. The ability to quickly and easily search for and find all relevant condition monitoring data for an asset could collectively save hundred's of person-hours across the enterprise each year. This is particularly true if the organisation is involved in detailed reliability improvement projects, such as RCM, where a detailed analysis of component history and failure modes may be required. In this case, a detailed condition monitoring history is a good complementary source of failure data to the work order history contained in the CMMS system.

Ability for multi dimensional data analysis: The information system will allow maintenance personnel to effortlessly retrieve a complete condition monitoring history for a particular component. Just as easily, the information system can retrieve alternative views of the data, such as a snapshot of the current health of all assets across the plant. This particular view of the data will result in maintenance activity being better directed towards those assets that need it the most. If a criticality analysis of the plant has been conducted, this information can be combined with the condition data to show a matrix of condition severity versus component criticality. Components that are in poor condition *and* highly critical with respect to risk to safety, environment or production potential are flagged to ensure they receive prompt attention.

Other views of the condition monitoring data may include various exception reports, for example the system could report on any items of equipment that were be inspected for some reason, for example, access to the asset was not granted by the operator. Risk is reduced by identifying those assets where inspections are repeatedly missed, particularly if the asset is highly critical. Another example would be an exception report of outstanding maintenance recommendations. This can help ensure that maintenance personnel acknowledge and act on maintenance recommendations made by the condition monitoring technicians and that nothing falls through the cracks.

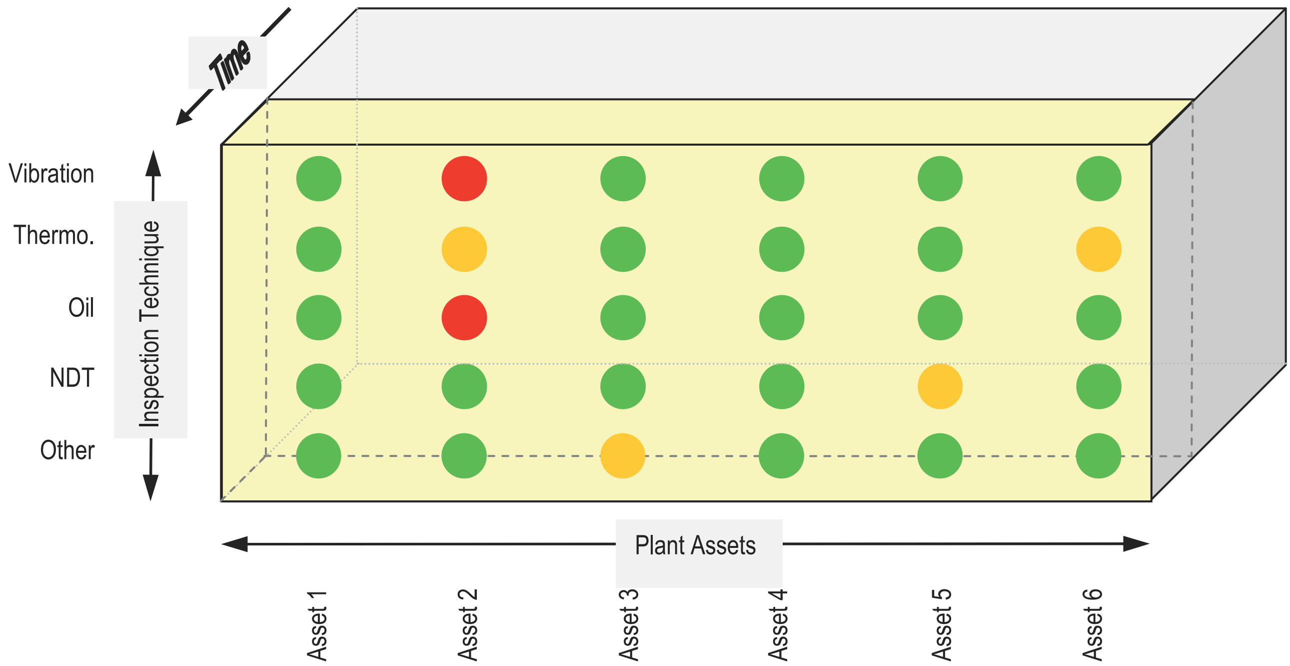

Figure 4: A dedicated information system enables multi-dimensional views of the data. In this example, maintenance personnel can view an up-to-date snapshot of overall plant health. Based on the most recent vibration, thermography and oil surveys, Asset 2 is currently in poor condition and requires maintenance

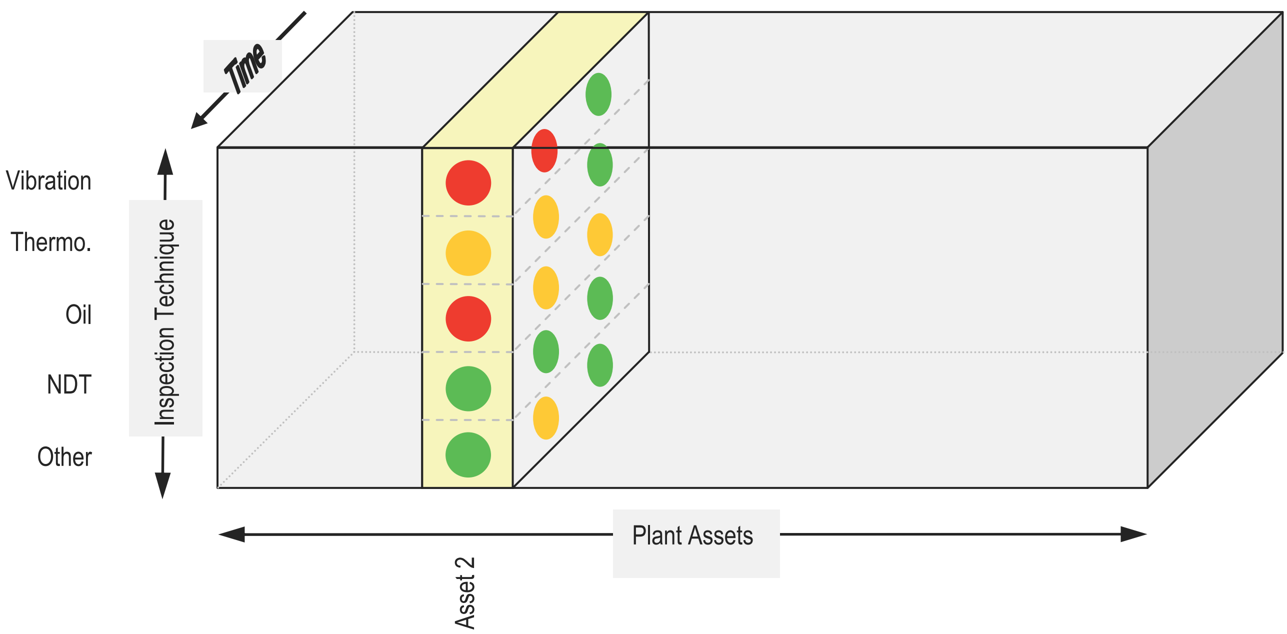

Figure 5: In an alternate view of the data, the user is able to view a complete condition monitoring history across all inspection techniques for Asset 2. This holistic view of the health of Asset 2 enables the maintenance personnel to make the most informed maintenance decisions.

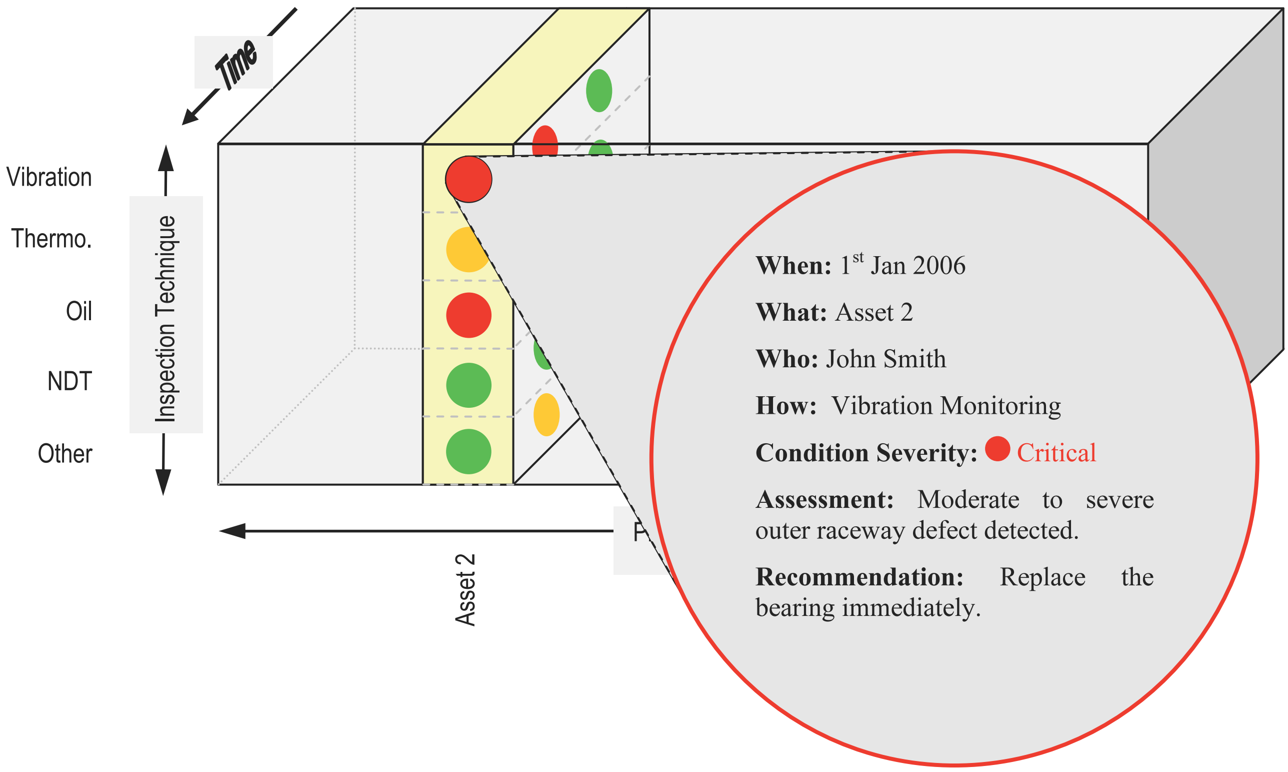

Figure 6: With a few mouse clicks the user can drill down into the individual details of each inspection

Reduced failures through rigorous management of Maintenance Recommendations It becomes easier to actively manage the maintenance recommendations made by the various suppliers of condition monitoring services. The information system can track and flag any assets that have outstanding maintenance recommendations which helps ensure that nothing falls through the cracks. This is also an obvious integration point with the CMMS system. Ideally, maintenance personnel can review the list of outstanding maintenance recommendations on a daily or weekly basis and easily trigger work orders in their CMMS system with a few simple clicks, saving data entry time and increasing data integrity. Effective management of maintenance recommendations also gives important feedback to the condition monitoring technician who needs to know whether previous recommendations were followed or deferred before conducting subsequent surveys on that asset.

Calculating the true value of the condition monitoring program: The organisation can understand and quantify the value of the condition monitoring program by tallying the total savings of avoided downtime as a direct result of the recommendations made by condition monitoring technicians. This can assist the maintenance group justify the annual condition monitoring spend.

Monitoring key performance indicators: Centralising the condition monitoring data enables a number of KPI's to be monitored. An example would be an overall score of plant health. A successful condition monitoring program should result in this score being maintained or improved over time. Different areas of the plant can be benchmarked against each other or a nominated best-practice goal. Another example would be a score of the number of outstanding maintenance recommendations in each area of the plant. This will rank each area on how quickly the maintenance personnel are acting on the recommendation made by the condition monitoring technicians.

Ability for data value adding: The process of grooming the condition monitoring data into a common format enables potentially limitless analysis to be conducted, at the asset, plant or even enterprise level. Over time, the collective value of this data becomes much greater than the sum of its parts, allowing enterprises to convert this data into more valuable knowledge. Consider the following examples

1. *Value add 1: Optimizing the condition monitoring program*: The information system can identify the components that remain in "as new" condition over an extended period of time. The organisation can periodically conduct a detailed analysis of these components and perhaps increase the inspection interval or even remove the component from the condition monitoring program all together.

2. *Value add 2: Enterprise wide query for problem components*: If a problem component is identified within an organisation it becomes easier to find out whether other areas within the organisation or even the enterprise are experiencing similar health problems with that component. This may help identify components where design revision is required or an alternative component should be sourced.

3. *Value add 3: Enterprise wide benchmarking of similar assets:* The long term condition of similar assets across the organisation can be compared. This can highlight maintenance practices that result in better long term asset performance. Conversely, poor or inconsequential maintenance practices can be identified and eliminated.

5 THE ROADMAP – HOW TO MAKE THE TRANSITION FROM AD-HOC TO BEST-PRACTICE CONDITION MONITORING DATA MANAGEMENT

Like any business process improvement project, the path to achieving best-practice management of condition monitoring data can be difficult. Significant challenges can arise in obtaining the support of management and stakeholders as well as coordinating all of the affected parties, particularly if there are multiple sources of condition monitoring data. It is important to begin by conducting a thorough analysis of the existing systems in the organisation versus the desired best-practice. From there, the scope of work becomes clearer and a cost/benefit analysis can be presented to stakeholders. It is likely that a cost/benefit analysis will strongly support the investment in a best-practice approach to condition monitoring data management.

A suggested approach to the process improvement project is outlined below

1. *Choose a best-practice champion:* Nominate someone within the organisation, or even a third party, to take responsibility for spearheading the push towards best-practice data management. The champion should be able to demonstrate the following experience and capabilities.
    a. Familiarity with data management and information systems.
    b. A basic understanding of the technology and processes used for each of the condition monitoring techniques
    c. A broad understanding of the organisation and all sources of condition monitoring data (both internal and external)
    d. Excellent communication and project management skills
    e. The champion should have the authority to commandeer the required resources to keep the project moving. This may include OEM's, in house and contract Condition Monitoring suppliers, maintenance personnel, management and other support personnel (IT Support Staff for example)

2. *Map the current business processes in the context of condition monitoring data:* Conduct an analysis of all sources of condition monitoring data across the organisation. This could include in-house technicians, OEM's, condition monitoring contractors and permanent on-line systems. For each source of data document the data format and how it is delivered to the maintenance personnel. Also document how the data is then permanently stored and where; filing cabinets, network hard drives, information systems, etc.

3. *Map the desired business process:* Identify and map the ideal business processes that would allow the organisation to achieve the benefits of best-practice condition monitoring data management. In particular, consider the ideal information flow between the condition monitoring technicians and the consumers of the data.

4. *Determine the functional requirements of the information system:* List the functions that an ideal information system will perform. Consider the various users of the system and the way in which they need to consume the data. For example, a maintenance manager might just need to see a rolled up summary of current plant health each day while a planner may need to see a holistic view of the condition monitoring data for an asset. Can the existing CMMS system be customised to meet these requirements? Is there an existing off-the-shelf solution that can be adapted or is there are need to develop a dedicated system?

5. *Decide on the people required to implement the desired business process:* Achieving the change to best-practice analysis above will require the ongoing efforts of a number of people, both inside and outside the organisation. Identify which people will be affected and how. If necessary, precisely document the changes that will be required from these people and the ongoing responsibilities and expectations moving forward.

6. *Decide on the processes required to reach the desired business process:* A new set of processes will be required to ensure that entire system operates effectively on a day-to-day basis. The data format and data entry and transmission expectations need to be documented. New training processes will need to be developed and delivered to personnel who supply condition monitoring data to the system. Training will also be required for the maintenance personnel who consume the data on a day-to-day basis.

7. *Conduct a gap analysis:* By comparing the current verses the desired business processes, determine the scope of work required to bridge the gap.

8. *Formulate a plan to implement the required changes to the processes, people and information systems*. At this stage the scope of work should be clearer and a work breakdown can be formulated. From this work breakdown the cost and duration of the entire process improvement project can be estimated.

9. *Conduct a cost/benefit analysis*: Compare the estimated cost of the project to the potential long term benefits. To estimate the financial benefits of a best-practice approach, consider the ongoing savings through
    a. Eliminated failures due to better integration and communication of condition monitoring data. For this step it may help to analyse a number of previous failures to determine whether a best-practice approach to data management may have eliminated the failure or reduced it's financial impact.
    b. Time saved through instant access to integrated condition monitoring data across the enterprise
    c. Potential benefits of the ability to convert data to knowledge through data mining across the enterprise.

    In many organisations, the cost benefit analysis will show a payback on investment well within the first few years. This detailed cost/benefit analysis can be presented to the organisation stakeholders and a go/no-go decision can be made.

10. *Formalise a project plan and communicate the plan to all affected parties:* Provided that stakeholders are now committed to the project, the work breakdown can be more formally set into a project plan. The plan should set some specific implementation goals and deadlines. It will also show the requirements for labour and financial resources to allow the project to be accurately budgeted. Use the plan and other supporting material to communicate to all effected parties
    a. The objectives of the process improvement project
    b. The anticipated benefits of moving to a best-practice approach
    c. How they will be effected during the implementation phase of the project and what the ongoing expectations are
    d. Where the project deadlines and milestones are.
    e.

5.1 The Pitfalls and Challenges

There are a number of pitfalls and challenges that may arise when improving the condition monitoring data management processes. Some of these challenges are identified and risk mitigation strategies are suggested.

Lack of stakeholder support: It is vital to the success of the project that adequate resources are allocated and there is full support from stakeholders. To ensure this is the case it is critical that a detailed cost / benefit analysis is conducted and presented to the stakeholders so that the true value of the process improvement project is understood from the start. This is not a process improvement project that can be delegated to an employee to be undertaken in their "spare time". It requires dedicated resources and the cooperation of a number of parties both inside and outside the organisation.

Relying on the CMMS to manage condition monitoring data: Typically, existing CMMS systems are not ideally suited to managing large volumes of condition monitoring information in the manner described above. To do so the CMMS will likely require some customization, which may be both time consuming and expensive. A better solution may be to adopt or custom develop a dedicated information system specifically for this task. The chosen information system may be integrated with the CMMS system where logical, for example, progressing a maintenance recommendation into a CMMS work order.

Difficulties in integrating multiple sources of condition monitoring information: In some organisations there will be many sources of condition monitoring data. This can make it difficult to "groom" the condition monitoring data into a common format. One way to mitigate this risk would be to narrow the scope of the initial project to a smaller part of the overall condition monitoring program. For example, an organisation may choose to integrate only oil and vibration monitoring data to begin with. This will reduce the initial cost and risk of the project and allow teething issues to be rectified before the scope is widened to include the remaining condition monitoring techniques. Another way to mitigate this risk would be to consolidate the suppliers of condition monitoring data across the organisation, hence reducing the sources of data. Once the system is in place, it is also vital to ensure that all suppliers of condition monitoring data (both internal and external) strictly adhere to the established data entry processes to ensure data integrity and the completeness of the data. This again highlights the importance of well defined and well communicated processes.

6 CONCLUSION

Best-practice management of condition monitoring data isn't itself a solution to overall plant reliability. However, it is an essential part of the wider maintenance program. It is difficult for organisations to achieve maintenance program maturity when there is an ad-hoc approach to storage and management of condition monitoring data. With a robust data management system in place organisations save significant time and money in the short term through quick and easy enterprise wide access to the data and through more informed and timely maintenance decisions. In the long term these organisations are able to convert this data into knowledge to optimize the predictive maintenance program and improve overall plant reliability.

OPTIMIZATION OF INTENTIONAL MISTUNING FOR BLADED DISK : INTENTIONAL MISTUNING INTENSITY EFFECT

ByeongKeun Choi[a], Kim Hack Eun[c], Kim Hyo Jung[b], Jeong Haneol[b], Gu DongSik[b], Kim Myung Kwan[c] Author

Abstract: In turbomachinery rotor, there are small differences in the structural and/or geometrical properties of individual blades, which are referred to as blade mistuning. Mistuning effects of the forced response of bladed disks can be extremely large as often reported in many studies. In this paper, the pattern optimization of intentional mistuning for bladed disks considering with intentional mistuning intensity effect is the focus of the present investigation. More specifically, the class of intentionally mistuned disks considered here is limited, for cost reasons, to arrangements of two types of blades (A and B, say) and Genetic Algorithm is used to optimize the arrangement of these blades around the disk to reduce the forced response of blade with intentional mistuning intensity levels.

Key wards : Intentional Mistuning, Mistuning Intensity, Bladed Disk, Pattern Optimization

1 INTRODUCTION

In a dynamic analysis of a turbomachinery rotor, one traditionally has assumed that the blades are identical. But, in practice there are small differences in the structural and/or geometrical properties of individual blades, which are referred to as blade mistuning. Much of the vast literature on this topic [1-5] has assumed these differences to be small and to arise either during the manufacturing process and/or as a consequence of in service wear. The motivation for considering such small variations is that their effects of the forced response of bladed disks can be extremely large as often reported in the above studies. Interestingly, the large sensitivity of the tuned system to these small variations has been linked [3] to its high level of symmetry.

In this light, it would appear beneficial to design bladed disk not to be tuned, namely to exhibit intentional mistuning, to reduce the sensitivity of the forced response to unintentional mistuning. Certainly, the consideration of intentional mistuning is not new [1,2] however, in the context of forced response, some papers [6,7] have only recently investigated the use of harmonic patterns of mistuning. Recently, the authors have investigated and identified the effect of intentional mistuning which can significantly reduce the magnification of the forced response due to unintentional random mistuning. [8,9]

In this paper, the pattern optimization of intentional mistuning for bladed disks considering with intentional mistuning intensity effect is the focus of the present investigation using the two sets of blades A and B. Genetic Algorithm is used to obtain the pattern(s) that yields small/the smallest value of the largest amplitude of response to a given excitation in the absence of unintentional mistuning using simple model (one-degree-of-freedom per blade) of bladed disks.

2 OPTIMIZATION APPROACH

In view of the complexity and cost of intentional mistuning, one should not look simply at set patterns, for example the harmonic patterns [7] but rather one should optimize the pattern to reduce as much as possible the amplification of the forced response to a given excitation or set thereof. Accordingly, it was suggested by authors that the use of intentional mistuning is probably not a standard design tool but would be very valuable if: (a) it yields a large decrease in sensitivity to unintentional mistuning, and (b) it involves a minimum number of types of blades, ideally 2. [8,9]

Therefore, in this paper, the disk will first be assumed to support only two different types of blades (blades A and B, say) and their arrangement that yields the smallest amplification of the forced response will be sought with different intentional mistuning intensity. Many sets of blades A and B were selected to change the intentional mistuning intensity having natural frequencies lower and higher, respectively, than the tuned ones (type C) in this paper.

Mistuning also produces a very nonlinear effect on the forced response. That is, by switching the order of the blades around the disk, dramatic differences can be obtained in the variability of the blade-to-blade amplitudes of vibration as exemplified in particular by the harmonic mistuning analysis of Mignolet et al. [4]. It might thus be suspected that there exists a series of local optima in the complex, high dimensional space over which the optimization must take place. In this light, the present optimization effort has relied on the use of Genetic Algorithm (GA) [10].

3 SIMPLE GENETIC ALGORITHM

GA are particularly well suited for the present effort because the design variables only admit discrete values (i.e. a specific blade is only of type A or B), see References [10] for further details. The simple genetic algorithm (SGA) used here relies on a population of n_{pop} bladed disks each of which is a random arrangement of N genes (the type A or B of the different blades). Accordingly, each bladed disk can be characterized by a sequence of N A and B letters, for example AABBBBAA…, which evolves from one generation to the next according to the rules of selection, crossover, and mutation until all the chromosomes yield essentially similar values of the fitness or objective function(the maximum amplitude of blade response).

The fitness proportionate selection, the single point crossover technique and an exponentially decreasing mutation function was used in the present investigation. Also, the one elite reservation strategy was used in this paper according to which the best disk is retained unchanged from one generation to the next.

4 SIMPLE BLADED DISK MODEL

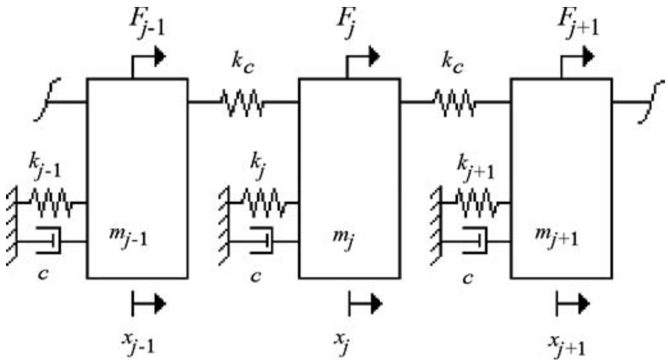

Figure. 1 Single-degree-of-freedom per blade disk model

$$F_j = F_o \cos\left(\omega t + \frac{2\pi r (j-1)}{N}\right)$$

$m_t = 0.0114$ kg, $k_t = 430{,}300$ N/m, $c = 1.3814$ N·s/m, $N = 4$ blades, $F_0 = 1$N, $r = 3$,

k_j : normal distribution of mean k_t and standard deviation σ

To identify the effect of intentional mistuning intensity to optimum pattern of intentional mistuning, the SDOF per blade model shown in Fig. 1 was first considered with the coupling stiffness (k_c = 45430 N/m) and damping coefficient ($c = 1.3814$ N s/m) with only 4 blades was considered in this paper. Specifically, each of the N blades is represented as a single mass (m) which is connected to the ground (i.e. the disk) and the aerodynamic and structural coupling between blades are modeled by springs (k_c) and dashpots (c). In the sequel, it is assumed that the coefficient vanishes in this paper. The values of mass (m = 0.0114 kg), and stiffness (k_t = 430,300 N/m) have already been used in a previous investigations to model a high-pressure turbine stage is used in this paper.

The computations proceeded as follows. The bladed disk model and engine order of the excitation were first selected. The SGA described above was then used to obtain the intentionally mistuned disk formed of blades A and B such that the maximum of its response over the entire frequency range was the smallest possible.

First, the intentional mistuning intensity to optimum pattern of intentional mistuning is identified. Many sets of blades A and B were selected to change natural frequencies lower and higher, respectively, than the tuned ones (type C). In analysis, the stiffness of A and B type blade is selected to have lower and higher than the tuned ones. For example, in table 1, A(0.9) and B(1.1) means that A and B have natural frequencies 5% lower and 5% higher than C. The optimum pattern of intentional mistuning is searched with 45,430 N/m (an average to strong blade-to-blade coupling level) by Genetic Algorithm.

Table 1 show the comparison of optimization result by Genetic Algorithm for each intentional mistuning intensity level with the tune system (all C:1.0682e-4 m and all B) in 3th engine order case.

Table 1 The comparison of optimization result by Genetic Algorithm for each intentional mistuning blade set with the tune and other mistuning pattern

Mistuning blade type		Optimum distribution
A	B	
0.7	1.3	BBBB = 9.5817e-5 m (ABBA = 1.0026e-4 m)
0.8	1.2	ABBA = 9.7014e-5 m, (BBBB = 9.9172e-5 m), 9.18%
0.9	1.1	ABBA = 9.9242e-5 m, (BBBB = 1.028e-4 m), 7.09%
0.91	1.09	ABBA = 1.0186e-4 m, (BBBB = 1.0326e-4 m)
0.9125	1.0875	ABBA = 1.0261e-4 m, (BBBB = 1.0305e-4 m)
0.92	1.08	BBBB = 1.0344e-4 m, (ABBA = 1.0536e-4 m)
0.94	1.06	BBBB = 1.0425e-4 m, (ABBA = 1.163e-4 m)
0.96	1.04	BBBB = 1.0529e-4 m, (ABBA = 1.2457e-4 m)
0.98	1.02	BBBB = 1.0619e-4 m, (ABBA = 1.1438e-4 m)

In Table 1, the optimum pattern that yields small/the smallest value of the largest amplitude of response to a given excitation by GA was changed according to the intentional mistuning intensity (mistuning blade type) level. The genetic optimization algorithm yielded the configuration ABBA and BBBB the highest responding blade in each mistuning blade type. Fig. 2 ~ 4 shows the forced response of optimum, tuned and other A/B patterns in three mistuning type. It is identified that ABBA are better then tuned and other patterns in cases of A(0.9), B(1.1) and A(0.9125), B(1.0875). But in case of A(0.94) and B(1.06), BBBB is better than tuned and ABBA.

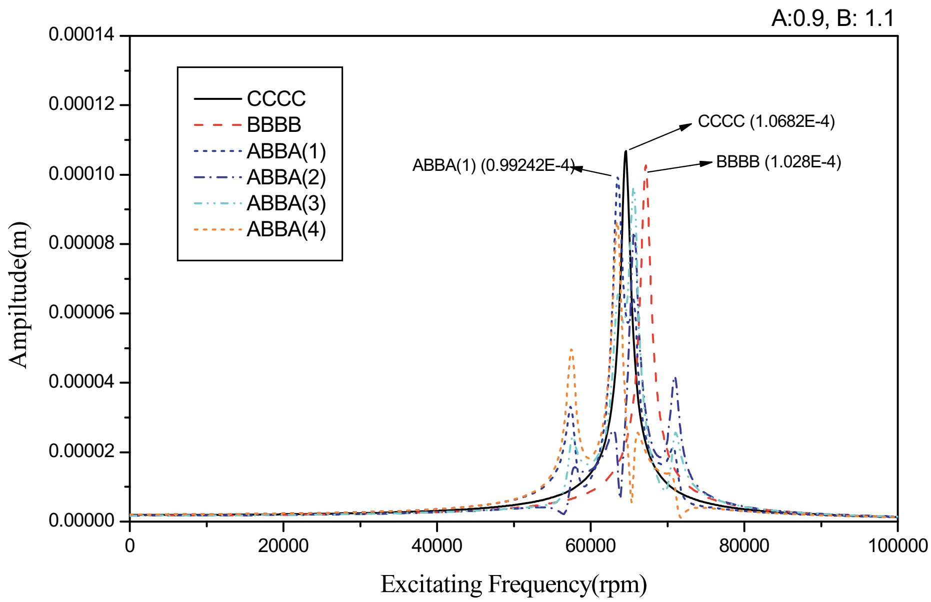

Figure. 2 Comparison with forced response of optimum, tuned and other A/B pattern(A:0.9, B:1.1)

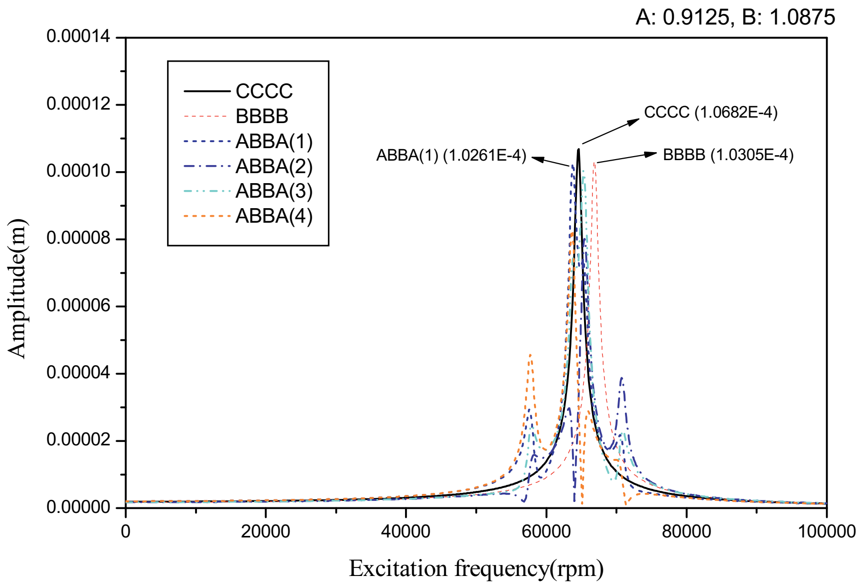

Figure. 3 Comparison with forced response of optimum, tuned and other A/B pattern(A:0.9125, B:1.0875)

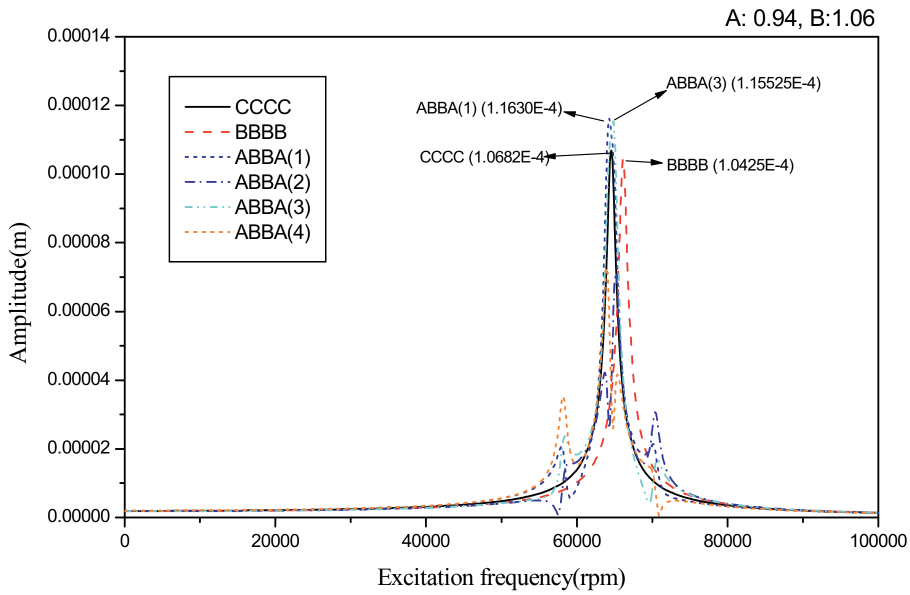

Figure. 4 Comparison with forced response of optimum, tuned and other A/B pattern(A:0.94, B:1.06)

According to Table 1, in A(0.9), B(1.1) and A(0.8), B(1.2), the max amplitude of blade is reduced to 9.18% and 7.09% than tuned one respectively. So, in this paper, more detail analysis around the A(0.9) and B(1.1) is needed to identify the effect of intentional mistuning intensity to optimum pattern of intentional mistuning. Table 2 show the comparison of optimization result for intentional mistuning intensity levels around A(0.9) and B(1.1) with the tune system (all C and all B) in 3th engine order case.

In Table 2, as the gab between A and B is larger, all A become worse; max amplitude is increased while all B and ABBA become good; max amplitude is decreased. Also, if the gab between A and B is equal, the larger A or the larger B is better than others. That means that the max amplitude is more reduced than tuned one.

Table 2 The comparison of optimization result for intentional mistuning intensity with the tune and ABBA

A	B	B - A	All A	All B	ABBA	Compare to all B	Compare to all C
0.9	1.1	0.2	1.1155e-4 m	1.028e-4 m	9.9242e-5 m	3.46%	7.09%

5 SUMMARY

The investigation of this paper focused on the pattern optimization of intentional mistuning for bladed disks considering with intentional mistuning intensity effect is the focus of the present investigation using the two sets of blades A and B. Genetic Algorithm is used to obtain the pattern(s) that yields small/the smallest value of the largest amplitude of response to a given excitation in the absence of unintentional mistuning using simple model (one-degree-of-freedom per blade) of bladed disks.

Through the optimization, it is found that the optimum pattern that yields small/the smallest value of the largest amplitude of response to a given excitation by GA was changed according to the intentional mistuning intensity (mistuning blade type) level. The genetic optimization algorithm yielded the configuration ABBA and BBBB the highest responding blade in each mistuning blade type in Table 1. Also it is identified that the gab between A and B is larger, all A become worse(namely, max amplitude is increased) while all B and ABBA become better(namely, max amplitude is decreased). If the gab between A and B is equal, the larger A or the larger B is better than others, namely, the max amplitude of blade is more reduced than tuned one in Table 2. Therefore, the effect of intentional mistuning intensity should be considered to optimize the intentional mistuning pattern which can reduce the forced response in blade.

IDENTIFYING AND MANAGING THE COMMUNITY INFRASTRUCTURE ASSET RENEWAL GAP

J Hennessy [a] and DG Platt [b]

a Municipal Association of Victoria, Melbourne, Victoria 3000, Australia.

b Anstra, Melbourne, Victoria, Australia.

Abstract: Sustaining our community infrastructure and assets is potentially the greatest challenge faced by Local Governments across Australia. At risk is the continued sustainability of assets which support the delivery of many of our community services. Most states have identified a substantial emerging gap in Local Government's capacity to renew it assets. We suggest the problem is broader than the conventional asset management activities and fundamentally requires that we have informed debate at both the national and local levels. In order to have such an informed debate we need access to reliable, consistent and relevant information. However, experience has shown that trying to obtain this information is difficult. In most cases it does not exist and where it does exist it is frequently inadequate. This paper outlines a project that is currently in progress that aims to develop a national framework for the exchange of community asset information. As a result we hope to be able to inform the debate that must occur if we are to solve the issue of the renewal gap for community assets.

Key Words: local government, renewal gap, community, assets, reference model, information framework

1 INTRODUCTION

Sustaining our community infrastructure and assets is probably the greatest challenge faced by Local Governments across Australia. The issue is not asset management as an end game, rather the continued sustainability of the communities in which we live, work and recreate. To put the problem in perspective Local Government is responsible for 81% of the nation's roads, has over $154 billion of assets, of which roads are 64% [1] and in 2003/4 spent over $3.8 billion on local roads [2]. Field observations suggest that a large proportion of this infrastructure is rapidly approaching the end of its useful-life, with a large gap emerging between our ability to sustain the renewal of these assets into the future. Whilst the astute have been able to foresee the problem it is only recently that governments have started to systematically assess the situation and quantify the problem. Over the last decade the states have each initiated projects that will help them better understand the true extent of the problem [3].

In Victoria the process of developing a shared understanding across all councils took its first major step through a review of asset conditions and asset management practices in 1997-1998, "Facing the Renewal Challenge"[4]. The outcome of the review was that for the first time it was possible to forecast community infrastructure and asset renewal requirements across the State using quantifiable and consistent measures that looked beyond the immediate budget cycles.

The Municipal Association of Victoria (MAV) has responded to this challenge through its development of the Step Program. The Step program has four key pillars, policy, strategy, plans and operations and through these four streams seeks to continue developing the collective understanding of the challenges faced by councils to develop realistic and achievable outcomes for their communities.

Through the Step Program the MAV has been able to develop a better understanding of the Renewal Gap for the various asset classes. A summary of these results showing the capital funding gap over various time horizons is shown in figure 1.

Evidence from programs, such as Step, demonstrate that the renewal gap is real. The issue is how to face the challenge. Continued professional development of asset management is core but in-itself is probably insufficient. We need to understand the purpose served by community assets; transforming the traditionally narrow focus on activities associated with asset management to the outcomes that community infrastructure and assets enable.

Ultimately, the purpose of renewing assets is not to preserve them but to enable communities to achieve the outcomes they belief are important to them and potentially their children. Within this context the debate about the renewal gap should not be restricted to a small subset of asset managers. Managing the renewal gap is an issue that goes to the heart of our aspirations for a safe thriving and prosperous community in which we learn, work, rest and play. Decisions about how we manage the gap will inevitably impact our vision for the community in which we live.

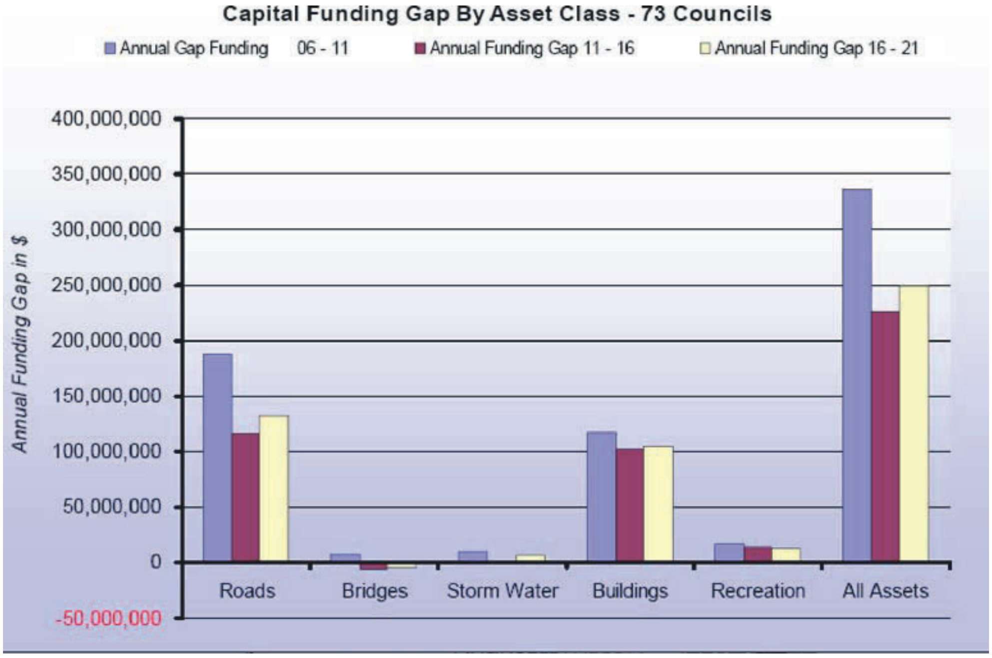

Figure 1. MAV Step Program Capital Funding Gap [5]

In order for the debate to be meaningful it must be supported by sound information. Communities must have access to the right levels of information so as to be empowered to make knowledgeable, even wise decisions about their future. To limit the depth of information or provide superficial summaries is to remove the right from our communities to participate in planning their future. The gap is real and without innovative thinking and potentially some significant changes to the way we manage them the gap will continue.

Understanding why we have a funding gap is important, not least so that we can learn from history. However, it is not the purpose of this paper to explore these issues, this has been done by others [4]. We suggest that the most appropriate way to manage this funding gap is through engagement and empowerment to make sound sustainable decision at both the local and National level.

2 NATIONAL DEBATE

The evidence collected through state programs such as Step [4] suggests that the problem is universal. However, in order to develop a well-founded debate at the commonwealth level we need collectively to aggregate the evidence to present a national perspective. Unfortunately, achieving this has been very difficult as there is no universally agreed core data set or commonality in the definitions or standards used to report information.

Engaging the Federal Government in a debate about innovative ways to bridge the gap in local resources required to sustain the well-being of our communities will require demonstrable evidence of a consistent national problem. In today's political environment there are many other issues competing for the attention and investment of federal resources, many of which have a higher profile in the public arena, such as emergency management, homeland security, refugees and energy and greenhouse emissions etc. The management of community assets and infrastructure has been delegated to Local Government. Local Governments sustain these assets through local rates and grants received from the Federal and State Governments. The impetus to change the status quo lies with Local Government; it must substantiate its case that the level of well-being we believe is appropriate for Australian citizens is not sustainable through the existing arrangements. Moreover, the onus is on Local Government to propose innovative alternatives that demonstrate sustainable and achievable outcomes, anything less is to abdicate the responsibility that has been delegated to it. However, the problem is a collective problem, it is not one that either Local Government or Federal Governments can solve in isolation. The issues are made complex by their interdependencies; robbing Peter to pay Paul is unlikely to provide a sustainable solution, we need to take a holistic approach, which is grounded in truth rather than opinion and myth.

To do this we need reliable, consistent and relevant data; data that can be aggregated to the state and national level yet substantiated down to a local level. To date the ability to generate this quality of information has remained illusive.

3 LOCAL DEBATE

The national debate is primarily focused on the redistribution of resources. The debate within local communities also focuses on the redistribution of resources but in a quite different way. The local community must grapple with the finality of resources. They must understand the potential impact caused by a change in the level of asset preservation on the outcomes and well-being of the whole community.

A realization that under the existing arrangements the sustainability of the outcomes supported by community assets is no-longer viable should trigger a double loop learning debate. The first loop looks at the practices of asset management; can we improve, can we close the gap – there is considerable onus on the professional practitioner to demonstrate improvement. The second loop looks at why we need the asset – the debate must explore the aspirations of the community, understanding the well-beings of our community:

- physical well-being – safe, efficient workable healthy
- economic well-being – thriving and prosperous local economy
- social cultural and spiritual well-being – balance, diversity, amenity, beliefs (not always easily measured as it goes beyond the tangible but often conspicuous by its absence)
- environmental well-being - sustainability, footprints, aesthetics, clean air, clean seas, healthy beaches etc.

It is the second loop that sets the terms of reference in which the professional asset manager operates. The problem is not simple. You can seldom plan to change the level at which an asset is preserved without consideration of several interdependent systems. Consider a drain, and the impact on flooding, which impacts the economic and emotional hardship endured, the value of property the attractiveness of the area or the health of the area. There are many interconnected links between the asset, the services it supports and the outcomes delivered to the community. If the level of service provided by the asset has to change then invariably the outcomes in the community must also change. This is a debate that ought to occur within the community, it may be facilitated by the professional asset manager but we argue it is ultimately a decision that must be made by the local community.

4 INTERDEPENDENT SYSTEMS

The need for asset information is not confined to the asset manager. Making our communities better, safer and more sustainable places requires innovative planning and informed decision making with many different and diverse organisations having a role to play. Many of these organisations are dependent upon Local Government’s services and asset knowledge. Many need access to timely information regarding the service/asset.

Not only are many of these systems dependent upon the services provided by community assets, but they are each interdependent upon the other, a change in the carrying capacity of a bridge structure can impact an emergency management plan, or visa versa a change in the type of proposed response vehicle could have an impact on the level at which the bridge asset needs to be preserved.

The commissions that define the purpose of these organisations are varied, ranging from the planning of integrated transport networks, to the management of counter terrorism for events such as APEC, or mitigation planning for the next bush fire or flood. Arising from their unique commissions each organisation has its own needs and more importantly its own view of the world, which usually results in their having a different view as to how the information should be structured. These individual views of the world are what make the exchange of information difficult. Currently, there is no universal language for the exchange of asset data or the development of consistent asset processes. However, it is our conjecture that their motivations are more tightly coupled, in that most organisations are motivated by the need to ensure the sustainable well-being of the communities they serve. It is this uniting factor that gives us hope that we can develop a shared information framework to support local and national dialogues.

5 FACILITATING GOOD DECISION MAKING

Currently, there are no agreed reference frameworks that consistently describe community infrastructure and assets, such as the road or drainage networks. Organisations that provide services across boundaries are faced with the challenge of aggregating a diverse range of municipal data. Likewise, when councils provide information to 3rd party agencies they find themselves undertaking a massive amount of duplicated effort as each agency describes the problem from their perspective.

As a result the problem is often deemed, too hard and decisions are based on perception not reality. Moreover the lack of information generally means that the only person capable of making an informed decision is the asset manager who is able to draw upon experience and tacit knowledge. However, there is no guarantee that the motivation that steers the heuristic decision making process is aligned with community needs. Furthermore, if we are to solve the issues raised by the renewal gap we will need to be innovative, more of the same will simply exasperate the problem.

In nature the most innovative environments are often the interfaces between systems such as the sea shore, the river bank, the forest edge. Applying the analogy to our situation we suggest that the best way to foster innovation in managing assets is to encourage the interface between asset managers and the multiple communities that have an interest in the outcome; the well-being of our community. We anticipate that the best opportunity for innovative solutions to our problems will arise from the diversity of interaction between communities.

In order to facilitate this interactivity we need to empower our participants with sound information. We need to ensure that the information is consistent at all levels of debate, from local through to national.

6 WHERE ARE WE?

We have got to the point where:

a renewal gap can be substantiated at the state level,

we recognise the need for Local Government to develop a case at the national level,

we understand the need to go beyond traditional asset management activities to manage outcomes,

there is a growing appreciation of the interdependence on shared information between agencies,

solutions to our problems will require innovation and collaboration across communities.

In order to progress there is substantial evidence to suggest that the major impediment is the lack of quality data [7], [8]. This impediment is expressed strongly in a recent review of the commonwealth road funding which was tasked with recommending a revised formula for the interstate distribution of the local road grants based on an assessment of the relative needs of the States for expenditure on maintenance and preservation of local roads. The review found that

"The data available on local road expenditure, local road use and the inventory of local roads and bridges to undertake the assessment of maintenance expenditure on local roads are far from ideal. This indicates that judgments about the most appropriate assessment methods need to balance conceptual considerations against considerations of the consistency and reliability of the available data.

The inadequacy of data that is critical to this Review raises concerns about how well we will be able to satisfactorily fulfil the requirements of the terms of reference." [7]

7 INTEGRATED INFORMATION FRAMEWORK

We need an integrated information framework, one that enables us to address the information needs at community, state and national levels. We don't want three more layers of information management. We must stop solving our problems in silos and work towards a systemic approach that can be scaled nationally; we need nationally consistent data. But not in the way that we have traditionally approached the problem, where for each problem we request yet another view of council data, slightly different from the last possibly varying one or two dimensions. But almost always cast from the perspective of the requesting agency. Typically the capability of these data models to be repurposed or to evolve with changing requirements is very limited, see figure 2. In most cases as the requirements change the cost of repurposing previous work escalates, making it easier to start yet another data exchange table. In contrast we propose an object model developed from the perspective of Local Government. Founded upon the responsibilities and obligations managed by councils and cast from the perspective of managing services within the local community.

The approach is to build an integrated model that spans the services across the whole spectra of council. Starting with councils' core data sets the framework builds out in a modular approach. Each data set is effectively its own holon but when combined forms an integrated system.

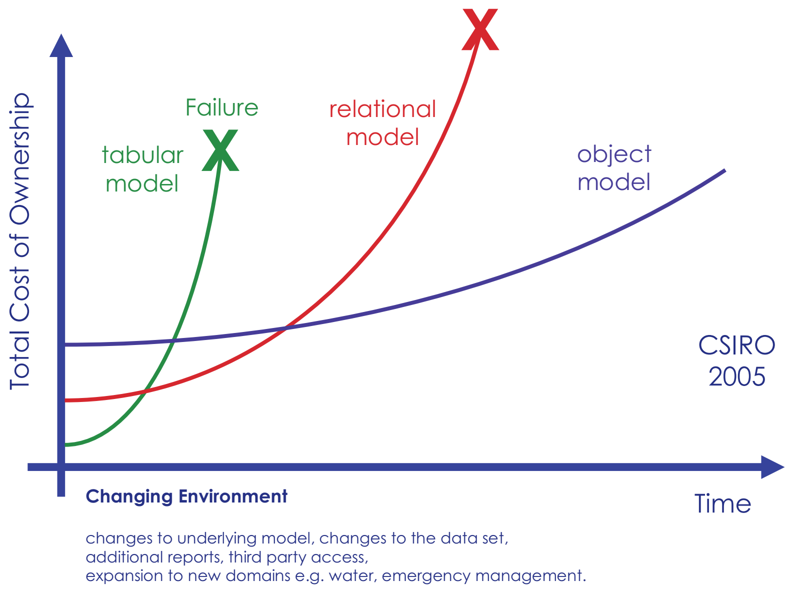

Figure 2. The Failure of Tabular Models to Support a Changing Environment. CSIRO 2005 unpublished.

The development of data modules is "Purpose Driven" where our fundamental purpose is

"the sustainable wellbeing of our communities"

The object of our concern may well be the physical asset, but the purpose that motivates the development of an information framework is not a bigger, better or perfectly preserved asset, rather a thriving and safe community.

Understanding that our purpose is larger than the asset itself is critical. The building of an information framework that serves the sustainable wellbeing of our community requires systemic thinking. It is this motivation that enables us to determine what information we need to manage and maintain. Furthermore, it is a motivation that is shared by other agencies [9].

All too often in public service the bar is set too low, the system is highly constrained within a very tightly defined terms of reference. Talk of a holistic or systemic approach is rhetoric; we do not expose ourselves to systemic thinking! We are incapable of thinking beyond our organisational boundaries. In asset management we have a situation where the organisational overlaps are multiple, the needs are different but not unrelated the motivation is fundamentally the same. We have an opportunity to do something different. To start thinking systemically, to break out of the silos and develop an information framework that serves multiple operational objectives.

The key to our success lies not in attempting to build some all encompassing system from the onset, but rather in defining an architectural framework that enables the progressive expansion of the core modules in an open and transparent manor. If our purpose is to support the sustainable well-being of our community then in order to make good decisions in planning for such a future the community and council require a holistic view of the municipality that provides an understanding of the interdependency between:

people and communities,

services,

resources – finance and depreciation,

physical environments,

governance and legal frameworks,

assets – infrastructure and amenities.

In order to help foster that understanding our asset management systems must support an information service that transforms the multiple, inconsistent and not so readily accessible asset data sources used to manage the diverse range of assets and the lifecycle of activities associated with them into a common view of assets that is harmonised with the other core services managed by council.

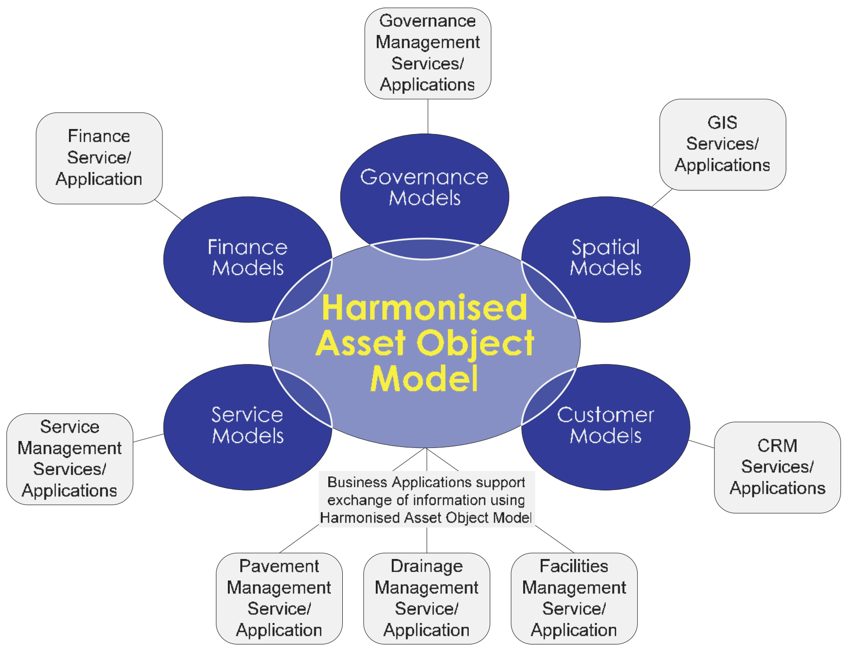

Figure 3. Harmonised Asset Reference Model Architecture

It is not just information about assets that our communities and council need; they require a whole range of knowledge. Because we are asset managers focused on the issues of renewal and the sustainability of our services the architecture diagram in Figure 3 deliberately represents the situation as an asset centric model. If we represented finance or customer management, we could transform the architecture to place these models at the centre. However, an asset centric starting point provides one of the best opportunities to act systemically.

The integrated information framework is not a solution to the Asset Renewal Gap, rather a necessary service that empowers people with information to make better decisions. The core component of the Information framework is a harmonised reference model. Essentially this is a common agreed reference model that enables the interoperable exchange and use of information relating to community assets.

The framework provides a mechanism for the exchange of information between the multitude of parties that have an ongoing need to access community asset data and the 600 local councils that are responsible for its collection and maintenance.

The Harmonised Reference Model is an object-oriented model of assets that councils manage on behalf of their community.

The Reference Model Contains:

1. Semantic Definition of the objects (people, roles, services, assets etc) that form part of the asset reference model.
2. UML static structure class model of objects.

Characteristics of the reference model are:

1. it is based on real world objects; as far as is possible the objects modelled are valid and readily recognisable constructs of the real world,
2. it has a modular component based structure, where objects are modelled once and may have multiple relationships,
3. it has the flexibility to manage inconsistencies; in building a harmonised model we recognises that there will be both a tight and loose fit between the model components and data stored in supporting business applications,
4. it is responsive to being viewed from multiple different perspectives; you should be able to ask lots of different questions of the same model,
5. there is a consistent interface used to access data across all components.

The methodology for developing the reference model is based on the object paradigm and endeavours to create as realistic a representation of the real world as possible. The outcome of this process is a model that remains robust and effective when viewed from multiple perspectives. The one model is better able to serve multiple purposes in supporting a diverse range of user needs.

8 THE BENEFITS

The benefits of an integrated information framework for asset data are that it will

1. enable the timely and efficient exchange of data,
2. ensure the interoperability of information exchanged across internal and external boundaries,
3. enable the aggregation of data from different areas,
4. facilitate the analysis and comparison of data.

The framework will lead to a more accurate and comprehensive understanding, at all levels of community - form local to national, of the services supported by our assets and the levels of investment required to sustain or improve the service outcomes.

The Information Exchange Framework will enable investment and funding organisations to substantiate wider planning decisions with factual data that is aggregated across organizational boundaries.

The agreed asset management ontology combined with the facility to exchange field values will deliver a more robust and better-informed platform for making decisions; in particular, where these decisions relate to the planning of sustainable development and services within our communities and the mitigation of hazards.

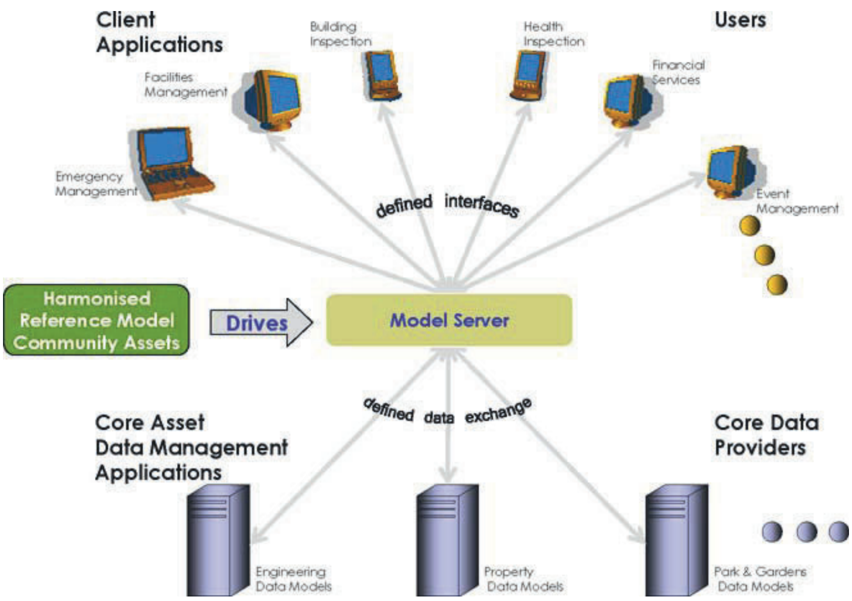

Figure 4. Integrated Information Framework Enables Multiple use of Asset Data

The end-to-end system will deliver more sustainable information management; the framework will provide the basis for a common standard for the representation of asset information. Thereby, reducing the requirement to support multiple exchange formats and bespoke system integrations. Data managers, such as utilities and councils will manage the data once, 3rd parties that require access to the data will obtain a consistent and agreed view of the data, minimizing the number of data mappings that have to be supported.

The information framework will enable councils and others to collect and maintain once, use many times without the repeated need to repurpose, see figure 4.

9 THE JOURNEY TO DATE

We set ourselves the following goals:

1. to develop an integrated information framework for community based asset management.

2. to establish technology environments for the interoperable exchange and management of asset data.

9.1 Progress

Our primary development has been in the area of Local Roads, working with both Queensland and Victorian Local Governments. We have developed a core object model based on the Queensland Roads Alliance data requirements. Work is currently being completed on a model driven server that will facilitate the interoperable exchange of physical data.

The model has as one of its foundations the concept of a network, which can be applied to other asset types such as drains, signs, footpaths etc. and work has just commenced on the extension of the model to include these assets.

Research Objectives

The outcomes of this project will be achieved through the following objectives:

The development of an "Integrated Information Framework" that will establish a methodology and ontology for the exchange of community based asset data. The framework will be instantiated through the development of reference models for local roads, drainage and irrigation networks and public furniture and signage.

The development of a harmonise interface with spatial modelling standards, namely, the ICSM Spatial Reference Model.

The development of a harmonise interface with Architectural and Civil Engineering (ACE) modelling standards, namely, the IAI IFC models.

The development of a model server to support the interoperable exchange of information between councils and other users, including shared service components and the extraction of data from backend systems.

10 NEXT STEPS

10.1 Framework Release

Over the next 12 months we intend to release further aspects of the framework, including:

1. Governance Arrangements regarding the knowledge and intellectual property generated in the Reference Model, including the process of acquiring consensus. The models are currently governed by an open source type license; the intent is to continue this form of license for the model but not necessarily the products that derive from it.
2. Partnership Arrangements and the mechanisms for dissemination of knowledge to practitioners and industry partners. There are many organisations operating in the area of public infrastructure and asset management. Our goal is to form strategic partnerships with key players to facilitate the acceptance, promotion and implementation of the model at a national and international level.
3. Publication of the Framework and Reference Model which represents the conceptualisation of our knowledge - an ontology; it will provide a controlled vocabulary that enables the description of relevant objects and the relations between them to be expressed in a formal way. It will provide a grammar for using the vocabulary terms to express meaningful concepts within asset management. The formal conceptualisation of our knowledge enables practitioners to make consistent, repeatable queries and assertions about our community assets.
4. Expansion of Scope of the network model to include water infrastructure assets.

10.2 Spatial Realisation

The ability to relate visually to models of the infrastructure/asset in planning and response is perceived by many practitioners as critical. Textual descriptions are considered insufficient to manage the complexities of the modern urban environment. There has been significant development in building similar reference models within the geospatial community. However, their focus has largely been on displaying the feature and its immediate attributes. The complex inter-relationships between assets their environment and the social context in which they exist has been ignored. Therefore, we need to bring these fields together in a harmonized interface.

Furthermore, as we continue to develop evermore-complex urban environments the need to exchange richer 3 & 4 dimensional information about the built environment becomes increasing relevant. The ACE community has been developing similar model to enable interoperability between all of the parties involved in building development. As a result the IAI has developed the Industry Foundation Class (IFCs) models for the interoperable exchange of 3D building data; which is now supported by all the major CAD vendors.

It is essential that we develop a harmonized approach with both the IAI and GIS communities, developing an asset reference model that is harmonized with these, whilst retaining its relevance in the broader community of users. In the next phase of work we will be developing a harmonise interface with spatial modelling standards, namely, the ICSM Spatial Reference Model and a harmonise interface with Architectural and Civil Engineering (ACE) modelling standards, namely, the IAI IFC models.

10.3 Model Driven Server

Without a tool to exchange information the reference models remain largely theoretical. A model driven server provides the realization of the benefits of the models to practitioners. In simple terms the model driven server is a data-store that can receive information from multiple sources, aggregate and store it in a managed environment that then allows other users to access that data; combining and manipulating it in ways that are relevant to their needs. The model is transparent and accessible to all, the model server provides the interoperability between systems.

Why model driven? Model driven primarily defines that the process of change is driven down from the model rather than up from a database implementation. The data-store is always maintained as a faithful representation of the reference model; change is driven by changing the model. A model driven server empowers practitioners to maintain control and influence over the reference model, whereas in more traditional approaches that control and influence is often usurped by the specialist technicians that maintain the database.

Queensland in partnership with the CSIRO are currently developing a model driven server for the Roads Alliance data, other similar servers are also planned but are currently not specified.

11 CONCLUSIONS

The asset renewal gap is a reality for Local Government. A solution to the gap requires debate at local, state and national levels. Its solution is not simply better asset management activities. What is needed is an honest dialogue with the communities about their aspirations for their communities.

If the dialogue is to be honest and meaningful participants must be informed.

Current information exchange is inadequate and difficult to aggregate at a national level. It is currently very difficult to present a consistent nation case for the renewal gap.

We propose that the problem is best solved by a national information framework that will enable the exchange of information between jurisdictions.

The framework should adopt a systemic approach to identifying and managing the necessary information.

The beneficiaries of such an approach would be the broad group of communities that all have a dependency on community assets. The collection and management of information would be handled once and used many times.

TECHNOLOGY MISSION ON INDIAN RAILWAYS

Nalinaksh S Vyas

Indian Institute of Technology, Kanpur 208 016, India

Abstract: Railways have been the instrument of technology development and growth in India. Introduction of railways in India is considered to have ushered in the industrial revolution and later facilitated industrial development. A Technology Mission on Indian Railways has been launched recently by the government. The effort is sponsored jointly by the Ministry of Human Resource Development, Ministry of Railways and a consortium of private industries. The goals and objectives of the mission include (i) development and adoption of state-of-art safety and control technologies through projects aimed towards achieving higher throughput, lower cost of transmission and safer train movement (ii) encouraging and initiating R & D activities pertinent to Railways in academic institutions and laboratories and establish convergence and synergy among them (iii) dissemination of technologies through participatory approach to other application areas. The paper describes some projects in technical detail and discusses issues pertaining to mission implementation and monitoring.

Key Words: Railway Technology, Indian Railways

1 INTRODUCTION

Indian Railways span a route of over 63,000 kilometers, over four different gauges. More than 13 million passengers travel on 14,000 trains and well over 1.4 million tones of freight are transported everyday in 6000 freight trains between 8000+ stations, aided by a fleet of 7,300 locomotives, 45,000 coaching vehicles and 280,000 goods wagons [1,2,3]. This massive network is in a process of continuous change and upgradation.

A Technology Mission has been recently launched to focus national attention and drive technologies in monitoring, control, communications, design, electronics and materials for Railway Safety. Earlier national programs on space and defence research did not merely achieve goals specific to the missions, but also provided impetus to technology endeavours in institutions all across the country. A Technology Mission on Railways will similarly help to initiate and incubate design and development projects of significant importance. The Mission objective is to develop and adopt state-of-the-art safety, control and design technologies defined by needs related to Indian conditions.

The projects currently in progress include Track Side Bogie Monitoring System; Derailment Detection Devices; Sensors for Detecting Hotboxes, Hot Wheels; On Board Diagnostics; Wheels and Axles of Improved Metallurgy; Corrosion Prevention Of Rails; Rail Flaw Detection Instrumentation; GPS based Rail Mapping & Train Navigation; Fog-Vision Instrumentation etc. Projects are executed through a trident consortium comprising of railway organisations, academic and research institutions and industry. The constituents of the consortium collaborate to bring domain specific expertise and share responsibilities. IIT Kanpur is the Nodal Agency. Features of various projects undertaken by the mission are described in this paper.

2 MISSION PROGRAMS

The Mission is divided into four Programs: each Program comprises of the following individual projects.

- Mission Program 1 (Traction and Rolling Stock): 1) Track Side Bogie Monitoring System 2) Derailment Detection Devices 3) Sensors for Detecting Hotboxes, Hot Wheels 4) On Board Diagnostics 5) Wheels and Axles of Improved Metallurgy 6) Measuring Wheel Technology
- Mission Program 2 (Tracks And Bridges): 1) Corrosion Prevention Of Rails 2) Improved Fastenings 3) Rail Flaw Detection Instrumentation 4) Environmental Friendly Coach Toilet Discharge System
- Mission Program 3 (Signals And Communications): 1) GPS based Rail Network Mapping and Train Tracking
- Mission Program 4 (Fog-Vision Instrumentation)
- The background and objectives of the individual projects are described below.

2.1 Trackside Bogie Monitoring System

The objectives of this project include (i) development of an automated system to be installed along the track for detecting faults in bogies of Rolling Stock and (ii) development of instrumentation for detection of falling components of the rolling stock which may cause derailment.

Reprofiling and replacing worn wheelsets constitutes a significant portion of rolling stock maintenance costs. Failure to detect misaligned wheelsets increases their removal rate. Misaligned wheelsets also responsible for increased fuel consumption and accelerated track deterioration. Visual inspections can detect only those wheelsets that have worn out appreciably. Typically, about 5% of wheelsets have abnormal behavior. The misaligned wheel sets represent a serious safety risk and earliest detection of misaligned wheelsets is essential.

Another concern is the falling parts of rolling stock. Occasionally, parts of rolling stock come off due to failure of fastening. These are normally detected by visual inspection. Falling parts may also cause derailment and there is need for automatic detection and warning

An optical system is being developed in this project to monitor (i) Angle of Attack (AOA), (ii) Tracking Position (TP), (iii) Inter-Axle Misalignment (IAM), (iv) Tracking Error (TE), (v) Angle of Attack (AOA). AOA of a wheel set is the angle between the track radial line and the center line of the wheelset's axle. For a good wheel set : AOA < 1 mrad.

TP of a wheel set is the position of the center of the wheel set with respect to the track centreline. IAM of a bogie is the angle formed between its two wheelsets (IAM = the angle of attack of the leading wheelset (AOAL) minus the angle of attack of the trailing wheelset (AOAT). TE of a bogie is lateral distance between the centers of the bogie's wheelsets (TE = TP of the leading wheelset (TPL) minus TP of the trailing wheelset (TPT)).

2.2 Derailment Detection Devices

This project envisages development of on-board equipment for sensing derailment possibilities of rolling stock. Development includes appropriate instrumentation and signal processing strategy and its integration with the existing brake system for minimizing losses due to dragging of derailed vehicle. Presently there is no instrumentation on Indian Railways for detecting derailment possibilities.

The process of derailment is characterized by heavy misalignment of the axle along with large oscillations and jerks. Vehicle dynamics software packages are being employed to carry out simulation of vehicles running on new or worn wheels. MEMS sensors for detecting vertical, horizontal accelerations and tilting have been identified and test runs are being conducted on Northern Railways. Recorded data is to be employed to arrive at suitable criteria for derailment detection.

2.3 Instrumentation for Hot Boxes and Hot Wheels

Hot wheels are caused by brake binding, while Hot Boxes are caused due to bearing failures. These may lead to rapid seizure, derailment, damage to rail, etc. Instrumentation is needed which can raise an alarm to driver or to the next station/control post through signalling or Radio Link, in case of development of abnormal conditions. The task involves development of an integrated approach to data acquisition and processing from various sensing systems – axle counter, trackside monitoring, vehicle identification, end of train identification, etc. The sensors need to detect box temperatures >80°C (or >25°C above ambient) during a very fast box transit time which is less than 4ms. In the case of Hot Wheels alarm should be raised on observation of temperatures of the order of 250°C, with similar sampling rate as for hot boxes.

2.4 Development of Wheels and Axles of Improved Metallurgy

Activities for developing steel of improved metallurgy for wheels and axles for better safety, reliability and enhanced carrying capacity without substantially altering design parameters. This is a large size project considering that Indian Railways currently have a population constituting of 1440000 wagon wheels, 280000 coach wheels, 72000 locomotive wheels and half the number of axles for each of the two; additionally several thousand new wheels are needed every year. The procedure adopted involves identification of some steel compositions and laboratory scale trials on variable solidification and thermo-mechanical processing parameters for the purpose of controlling the microstructures. Subsequently, their tensile properties, toughness, fatigue resistance and wear resistance are evaluated. The next step is production of steel samples on the pilot scale under optimized processing parameters. Data analysis and review is to be further carried out to standardize new processing parameters.

2.5 On Board Diagnostics

The objective of this project is to develop on-board diagnostics for diesel and electric locomotives through a microprocessor based control system. Diagnostics on existing locomotives is presently confined to trouble shooting knowledge of the driver. The present exercise includes development of appropriate instrumentation and signal processing strategy for various equipments which form part of the transmission and also for other auxiliary machines on board the locomotives. It will enable real time monitoring of vital locomotive equipments like prime mover, rotating machines, traction motor suspension bearings, axle bearings, radiator drive, compressor, transformer, tap changer, pantograph, etc on electric/diesel locomotives. The system will also have self-diagnostic features.

Typical problems in diesel locomotive and electric locomotive rotating machinery include Unbalance, Misalignment, Bending resonance, Oil Film Whirl, Cocked rotor, Shaft distortion, Mechanical looseness, Rotor rub, Gearbox defects, Asymmetric shaft etc. The diagnostic system will include on-line data-acquisition and display over multiple-channels simultaneously, frequency analysis and real-time FFT display, RMS value computation, trending analysis, data storage with date-time information, safe, tolerable and alarm limits for all channels, automatic visual and audio alarm in case of limit crossing, algorithmic diagnosis scheme and communication from rolling stock to the central control.

2.6 Measuring Wheel Technology

In this project instrumented wheel-sets are to be developed for measurement of the instantaneous vertical and horizontal forces at the rail-wheel contact point. Separate instrumented wheel-sets are being developed for locomotive, coach and wagons. Development of an Instrumented Wheel is important for a variety of reasons, particularly safety implications of rail-wheel interaction. The instrumented wheel set measures lateral and vertical forces and strains between a wheel flange and the rail-head. The relative magnitudes of the horizontal and vertical forces and their frequency characteristics hold the key to understanding of various wheel-track phenomenon. The Measuring Wheel is expected to serve as a major tool for carrying out studies on rail-wheel interactive forces, derailment analysis, wheel profile optimisation, bogie hunting etc. Measuring Wheel is also essential for analysis of various types of stresses coming on rail and wheels during rail wheel interaction before introduction of any new rolling stock in Indian Railways. The instrumentation includes strain-gauges and piezoelectric crystals which sense the dynamic phenomenon and transmit signals through telemetry. Equipment and the processors of primary handling data will be located on the axle of wheel set. Information from the rotating wheel pair will be transmitted in a digital code inside the coach for registration and processing.

2.7 Corrosion Prevention of Rails

This project investigates the problem corrosion, which is a major safety concern for railways. It affects the serviceable life of most track components, resulting in frequent replacement of rails. The major corrosion concerns are (i) the rail foot, under the liner location (ii) jamming of elastic rail clips (ERC) in the insert (iii) weldments and (iv) stray current corrosion. Corrosion begins at the rail foot which results into loss of rail section leading to fractures. Jamming makes it difficult to extract the leg of elastic rail clips (ERCs) from the insert for maintenance. Clips/inserts/sleepers get damaged during maintenance, while extracting the ERCs, resulting into heavy loss. The present work expects to specifically tackle corrosion under the liner location on rail foot and at weld collars.

2.8 Rail Fastenings

Rail fastening system consists of - Elastic Rail Clip or ERC, metal or GFN (glass filled nylon) liner, SG (Spheroidal Graphite) iron insert and grooved rubber pad. This project is aimed at stress and life analysis of the existing fastening system and its redesign.

2.9 Rail Flaw Detection Instrumentation

Common types of rail flaws include: transverse defect in rail head, Gauge face corner defect, rail weld defect (AT weld), bolt-hole defect, piping defect, half moon cracks at the weld. It is evident that flaw detection requires multiple probing activities. The objective is to build a non contact type ultrasonic testing system with sufficient storage and processing capabilities. The instrument vehicle will be operable manually at walking speed as well as speeds upto 80 km an hour.

2.10 Environmental Friendly Toilets

The stretch of the Indian railway network is long and in some cases a passenger may be required to spend up to three nights on a train. The existing coach toilet system in the Indian Railways' passenger trains consists of a lavatory in which the excreta are discharged directly to the ground through the lavatory chute. The design of the toilet is simple, robust, almost maintenance free and by and large convenient to a variety of users,. However, the present system raises major concerns regarding discharge of fecal matter on the track. These concerns include: damage to the rails, unacceptable aesthetic and hygienic/sanitary conditions, particularly on the railway stations, and non compliance to the environmental standards. Prototype physico-chemical and biological toilet systems are being currently investigated. Prototype residue management systems for installation in railway yards/stations are also being explored.

2.11 GPS Based Rail Network Mapping & Tracking

The objective of this project is to (i) develop an effective way to collect and disseminate information dynamically of every train in a given geographical boundary for its location, speed and direction of movement and (ii) ensure better and selective dissemination of information to passengers. Train tracking system using Global Positioning System (GPS) is being developed. Each train will have train locator unit to receive information from GPS satellites and continuously identify the position of train with information about train location (latitude and longitude values). GSM is to be used for connectivity and wherever needed use as an alternate location identifier. The data logger can also be used to provide services for a variety of applications like a central train enquiry system, anti- collision device, train charting etc.

2.12 Fog Vision Instrumentation

The project envisages development of instrumentation for improving the visibility during foggy weather. Train movement gets severely hampered during foggy climatic conditions in the northern part of the country. The foggy weather conditions consistently worsen during winter with fog getting more opaque. Such weather conditions prevail for nearly two months. Instrumentation is required to enable the train driver to see through the fog for uninterrupted and safe train operation. Information like position of obstacles on the track ahead, track condition etc. should be made available on a graphical console display. The visible distance should be equal to the normal visibility of the driver in day light conditions. Sensing technologies to be investigated Fog Vision System solutions considered are (i) mm wave Radar based imaging system (ii) mm wave Radiometer (iii) Infrared Radiometer (iv) Ultrasonic Sonar. Deploying multiple types of sensors may be essential to cater for different scenarios. In such cases, data from multiple sensors are to be fused intelligently to give a single display on the console.

3 MISSION IMPLEMENTATION ISSUES

Indian Institute of Technology (IIT) Kanpur and Research Standards & Development Organisation (RDSO) Lucknow, the R&D arm of Indian Railways are the major collaborators in the mission. A trident consortium comprising of (i) Academic and Research institutions, (ii) Railway Organisations and (ii) industry is formed for effective definition and implementation of projects. The constituents of the consortium collaborate to bring expertise and share responsibilities. RDSO brings extensive domain knowledge and experience in articulation of problems and conceptualizing activities. Academic institutions like IITs and CSIR laboratories contribute towards problem analysis, design synthesis and prototype development and the industry is expected to provide inputs relevant for adoption of technology and its commercialization.

The funding components are as follows: (i) Ministry of Human Resource Development, 50% (ii) Ministry of Railways 30% (iii) Industry 20%. The anticipated duration of the mission is 3 years.

A Mission Implementation and Coordination Committee (MICC) was constituted by the government to implement and coordinate various projects of the mission. The Director of IIT Kanpur is the Chairman of the Mission and the Director General of RDSO is its Co-Chair. The committee includes representatives from the Department of Science and Technology (DST), Government of India and the Council for Scientific and Industrial Research (CSIR). Additionally, industry is represented adequately in the committee. The major tasks of MICC include preparation of Mission Management Manual, project team constitution, budget allocation and periodic project monitoring. Industrial partners are suggested by the individual project teams. A memorandum of understanding is required to be signed between the academic/research institution, railways and the participating industry partner for each project before initiating activity.

Issues related to Intellectual Property Rights of various participating agencies are being presently worked out. However the agencies have been assured about adequate safeguard of their interests, in consonance with their financial share in the project. Funds are released to IIT Kanpur by the government and are centrally managed according to the advice of the MICC. Allocation of funds for individual project teams will be made on the recommendation of MICC. Each participating agency submits an audited Statement of Expenditure and Utilisation Certificate to IIT Kanpur at the end of each financial year.

For each project under the mission the following are included as essential components of deliverables: (i) study report on the literature study conducted for various causes of the problem; (ii) analysis results for the various causes, (iii) plan for validating the analysis results, (iv) report on validation of the analysis results with experimental data, (v) specification documents on wheel metallurgy, track and engine electronics, (vi) one set of prototype units with necessary hardware and software for the technology demonstration purpose, (vii) Manuals like User Guide, Quick Reference Guide, Trouble Shooting Guide for the hardware and the software delivered

Mass production and deployment is not included in the scope of the projects.

4 REMARKS

Railways are the backbone of India's economy and an integral part of the social fabric. Unlike developed countries Indian Railways operate under vastly challenging circumstances of overcrowding, low cost of travel, longer trains etc. The challenges posed in terms of technology development and implementation, are also thus greater, varied and unique in nature. These challenges also provide enormous opportunities for utilisation of available human and technical resources for development of safer and economical railway network.

Abstract: This paper proposes a RSM-based hybrid evolutionary algorithm (RHEA) which combined the merits of the popular programs such as genetic algorithm (GA), tabu search method and response surface methodology (RSM). This algorithm, for improving the convergent speed that is thought to be the demerit of genetic algorithm, uses response surface methodology and simplex method. The mutation of GA offers random variety to finding the optimum solution. In this study, however, systematic variety can be secured through the use of tabu list. Efficiency of this method has been proven by applying traditional test functions and comparing the results to GA. It was also proved that the newly suggested algorithm is very effective to find the global optimum solution to minimize the weight for avoiding the resonance of fresh water tank that is placed in the after body area of ship. According to the study, GA's convergent speed in initial stages is improved by using RSM method. An optimized solution is calculated without the evaluation of additional actual objective function. In a summary, it is concluded that RHEA is a very powerful global optimization algorithm from the view point of convergent speed and global search ability.

Key Words: Genetic Algorithm, Response Surface Methodology, Tabu Search Method, Tabu List, Simplex Method

1 INTRODUCTION

Many dynamic analyses are focused on finding the maximum response and avoiding the resonance in a given structure under all excitation forces [1, 2]. Usually, these features provide the basis of a design limit and are thus employed to determine the dynamic characteristics of a structure and its weight. For this reason, weight minimization for reducing the response and avoiding resonance has always been a major concern to vibration analysts. Many classic optimization methods and commercial softwares have been developed and most of them are very effective, especially to solve the local optimum problems. However they are not so good tools to find a global optimum solution for the system. To overcome this disadvantage, many search algorithms have been developed seeking for a global optimum solution. One of the most popular methods is the genetic algorithm (GA) [3, 4]. The GA is an optimization algorithm loosely inspired by evolutionary and is a powerful and general global optimization method. It does not require the strict continuity of classical search techniques, but it allows non-linearity and discontinuity to appear in the solution space. Due to the evolutionary characteristics, the GA can handle all kinds of objective functions and constraints defined on discrete, continuous, or mixed search spaces. However, the global access of the GA requires a computationally random search. So, the convergent speed to the exact solution is slow. Furthermore, the coding of the chromosome for a large dimensional problem will be very long, in order to get a more accurate solution. This results in a large search space and huge memory requirements for the computation. To overcome these demerits, many researchers have studied to develop many hybrid genetic algorithms which combine genetic algorithm with other ones [5, 6]. These can save computation time and find the global solution as far as it goes. However, new algorithms are required for better accuracy and faster convergent speed to get an optimum solution in the complicated and big structures like ships.

To seek for the optimum solution of multi-peak function with high accuracy and high speed, a new hybrid evolutionary algorithm is suggested in this study. This combines the merits of the popular programs such as GA, tabu search method, response surface methodology (RSM) and simplex method. The algorithm, for improving the convergent speed that is thought to be the demerit of GA, uses RSM and simplex method. The mutation of GA offers random variety to finding the optimum solution. However, systematic variety can be secured through the use of tabu list of tabu search method. Especially, in the initial stages, GA's convergent speed can be improved by using RSM which is using the information on the objective function acquired through GA process and then making response surface (approximate function) and optimizing this. The optimum solution is calculated without the evaluation of an additional actual objective function, and the GA’s convergent speed is improved. Efficiency of this method has been proven by applying traditional test functions and comparing the results to GA. It was also proved that the newly suggested algorithm is very effective to find the global optimum solution to minimize the weight change for avoiding the resonance of fresh water tank that is placed in the after body area of ship.

2 CONCEPT OF RSM-BASED HYBRID EVOLUTIONARY ALGORITHM (RHEA)

The main idea is to reduce the evaluation number of the objective function by using RSM which is one among the designed experiments to reduce the repetitive number, since it is one of the demerits of optimum design. The RHEA consists of four main categories: GA for governing the general algorithm; tabu-list for systematic variety of solution; RSM for improving convergent speed for getting a candidate solution; modified simplex method for local search. Fig. 1 represents the flowchart of the RHEA. The left side of the flow chart shows global search region that is similar to the flowchart of standard genetic algorithm, excluding the function assurance criterion (FAC), Sh (part A), tabu-list (part B), and RSM (part C). These parts offer candidate solutions, which are considered as initial search points in the local search region. The right side represents the local search region. This part finds out the optimum solution by the modified simplex method, which use the final solution by results of global search as initial search point.

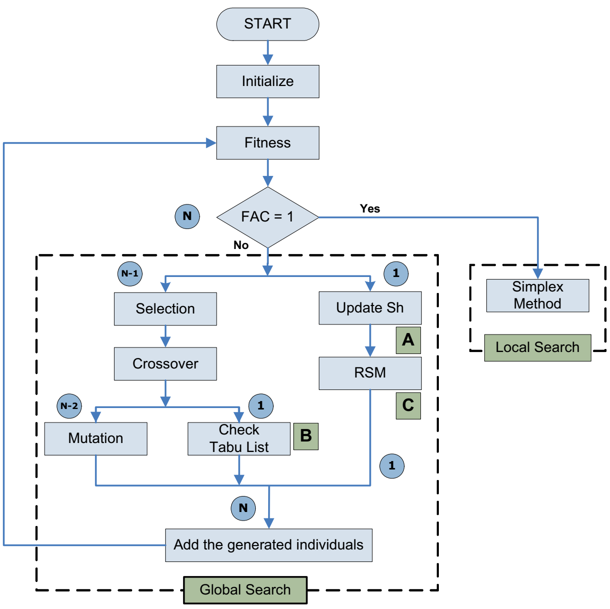

Fig. 1 Flowchart of RHEA

Part A in Fig. 1 shows the Sh region which provides the well distributed points to make a response surface. Part B in Fig. 1 shows that the tabu list is checked to have a diversity of solution. The one individual which is selected in GA's individuals after crossover is reviewed to secure the diversity of solution. If diversity of solution is secured, we select the individual and if not, we repeat the crossover process. That is, individual is selected when it is located far away from the dense area. Part C in Fig. 1 represents an RSM region. It is largely divided by 3 parts. Firstly, considering the boundary condition in the response surface for optimization, the upper and lower values of design variables can be considered in this calculation process. However, the merits of this method are diminished when addition constraints like natural frequency are considered, because it has to evaluate the objective function to get the results from external calculations. To overcome this problem, this study used Sh as training data and inferred the satisfaction of constraint condition using RBF network [7]. In this way, calculation of actual problems could be avoided. Secondly, it makes a response surface from Sh by using the least square method (LSM). Finally, the optimum solution of the response surface is calculated by using tabu search method. To increase optimization speed, gradient based algorithm can be used. However, the solutions satisfying constraint condition cannot be guaranteed since the constraint condition is difficult to define precisely. Also we adopt tabu search method which has an excellent initial convergent speed, because the implementation of the response surface concept is to search for the approximate candidate solution.

3 PROCEDURES OF RSM-BASED HYBRID EVOLUTIONARY ALGORITHM (RHEA)

RSM-based hybrid evolutionary algorithm (RHEA) is introduced as follows:

Step 1: Generate the initial chromosome $v_k\ (k = 1, 2, \cdots, pop\_size)$ randomly with n elements. *Step 2*: Generate the initial solutions, and estimate constraint and set up a parameter range. *Step 3*: Evaluate the fitness of individuals. *Step 4*: Evaluate the FAC, if it is satisfied, go to step 12 otherwise go to step 5. *Step 5*: Update Sh(a set of history) : $Sh = \{(X_{sh}, F) | X_{sh}\ R^N, F\ R\}$. where $X_{sh} = [x_1, x_2, \cdots, x_i, \cdots x_N]$, N is number of design variables. *Step 6*: Selection. *Step 7*: Crossover and check tabu list. *Step 8*: Construct response surface (RS) from Sh.

$$f_{rs} = \alpha_0 + \sum_{i=1}^{N} \alpha_{ii} x_i + \sum_{i=1}^{N} \alpha_{ii} x_i^2 + \sum_{i=2}^{N} \sum_{j=1}^{i-1} \alpha_{ij} x_i x_j \qquad (1)$$

where α_0, α_{ii}, α_{ij} are coefficients calculated by LSM.

Step 9: Train RBF network by Sh to construct the constraint conditions approximately. *Step 10*: Calculate the optimum design on the response surface by tabu search method and generate one individual based on X*. *Step 11*: Mutate and go to step 3. *Step 12*: Search the optimum solutions by the local concentration search (modified simplex method) for best candidate.

4 NUMERICAL EXAMPLES OF SEVERAL FUNCTION OPTIMIZATIONS

Three test functions are used to verify the efficiency of the proposed hybrid algorithm: the first one is the four-peak function [8], which has one global optimum with three local optima; and the second one is Rosenberk's function [9] which is known as banana function and has just one global optimum; and the last one is the Rastrigin function [10] which has one global minimum with 220 local minima.

Fig. 2 represents the convergent trend of objective function for each test function. According to the results, GRSM (GA+RSM) and GRSMT (GA+RSM+Tabu list) algorithms which are based on RSM have faster convergent speed and more accurate solutions than GA, which validated the efficiency of RSM on the calculation. Also tabu list enables convergence to solutions quickly on the multi-peak function due to the systematic diversity of solution. Table 1 shows the comparison of optimization results for the above stated three test functions. The evaluation number means total evaluation number of the objective function used in optimization procedure, and it is directly proportion to the total calculation time. According to the results, for all test functions, RHEA can give better solutions than GA on accuracy and convergent speed. For the Rastrigin function, which is very useful to evaluate the global search ability because there are many local minima around the global minimum, RHEA found global minimum with higher accuracy and less elapsed time compared to GA. According to these results, the proposed new hybrid algorithm is a powerful global optimization algorithm from the view of convergent speed and global search ability.

Table 1

Comparison of optimization results

Test function	Exact solutions	Methods	Results $f(x)$	(x_1, x_2)	No. of evaluation
Four-peak	$f(x) = 1.9543$	GA	1.927	2.403 e-3, 2.787 e-3	2353
function	$x_1 = x_2 = 0$	RHEA	1.927	2.736 e-3, 2.736 e-3	459
Banana	$f(x) = 0$	GA	1.640 e-5	9.960 e-1, 9.960 e-1	1046
function	$x_1 = x_2 = 1$	RHEA	0.0	1.0, 1.0	419
Rastrigin	$f(x) = 0$	GA	1.586 e-4	1.408 e-4, 8.15 e-4	2109
function	$x_1 = x_2 = 0$	RHEA	0.0	-3.076 e-9, -7.747 e-10	514

5 APPLICATION FOR OPTIMUM DESIGN OF FRESH WATER TANK OF SHIP

In the engine room and the after body area of the ship, there are so many tank structures in contact with fresh water, sea water or oil. Also these possibly subject to the excessive vibration during voyage because they are arranged around the main excitation sources of ship such as the main engine and propeller. If problems occur, it takes a lot of cost, time and effort to improve the situation because the reinforcement work for empting the fluid out of the tanks, additional welding and special painting and so on is required. It is therefore very important to predict the precise vibration characteristics of the tank structures at the design stage. Optimum design needs to be applied. Especially when the structure is in contact with fluid much analysis time is taken. So, a new hybrid optimization algorithm is required for getting a short analysis time and accurate solution. In this study, optimum design of a fresh water tank in an actual ship is carried out to verify the validity of the proposed optimization algorithm (RHEA) and the results are compared to that of GA.

5.1 Vibration Analysis of Fresh Water Tank

It is difficult to predict the vibration response of a local structure due to the complicated transfer mechanism of excitation force and the difficulty of assuming the damping ratio. Traditionally, therefore, the vibration analysis considering the design of avoiding resonance is conducted to prevent the local vibration.

In this study, the vibration analysis of the fresh water tank is carried out using NASTRAN which is a commercial finite element program and widely used for big structures like ships. Fig. 3 shows the model and arrangement of the fresh water tank. Fig. 4 shows the design variables and boundary condition of the fresh water tank. Considering the precision of analysis and time consuming modeling process, the range of modeling of fresh water tank is constrained to one side of the tank. The boundary conditions for the model are specified: the simple supports are used to the tank boundary area which is connected to the other bulkhead and deck.

In general, the design for avoiding local structure resonance in ships requires that the natural frequency of the structure must be two times higher than the blade passing frequency of the propeller under the maximum rpm of the main engine. In this study, design target frequency is set as above 14.02 Hz which considers safety margins and twice blade passing frequency of the propeller (12.13Hz).

Fig. 5 shows the first three modes and natural frequencies of the fresh water tank by NASTRAN. These three modes frequently occurred on the fresh water tank during voyage. Especially, the 1st mode (8.60 Hz) is a stiffener (stringer) mode which generates a strong vibration and much effect on the structure. In this model, the 1st natural frequency of the structure is also within the resonance region where twice blade passing frequency of propeller is 12.13 Hz. Therefore, the natural frequency of structure is needed to be increased up to the target frequency under the condition that the tank is fully filled. The natural frequency of structure which is contacting with fluid can be changed according to the water line of the tank. So, in order to design a safe structure, the three modes of the fresh water tank are concerned in this study.

Fig. 5 Mode shapes of fresh water tank

5.2 Optimum Design of Fresh Water Tank

Design variables: The main vibration modes on the fresh water tank are stiffener modes in transverse direction. One of the most important factors is the stiffness of stiffeners. In this study, the stiffener size and plate thickness of fresh water tank in Fig. 4 are defined as design variables in Eq. (2).

$$x = \{S1\ S2\ S3\ S4\ S5\ S6\ S7\ S8\ P1\ P2\}^{T} \quad (2)$$

where S and P mean stiffener size and plate thickness, respectively.

Constraints: The web length of stiffener L_w is restricted as two categories like Eq. (3) according to the shipyard's practice.

$$150 \leq L_w \leq 450 \text{ mm for stiffeners } (S1\text{-}S7), \quad 500 \leq L_w \leq 1000 \text{ mm for stringer } (S8) \quad (3)$$

The basic concept of local vibration design is also the minimization of the response at each point. However, it is difficult to evaluate how much the excitation force influences on local structure. So, in this study, natural frequency of the structure is restricted as Eq. (4) which considers a safety margin of twice blade passing frequency of the propeller.

$$\omega_n \geq 14.02 \text{ Hz} \quad (4)$$

Objective function: The objective function combines linearly the weight of fresh water tank with natural frequency of structure like Eq. (5). The objective is to get an economic and sound structure to reduce the weight of stiffener and to increase the natural frequency.

$$\text{Minimize } f(x) = \alpha\left(\frac{W_1}{W_0}\right) + \beta\left(\frac{\omega_t}{\omega_0}\right) \quad (5)$$

where, W_1 and W_0 mean current and original weight of stiffeners and plates, respectively. ω_t and ω_0 mean target and current natural frequency, respectively. α and β are weighting factors ($\alpha = 0.5$, $\beta = 0.5$).

5.3 Optimization Results and Discussion

The optimum design was carried out to get an optimal size of stiffener and plate thickness on the fresh water tank to maintain the anti-vibration design of it. Table 2 shows the results of the design variables before and after optimization. It shows that the stringer S8 is increased by 72% and the others by 4.0-52%. This result indicates that the most reasonable modification method is to increase the stringer which has an effect on the decreasing the span of the vertical stiffeners. In this case, however, the plate thickness does not have any effect on the natural frequency of the structure. Table 3 shows the variation of natural frequency and weight of structure before and after optimization. According to the results, the 1st natural frequency increased by 163 % from 8.6Hz to 14.02Hz, and the safety margin with twice passing frequency of the propeller correspondingly changed from -29.1% to 11.56%. Therefore, the structure is free from resonance. Moreover, the weights of stiffeners which are applied to the design variables also decreased in spite of higher natural frequency. In summary, the local vibration problems which require avoidance of structure resonance through the movement of natural frequency without additional weight has been successfully solved by the proposed optimization method. Table 4 and Fig. 5 show the comparison of optimization results between GA and RHEA. The evaluation number means a total evaluation number of the objective function used in the optimization procedure, and is directly proportional to the total calculation time. According to the results, RHEA can give better solutions than GA on accuracy and convergent speed. These results lead us to draw the conclusion that the proposed new hybrid algorithm is a more powerful global optimization algorithm from the view of convergent speed and global search ability.

Table 2

Comparison of original and optimal design variable

Design variable		S1	S2	S3	S4	S5	S6	S7	S8	P1	P2

6 CONCLUSIONS

This paper introduces RSM-based hybrid evolutionary algorithm, as a new kind of a hybrid optimization algorithm that combines the merits of the popular programs such as genetic algorithm, tabu search method and response surface methodology. This algorithm, for improving the convergent speed that is thought to be the demerit of genetic algorithm, uses response surface methodology and simplex method. The mutation of GA offers random variety to finding the optimum solution through the use of tabu list. Especially, in initial stages, GA's convergent speed can be improved by using RSM which is using the information on objective function acquired through GA process and then making response surface (approximate function) and optimizing this. The optimum solution is calculated without the evaluation of additional actual objective function, and the GA's convergent speed is improved. Efficiency of this method has been proven by applying traditional test functions and comparing the results to GA. It was also proved that the newly suggested algorithm is very effective to find the global optimum solution to minimize the weight for avoiding the resonance of fresh water tank that is placed in the after body area of ship. Finally it is concluded that the proposed new hybrid algorithm (RHEA) is a very powerful global optimization algorithm from the view point of convergent speed and global search ability.

ARMS Reliability Engineers

Abstract: Traditionally reliability effort and Reliability Centered Maintenance (RCM) studies have been conducted on a project basis and one of the most common pitfalls to a successful outcome is the effort involved in implementation of the resulting maintenance strategies. It is all too common for RCM plans to be developed which result in a significant reduction of business risk only to be never completely implemented. This paper outlines an enterprise approach to reliability analysis allowing for an efficient implementation or RCM projects. The benefit of the approach also allows for benchmarking across an organisation, performance tracking, triggering of analysis projects and efficient sharing of analysis data and results.

Key Words: Reliability Centred Maintenance, RCM, Analysis, SAP

1 INTRODUCTION

Traditionally reliability effort and Reliability Centered Maintenance (RCM) studies have been conducted on a project basis and one of the most common pitfalls to a successful outcome is the effort involved in implementation of the resulting maintenance strategies.

It is all too common for RCM plans to be developed which result in a significant reduction of business risk only to be never completely implemented.

This paper outlines an enterprise approach to reliability analysis allowing for an efficient implementation or RCM projects. The benefit of the approach also allows for benchmarking across an organisation, performance tracking, triggering of analysis projects and efficient sharing of analysis data and results.

2 IMPLEMENTATION

The outputs from an RCM study are the individual tasks which combine according to set business rules to form the maintenance plans. The implementation process generally involves either manual upload of SAP tables or an import using the Legacy System Migration Workbench (LSMW). The LSMW is capable of uploading data from excel spreadsheets into SAP tables provided the excel spreadsheets are configured correctly.

It is essential to have a resource familiar with the SAP tables to be able to correctly create all the upload tables required, due to the complex nature of the SAP table structure. If the LSMW is to be used the user also needs experience in the correct use of LSMW.

The tasks are combined into “Task Groups” or Maintenance Plans as per the business rules and work instruction type documents are completed ready for upload and linking.

Due to the nature of the resources involved to complete the process it involves interfaces between several departments and at times systems to complete the implementation. This factor alone greatly reduces the likelihood of an efficient implementation.

2.1 The living System

With rapidly changing business environments, and with most plants changing operating conditions, demands and procedures the maintenance plans require periodic review.

Most RCM analyses are completed within tailored computer programs which, depending on the chosen tool, allow relatively rapid update of parameters and therefore review of the maintenance plans. The challenge arises in updating EAM data to reflect any interval and maintenance plan detail changes.

For example, for a particular piece of equipment there may be a 3 monthly and a 6 monthly strategy, each of which contain a number of tasks. During a review it may be that one task which was conducted 6 monthly now has a recommendation to change to 3 monthly. In this case someone has to update several relevant SAP tables and also manually locate the appropriate work instruction documents, manipulate them and then reload to the correct location.

2.2 Interfacing Options

Essentially there are three options available to transfer data between the reliability project software and the EAM system.

1 Manual export and data update

2 Using standard data import applications (i.e. LSMW for SAP)

3 Enterprise Integration

2.3 Manual export and data update

The simplest method of data transfer is to actually export data from either system and then manually key information in to the source system. For example work order history can be extracted into MSExcel spreadsheets, analysed and then either manually keyed or using Windows Cut and Paste feature to enter data into the reliability project software.

By the same token resulting maintenance plans can be exported from the reliability project into a MSExcel spreadsheet and then from these exports data can be consolidated and segregated such that it can be manually keyed into the EAM system.

Advantages	Disadvantages
- Requires little pre-thought or planning with regard to consistency	- Difficult to work with large data volumes - Extremely time consuming data input and manipulation - Difficult to assure standards or consistency of analysis or ERP configuration - Extremely difficult to make large scale changes to existing SAP objects - High level of skills and knowledge required to extract, manipulate and upload data - Association between the maintenance strategy and its analysis is lost after upload to SAP - Low sustainability rate, i.e. overwhelming nature of human intervention and susceptibility to error leads to questioning of value and loss of motivation

2.4 Standard Data Import Applications

This method improves the efficiency of the manual process by utilizing standard data import applications which will read an MSExcel spreadsheet and import into the EAM data tables.

For example users of SAP can use the Legacy System Migration Workbench (LSMW) application to import a MSExcel spreadsheet. The spreadsheet needs to be configured correctly prior to the upload requiring the user to have a sound knowledge of the SAP data tables and their particular configuration for that installation.

Advantages	Disadvantages
- Allows faster methods of data entry compared with manual methods - Limited reuse of template files and configurations	- Difficult to work with large data volumes - Time consuming data input and manipulation - Difficult to assure standards or consistency of analysis or ERP configuration - Extremely difficult to make large scale changes to existing SAP objects - High level of skills and knowledge required to extract, manipulate and upload data - Association between the maintenance strategy and its analysis is lost after upload to SAP - Low sustainability rate, i.e. overwhelming nature of human intervention and susceptibility to error leads to questioning of value and loss of motivation

2.5 Enterprise Approach

Taking an enterprise approach provides a significant improvement in efficiency, accuracy and functionality by providing a robust interface along with methods of automatically configuring data in the required format.

Advantages	Disadvantages
– Extremely fast access to ERP Data – Object identity is maintained so much easier to find in the ERP system – Fast and easy uploading to ERP System – Assurance of ERP object and data standards – Works with large data volumes – Can make changes to large volumes of data – Association between the maintenance strategy and its analysis is retained after upload to SAP – High sustainability rate due to automated nature of solution and visibility of the ongoing value delivered	– Requires planning and pre-thought with regard to technical object design – Initial configuration effort

2.6 Comparison of Options

The following table outlines the functionality comparison of the interfacing options.

Feature	Manual	Spreadsheet	Integrated
Project capability	✓	✓	✓
Reliability block modeling	✓	✓	✓
Equipment tactics	✓	✓	✓
Life cycle costing	✓	✓	✓
Initial optimization	✓	✓	✓
Ongoing optimization	X	X	✓
Multi-project capability	X	X	✓
Enterprise capability	X	X	✓
Scalable	X	X	✓
Library management	X	X	✓
Closed-loop management	X	X	✓
Compliance alerts	X	X	✓
Predicted/actual comparison	X	X	✓
Portal publication	X	X	✓
KPIs	X	X	✓
Systematic SAP connectivity	X	X	✓
Monitor application of Corporate standards	X	X	✓

The Enterprise approach yields significantly greater functionality, whilst providing a sound basis for organisations to continually improve their maintenance strategies over time and also maximize the leverage from any reliability project completed by allowing benchmarking and templating across and entire organisation.

3 ENTERPRISE RELIABILITY MANAGER

The Enterprise Reliability Manager (ERM) can dramatically increase the efficiency of implementation by automating the grouping of tasks, creation of appropriate SAP tables and generation of work instruction templates. ERM can update SAP tables and removes the need to use another import facility such as LSMW.

ERM uses defined business rules to generate all tables and data and so ensures a consistent approach to data structure. ERM also conducts data integrity checks to ensure data tables are valid prior to updating in SAP.

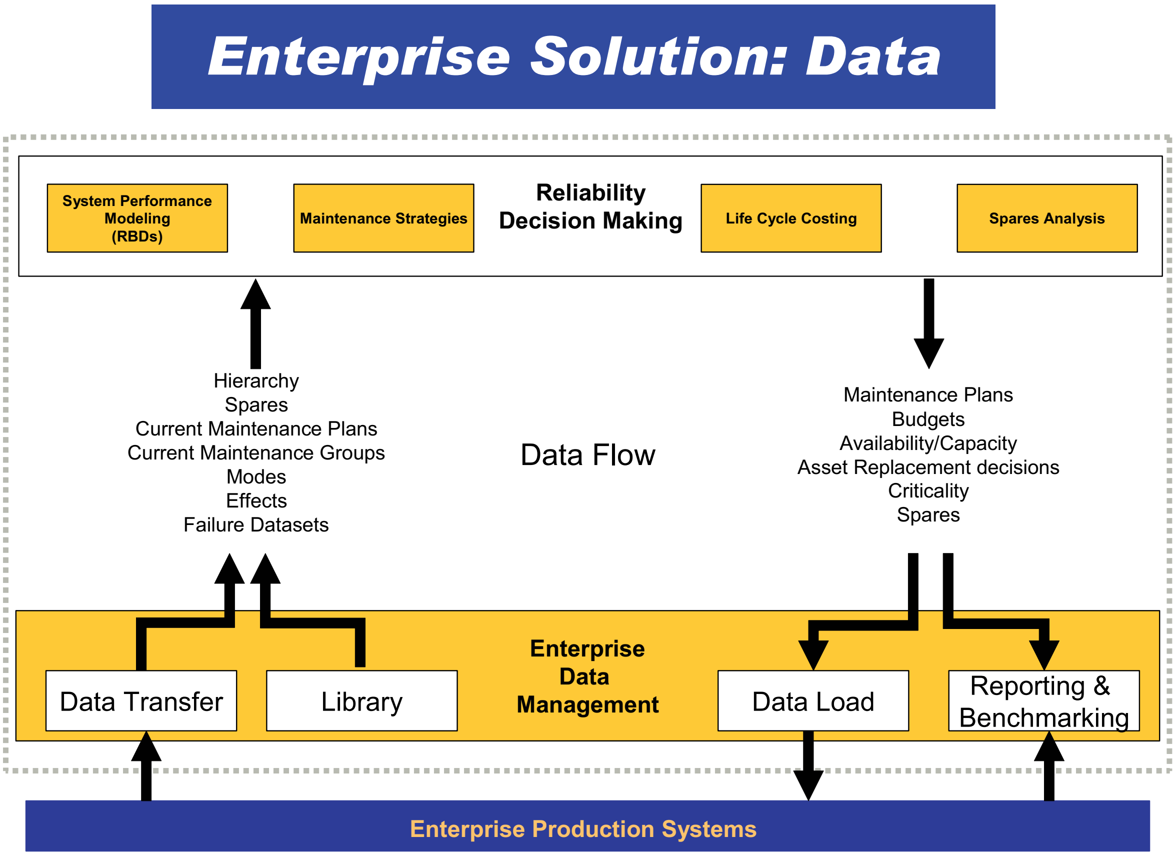

Figure 1 – Data flow within an enterprise level solution

The addition of an enterprise level solution provides a vehicle to take a truly site or organisation wide approach to reliability management. Since the ERM can upload/download data from SAP, a single instance of data can be maintained. Any reliability modeling or RCM analysis can be based on actual data from SAP, and the results can be stored for use as a template for the analysis of similar assets.

The ERM can then be used to provide benchmarking data across sites, comparisons of analysis for similar equipment and KPI reporting by tracking actuals against any predictions. The ERM monitors actual performance metrics and can be set to flag any deviations for analysis or review.

The ability to track the success of implementation is of great importance in terms of tracking the success of a reliability focus whilst also allowing a focus on continuous improvement and update by identifying deviations from predictions.

3.1 Enterprise Reliability Manager Applications

An enterprise approach to interfacing EAM data with reliability projects has three distinct categories which are considered below.

Addition of Assets – Unique assets

The category represents the case where a maintenance strategy needs to be developed for an asset and there are no similar assets within the organisation with useful information to use as a baseline.

In this category there may not even be an asset hierarchy in which case the reliability project provides the basis for the asset hierarchy, development of maintenance strategies and task lists.

Additional of Assets – Similar Assets

This category represents the case where a maintenance strategy is required for an asset which is similar to other assets within the organisation.

In this case an existing asset hierarchy and maintenance plans are utilized as a basis of the reliability project. On completion of the project an asset hierarchy, maintenance strategy and task list will be loaded into the EAM.

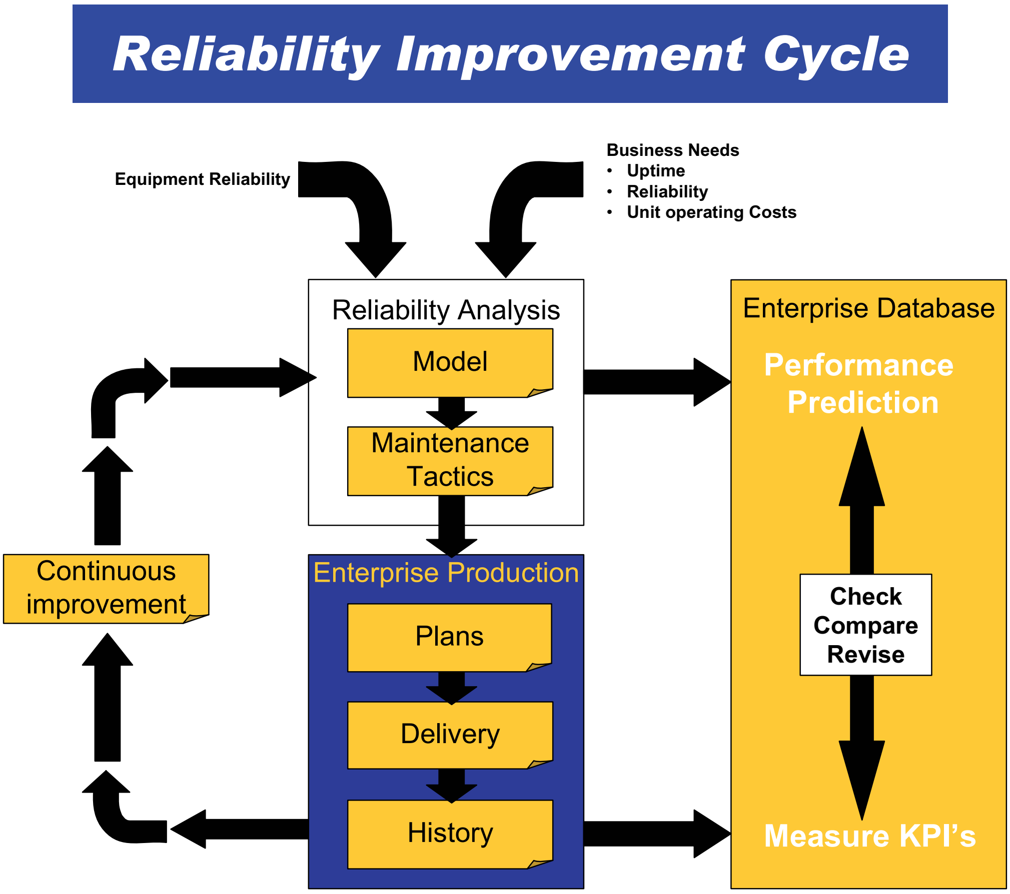

Figure 2 – Tracking Implementation Success & Continuous Improvement

Continuous Improvement

In this scenario existing EAM data is used as a basis or review. It is possible that the hierarchy structure is reviewed and updated along with maintenance strategies and task lists.

It is also likely that work order history will be loaded and analysed to help quantify maintenance strategy decisions as part of the review exercise.

Similar to above the asset hierarchy may be re-loaded along with revised maintenance strategies and task lists. In this case data will be modified rather than created.

In order for an Enterprise approach to be successful it needs to address the three scenarios above which represent the most common application of reliability studies.

4 CASE STUDY

The case study outlines below corresponds to the addition of assets – unique assets as outlined above. The reliability project provided the basis of the asset hierarchy and the maintenance strategies and task lists that were entered into SAP.

An RCM study that generated maintenance plans for a plant expansion consisting of approximately 200 items using RCMCost, was conducted over a 6 week period. 518 maintenance tasks were developed and optimized within the RCMCost program.

Typically these tasks would be grouped, configured and exported for upload using the SAP Legacy System Migration Workbench (LSMW). The tasks would also be configured into a standard work instruction document format ready for completion with detailed work instruction information. These documents would be completed manually, formatted and uploaded.

Several other tables and data would also need to be created and uploaded to SAP by an experienced SAP user

- Maintenance Strategy
- Maintenance Items
- Maintenance Plan Headers
- Task Lists
- Task List Operations
- Attached Documents

On this site several RCM studies have been completed and the implementation of the completed plans was a time consuming exercise which had actual seen the tables generated more than once to changing business rules.

The ERM generated the plans and tables in a fraction of the time estimated to configure and load the plans manually. This efficiency allows the users to focus on work instruction content rather than word document formatting etc. ERM applies consistent business rules to the generation of the strategies and Task lists.

In this particular case the site modified its business rules on the basis of other SAP improvement projects. The use of the ERM made this alteration quick and easy to reflect in the new plans, by simply updating the business rules and regenerating all the tables and documents.

5 SUMMARY

Whilst the benefits of RCM are understood by the reliability practitioners, and organisational view is naturally on results. The results of RCM studies rely on the implementation of the generated plans, then the ability to monitor and quantify performance improvements. Taking an enterprise view of reliability decisions and management ensures a high quality and efficient implementation process, whilst also providing a means to track the performance improvements against predictions.

DEVELOPMENT OF A NOVEL WIRELESS TRANSDUCER FOR MEASURING THE TRANSIENT TORQUE OF AN AUTOMOTIVE POWERTRAIN

Zhang N. [a], Chapman C. [a] and Crowther A.[a,b]

[a] *Mechatronics and Intelligent Systems Group, University of Technology, Sydney, Australia.*

[b] *Bishop Innovation Pty Ltd, North Ryde, NSW, Australia.*

Abstract: This paper presents the development of a specific wireless torque measurement system that is used to obtain the transient torque of automatic transmissions. Strain gauges are put on the surface of components that rotate and transfer power. The gauges are connected to a circular printed circuit board (PCB), which is mounted on the rotating component next to the strain gauges. The PCB contains an amplifier, low pass filter, A/D converter, microcontroller, digital RF transceiver and the power supply. The transmitted torque data is received by a stationary antenna and transceiver, which is interfaced to a PC to process, display and save the data.

The wireless torque transducer is installed at the output shaft of a 4-speed automatic transmission powertrain test facility for capturing the transient torque under various operational conditions. A number of tests are performed on the powertrain test facility with various specified disturbances such as tip-in, tip-out, 1-2 and 2-3 gear up-shifts. The transient output torque of the automatic transmission are measured and compared with those obtained from simulations performed with the estimated same operating conditions. The two sets of transient responses correlate with each other and hence demonstrate that the torque transducer meets the major design specifications.

Key Words: wireless torque transducer, powertrain dynamics, torsional vibration, gear shift quality.

1 INTRODUCTION

Fast and smooth gear shifts of transmissions used in automotive powertrains are desirable and often used as marketing tools in the car manufacturers' advertising. To evaluate the smoothness of a powertrain under various operating conditions and driver demands (eg heavy load, tip-in and kick-down gear shifts), the transient torsional response must be measured [1]. Furthermore, successful and cost effective measurement of transient torque of engine and transmission output, which is not currently available, can be used for the closed loop control of gearshifts.

Hwang et al [2] anaylsed free and forced vibration of a powertrain of an automatic rear wheel drive passenger vehicle and investigated torque converter clutch engagement shudder after applying tip-in engine torque input. Experimental measurements of the natural frequencies obtained from a powertrain correlated with those calculated. Jo et al [3] developed a powertrain dynamic model for an automatic rear wheel drive passenger car that included the dynamics of the unlocked torque converter with clutch stick-slip conditions. Again, analytical and experimental results for 1-2, 2-3 and 3-4 up shifts were presented and they correlated with each other reasonably well. The effects of activating element overlap, clutch control pressure and clutch friction were also investigated.

During acceleration and braking of a vehicle the speed ratios between rotating parts along with the powertrain change with respect to time and so the equivalent system parameters. In addition, there are multiple nonlinearities, which are often dynamically coupled with each other in a powertrain. To deal with these complexities, Zhang, el al. [4-5] developed the torsional finite elements and a procedure for formulating the integrated powertrain model, and the semi-analytical and numerical solutions schemes for dynamics of generic torsional systems and a complete powertrain with coupled nonlinearities. A novel powertrain test facility was developed for the validation of the obtained numerical simulations through experiments, both qualitatively and quantitatively [6-7]. All the major components of a vehicle powertrain system are integrated in the test rig, including a flywheel subsystem that simulates the inertia of the vehicle and a hydrodynamic dynamometer for simulating air drag. A specific wireless torque measurement system, capable of measuring transient torque while shaft rotating, was fitted within the facility.

This paper presents the development of the specific wireless torque measurement system that is used to obtain the transient transmission output torque. Strain gauges are put on the surface of components that rotate and transfer power. The details of the major components of the sensor system are provided. The wireless torque transducers are installed at the output shaft of the automatic transmission fitted in the powertrain to capture the transient torque under various operations conditions.

A number of tests are performed on the powertrain test facility with various specified disturbances such as tip-in, tip-out, 1-2 and 2-3 gear up-shifts. The transient response of the powertrain are measured and compared with those obtained from simulations performed with the estimated same operating conditions. Conclusions are drawn from the comparisons between the measured transient torque and those obtained from simulations.

2 TORQUE TELEMETRY SYSTEM

The torque measurement system used in the wireless torque sensor is described in Figure 1 as follows:

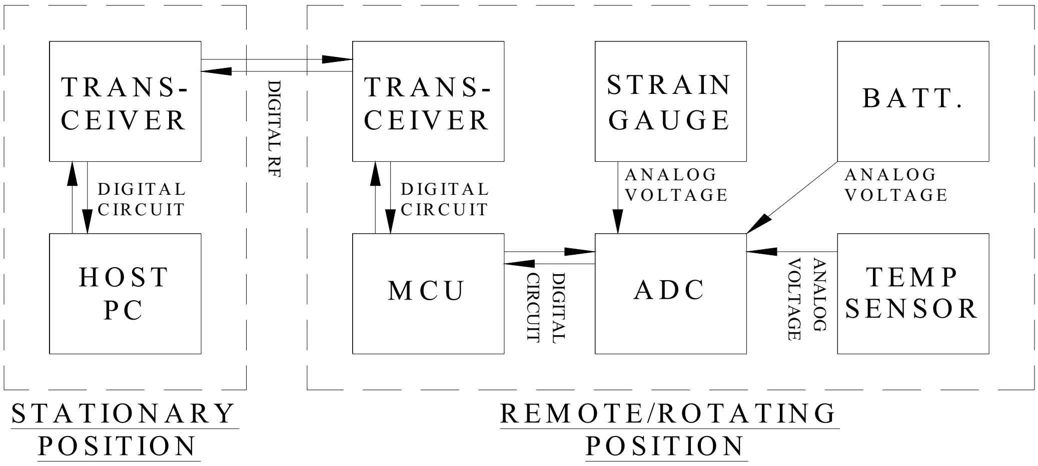

Fig. 1 Torque measurment schematic for Powertrain System

The micro-controller unit (MCU) is the Atmel ATmega8535. Its programming has been designed to take readings through its internal analogue to digital converter (ADC) upon command from the main computer. The commands are transmitted via the TR3100 transceiver. The host PC is used for controlling the remote circuit board functions. It contains an analogue section, a micro-controller, a radio transceiver, batteries and voltage regulators. The PCB take commands from the PC.

The features of the major sections of the PCB of the torque measurement system are provided below:

- Analogue section includes: a) instrumentation amplifier and filter for torque channel, with on-board shunt calibration; b) PCB temperature measurement via temperature sensing IC; c) battery voltage sensing.
- The selected micro-controller is Atmel Atmega8535, that features with a) MCU system clock speed of 7.3728 MHz; USART baud rate of 115.2 kbps; and c) ADC sample rate of 4.43 kHz.
- The radio transceiver is RFM TR3100, that features with transmitting protocol of Amplitude Shift Keyed (ASK) and transmitting frequency of 433.92 MHz.
- Three 3 Volts batteries were used and voltage regulators were used for each of the above major components.

The desired ADC sample rate is approximately 6 kHz. However due to the bandwidth limit of the RF link, the sample rate has been lowered to 4.43 kHz and every pair of samples is averaged to give a transmitted sample rate of 2.21 kHz. It is hoped that future development of the system will increase the actual sample rate to approximately 6 kHz, and use averaging to give us the maximum transmitted sample rate that the RF link will allow.

The user sends a command packet from the host computer to the remote module. The packet is in binary code sent via the radio telemetry to the micro-controller. This packet contains the user's command menu choice and the three menu parameters, one for ADC control and two for calibration timing. The packet contains a start vector at the beginning, a data separator between the vector and the data, a data separator between the data and the error checking and an end vector. The packet encoded as 12-bit binary symbols which are DC balanced in order to take full advantage of the available bandwidth. The host computer's received packet contains a start vector, 20 encoded ADC results (16 decoded results) and end vector.

3 MICRO-CONTROLLER UNIT HARDWARE

The software was written in the C programming language using CodeVision AVR. The CodeVision AVR program and compiler allows the software to be loaded directly onto the micro-controller unit through a serial port connection.

3.1 Command Functions

There are 8 possible functions within the command structure. The first 5 have been used and the last 3 are spare. Each command involves sending and receiving information from the PCB and error checking. The used five functions are briefly described below.

1. Wake command: The MCU is woken by the USART Receive Complete interrupt. Interrupts are special functions in programming that execute when necessary, rather than when called. This function also resets and starts the ADC. The wake command must be the first command function the MCU receives once turned on. It wakes the voltage regulator and sets the ADC to the 4.43 kHz sample rate.
2. Torque command: The torque readings are taken from the ADC multiplexer (ADMUX) channel 0. This channel has been set as the default channel in the program. The readings are put into a circular buffer with a maximum size of 16 samples. Then they are encoded from 10-bits to 8-bit bytes. After encoding the buffer is transmitted back to the host computer. Parameter A controls the sample rate for the ADC.
3. Temperature and voltage command: This command measures the temperature (channel 1) and the battery voltage (channel 2) on the remote PCB. A 12 microsecond delay has been included to allow for sufficient time for the ADMUX channel to change to channel 1 for temperature and then channel 2 for battery voltage. The ADMUX then returns to channel 0.
4. Shunt calibration command: For this command, readings are taken when pin B1 is set both on low and high. The readings are taken, sent back to the host PC and pin B1 is set to either high or low depending on which part of the function is being executed.
5. Reset and sleep command: This command resets the microcontroller, and puts the torque sensor into a low current sleep mode to preserve battery power. In this mode, the complete analogue section is turned off by disabling the analogue section voltage regulator, the microcrontroller ADC is turned off and the microcontroller is put into one of its sleep modes. In this mode, the only possible action that can be done is to receive and execute a wake command.

3.2 Encoding / Decoding On MCU

Encoding and decoding is needed for the ADC data and for the packetised data transmitted in both directions. The ADC data is encoded from 10-bit numbers to 8-bit bytes in order for the data to be packetised. The packetised data must then be encoded to 12-bit symbols in order to take full advantage of the available bandwidth of the transmitter.

3.3 Control of MCU Features

Universal Synchronous and Asynchronous Receiver Transmitter (USART): The USART controls the data being sent and received by the MCU. It has been set to use interrupts to process all data received and that to be transmitted. The data transfer rate between the MCU and the transceiver has been set to 115.2 kbps, as this is the fastest rate allowed by the TR3100.

Analogue to Digital Converter (ADC): The ADC has been set to free running mode at a clock speed of 115.2 kHz. Since one AD conversion takes 13 ADC clock cycles, this gives an effective sample rate of 4.431 kHz. The clock speed must be between 50 kHz and 200 kHz for maximum 10-bit resolution. The ADC is switched off when entering sleep mode so that a conversion complete interrupt does not cause the MCU to wake.

I/O Ports: Port A has been configured to be the ADMUX input (the alternate function for this port). Port B controls the voltage regulator on pin 0 and the shunt calibration for torque on pin 1. Setting the pin0 high or low turns the regulator on and off. Setting pin1 high or low toggles the step input for the shunt calibration. Port C controls the modes of the TR3100 transceiver by setting pins 0 and 1 either high or low. The setting of these pins toggles the 4 possible modes for the transceiver. Port D uses the alternate functions of pins 0 and 1 for the USART RX and TX data lines respectively.

3.4 Calibration of Torque Channel

After setting the gain of the instrumentation amplifier to suit the required torque measurement range, an end-to-end calibration was done to calibrate the complete torque measurement system. This was done with the powertrain stationary and applying a known static torque to the strain gauged powertrain component. The resulting change in torque reading is then noted at the PC.

3.5 Affect of Rotating Speed

The rotating PCB has been spin tested by mounting it on the shaft of an electric motor and driving the motor up to 6000 rpm. When this test was first performed it was noticed that the batteries moved inside their battery holders and contact was lost. An additional battery clamping clip on each battery was designed and installed. The test was repeated and no mechanical or electrical problems were observed.

4 A POWERTRAIN TEST FACILITY WITH THE STATE OF THE ART INSTRUMENTATION

A test facility with advanced instrumentation has been developed for experimental investigation of the dynamics of vehicle powertrains fitted with various types of transmissions [6]. Figure 2 shows the picture taken from the test facility and its major components include BTR 4-speed AT; Ford 6-cylinder engine, wheel hubs, tires and propeller shaft; and Spicer Axle's final drive. The facility can be used for: experimental validation of theoretical predictions of the transient characteristics of automatic transmissions during gear changes; implementation of closed loop control of gear shifts; and in particular, experimental investigations of torsional vibration of a complete powertrain caused by various nonlinearities and drive conditions.

Fig. 2 The powertrain test facility at Mechanical Engineering Laboratory of UTS.

All the major components of a vehicle powertrain system are integrated in the test rig, including a flywheel subsystem that simulates the inertia of the vehicle and a hydrodynamic dynamometer for simulating air drag. A specific wireless torque measurement system is currently under final testing. The developed wireless torque transducers are mounted at four points of interest on shafts throughout the rig. These transducers enable us to capture the transient torque at various shafts along the powertrain, such as the engine output shaft, transmission shaft, propeller and drive half shafts.

The torsional vibration characteristics of the test rig were determined and compared to those obtained from an existing car. The results showed that this test rig is a very good approximation to a real car and is thus suitable for experimental investigations of the transient characteristics of automatic transmissions. Reference [6] provides the design details of the facility and the above mentioned results.

5 TRANSIENT OUPUT TORQUE OF AUTOMATIC TRANSMISSION

The purpose of the experiment is to measure the output torque of a four speed automatic transmission during 1-2 and 2-3 gear shifts, and under tip-in and tip-out operation conditions. Comparisons are also made to those captured via the simulations. On the test rig, the automatic transmission is set in drive mode after the engine is started. The throttle position was increased and decreased gradually in order to trigger up-wards and down-wards gearshifts. The developed wireless torque transducer measures the transient output torque of the transmission during these shifts.

(1) Tip-in operation: a large throttle input was applied to the powertrain and the output torque of the transmission was taken while no gear shift took place during the short period of time. For this test, a light load was applied to the powertrain. Figure 3 shows the obtained output torque. It is noted that some data is missing in the plot, e.g., right after 2.5 seconds. This is due to the software trigger problem that exists in the microcontroller. We are currently working on an improved version of the rotating PCB that will remove this problem.

From the measured output torque, we observed that there was a significant torque oscillation after the sharp rise at about 1 second. The frequency of the torque oscillation is estimated between 6.5-8 Hz that is the same as the second natural frequency (6.9 Hz) obtained from the free torsional vibration analysis of the powertrain facility. The obtained second vibration mode indicates that the engine and automatic transmission have dominant vibration at this frequency when it is excited. Due the existence of certain damping and drag in the torque converter, the vibration was reduced significantly in the first 0.5 second.

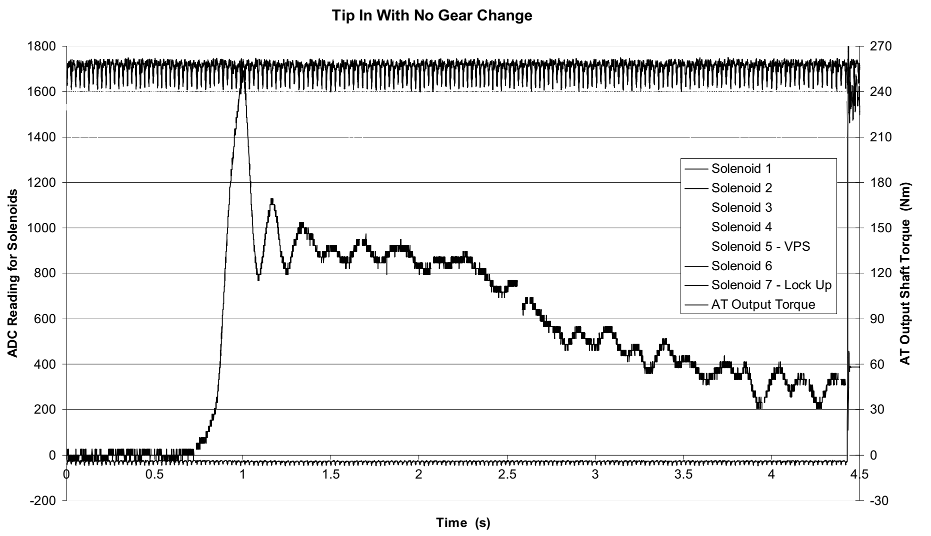

Fig. 3 Measured output torque of the automatic transmission under tip-in operational condition.

(2) Tip-out operation: after the powertrain reached a steady-state running condition with certain load, a minimum throttle input (idle speed) was applied to the powertrain and the output torque of the transmission was taken during the short period of time. For this test, a medium load was applied to the powertrain. It is noted that the torque was smoothly reduced to the minimum with small oscillations. The obtained output torque was not shown here due to lack of space.

(3) 1-2 and 2-3 gear shifts: For this test, light load was applied to the powertrain. A constant throttle position (20%) was applied and the vehicle (flywheels) was accelerated gradually and 1-2 gear and 2-3 gear up shift took place respectively. The transient output toque was captured during this period and was shown in Figure 4. From the transient output toque occurred during 1-2 gear shift, there was a significant torque hole in the torque phase and a rapid increase in the inertia phase. Similar phenomena was observed from the transient torque occurred during the 2-3 gear shift. The transient output torque during these two gear shifts was also captured from simulations on gearshift using the multi-rigid-body dynamic model of the powertrain, as shown in Figure 5 (solid line of the left plot and dotted line of the right plot). The transient output torque during 2-3 gear shift was also completed using a multi-degrees of freedom flexible powertrain model, as shown in Figure 5 (solid line of the right plot), in which significant torque oscillation occurred after the gear shift. This is partly due to a light damping in the system was assumed and the fluid drag in the transmission was ignored in the simulation. The torque oscillation is also evident in the obtained transient output torque during 2-3 gear shift shown in Figure 4 but it was reduced quickly due to significant damping in the powertrain system.

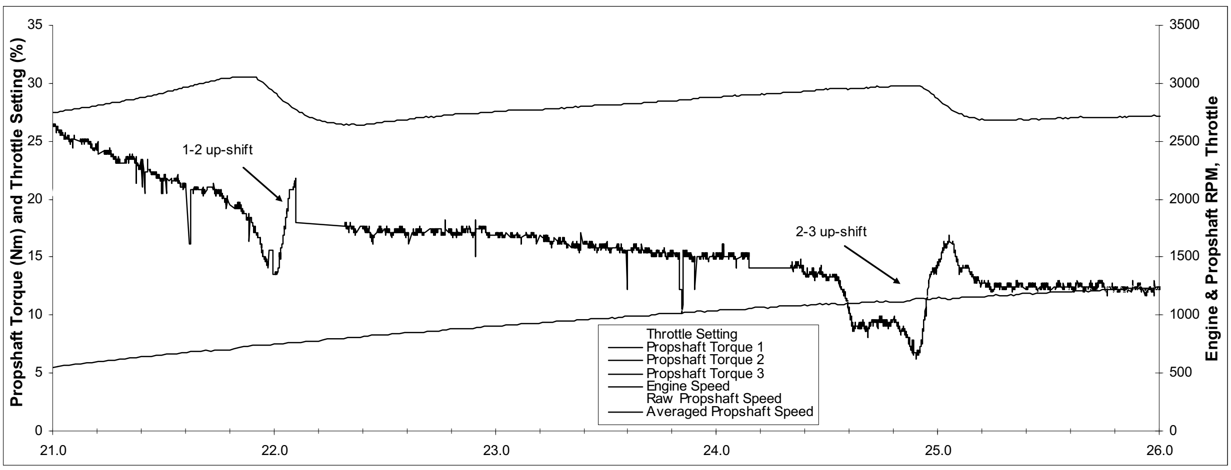

Fig. 4 Measured transient output torque of the automatic transmission during 1-2 and 2-3 gear shifts.

It should be pointed out that the torque sensor is not perfect. The data flow is periodically interrupted by a software handshaking issue, and occasionally a data packet will be corrupted by RF noise. Nevertheless, the key transient output torque during gear shifts was well captured in accordance with other measurements. Figure 6 shows the measured output torque, engine speed and averaged propeller shaft speed of the powertrain during 50 seconds of the operation.

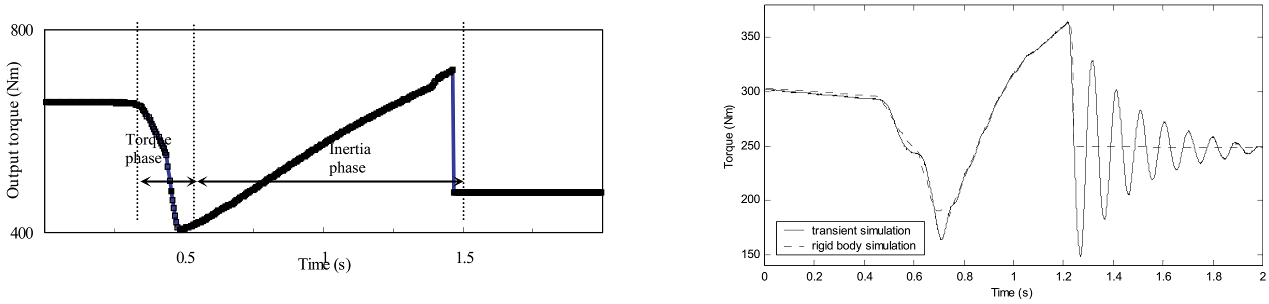

Fig. 5 Simulated transient output torque of the automatic transmission during 1-2 (left) and 2-3 (right) gear shifts.

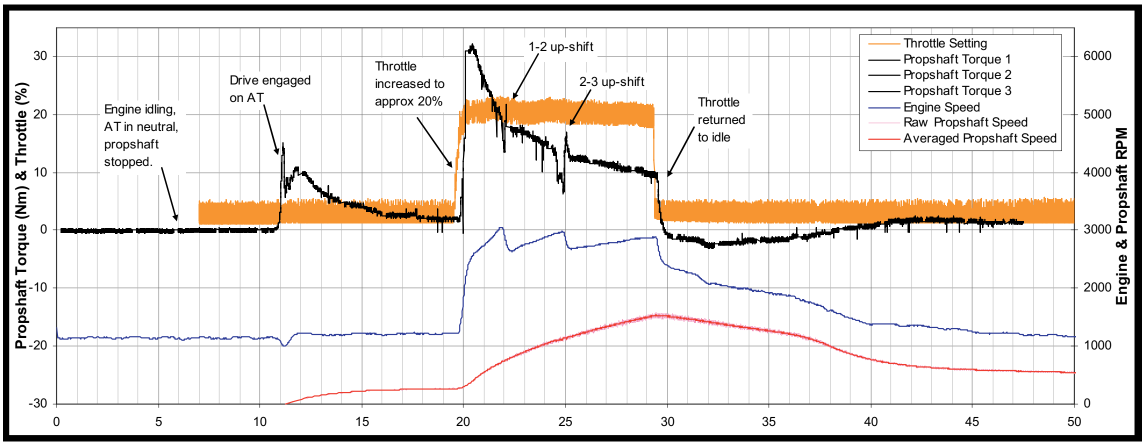

Fig. 6 Output torque of the automatic transmission and engine speed during 1-2 and 2-3 gear shifts.

6 CONCLUSIONS

This paper presented the development of a specific wireless torque measurement system that is used to obtain the transient transmission output torque. Details of the major components of the sensor, calibration and test tuning were provided. The senor was installed at the output shaft of a 4-speed transmission powertrain test facility for capturing transient torque. A number of tests have been performed on the powertrain test facility with various specified disturbances such as tip-in, tip-out, 1-2 and 2-3 up-dear shifts. The transient output torque of the automatic transmission are measured and compared with those obtained from simulations performed with the estimated same operating conditions. The two sets of transient torque correlate with each other. The experimental results show that wireless torque transducer works and meets the major design specifications. Some deficiencies existing in the current senor were also discussed.

CUT YOUR COSTS BY 75% - HOW A LITTLE PREVENTION CAN SAVE A LOT OF MONEY

Allan Bruce

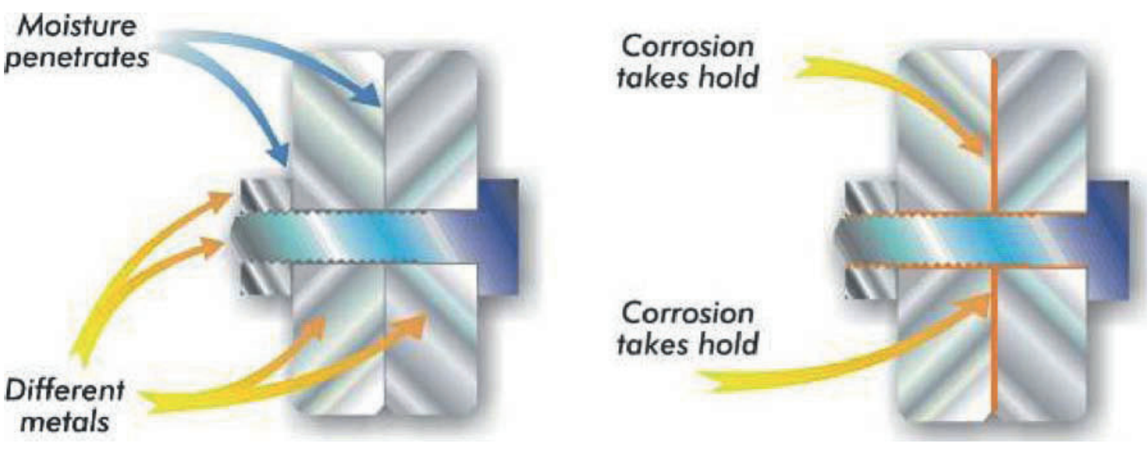
The Alocit Group, 112 Stirling Highway, NORTH FREMANTLE WA 615, Australia

Abstract: An introduction to cost benefits of the Enviropeel System, a system that uses a heating and pumping system to melt and spray a thermoplastic material in order to provide a corrosion-inhibiting protective coating around substrates of any size or shape. The material contains its own inhibitors, thus providing both passive and active protection for protected surfaces. As part of the development process, long-term testing of Enviropeel forms part of the DNV JIP Bolt Testing Programme, a programme which includes Conoco-Phillips and BP, at whose behest the tests were planned. First results after 18 months of the 10-year programme show very good results for Enviropeel. Case studies have shown from various areas around the world with a focus on the experience of the Enviropeel System in WA with BHP Billiton and Dampier Salt. Results over the past three to four years have been so spectacular, with projected lifecycles of equipment increased by a factor of 5, that the Enviropeel system has become standard practice due to the substantial cost savings.

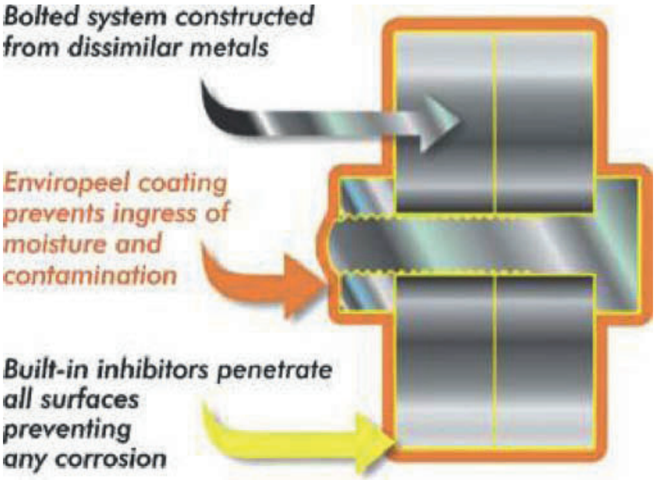
Key Words: Alocit, bolts, bolted systems, cost effective, component life, corrosion-inhibiting, dipping, , encapsulating, environment, Enviropeel, loading, mining, offshore, polymer, pulley, recyclable, renewability, re-usable, Robil, thermoplastic, samples, Slugger, flanges, valves, sprayable, Pilbara, conveyor bearings, BHPBilliton, Dampier Salt

1 INTRODUCTION

The Enviropeel system uses a specially designed unit to spray apply a corrosion-inhibiting thermoplastic barrier coating. It was developed to provide a solution for the many corrosion problems associated with bolted systems such as flanges and valves, by adopting a whole system approach rather than providing a variety of individual solutions for the wide range of problems that beset such systems.



When flanges or valves fail both safety and cost implications can be quite severe. At the most mundane level, replacement will probably involve costly shut downs, cutting bolts and refurbishment. Leaks can affect the environment and the potential for severe consequences is ever present. Bolted systems are vulnerable to corrosion in a number of ways. From galvanic corrosion because they contain a variety of components, often of quite different materials – stainless steel flanges with carbon steel bolts, for example. Gaps and voids bring pitting corrosion, assembly damages coatings and washers often fail.



Enviropeel isolates and encapsulates the substrate, depriving corrosion of the moisture it needs and bathing the entire system in corrosion inhibitor, actively preventing rust and ingress of contamination.

2 THE STATUS QUO

What levels of protection are provided by current systems? In truth, not a lot. Of course, you can keep cleaning and painting on a very regular basis but, at best, this locks all the bolt with accumulated paint and often leaves flanges streaming with rust in as little as 6 months. Flange protectors, tape wraps, bolt caps – all can play a part but are either partial solutions or so lock away the protected substrate that access is extremely difficult when required.

Pictured left is an example of what can happen despite the best efforts of engineers to provide protection.

Although caps have been used to protect the bolts - they are not protecting anywhere else - and they are not even possible to use on all the bolts because in some areas the heads are so close together access is impossible. Caulking has been used to try and protect the flange faces – but it has shrunk back, creating the perfect environment for moisture to get in and corrosion to accelerate!

And you have to feel sorry for the allen bolts at the base – they have no chance. Streaming rust from the structure above, galvanic corrosion from the various metals in the system – and a perfect collection point in the top of each bolt, apparently designed to collect water and generate corrosion!

3 WHAT DOES THIS HAVE TO DO WITH AUSTRALIA?

The flanges above show what we believe to be the best available protection for bolted systems – completely protected from its environment and actively protected by built-in corrosion inhibitors.

The pictures above show typical examples of what they were trying to prevent. Believe it or not, the picture on the right is a brand new pulley – or at least it was before two years of storage – the wrapping has failed and there is significant corrosion damage in the bearing

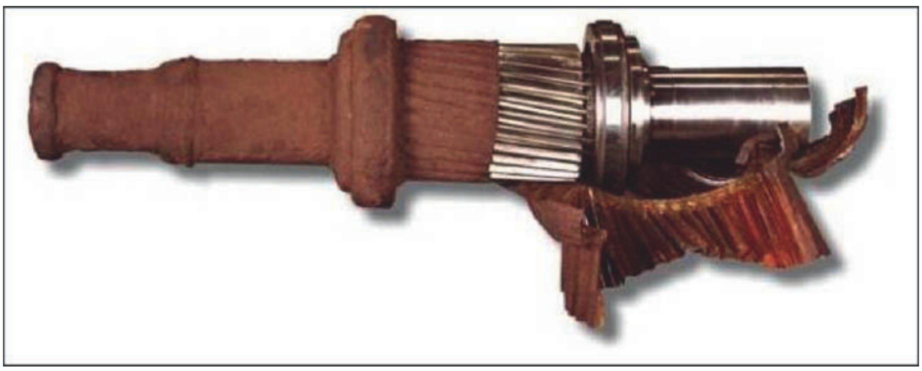
Enviropeel was first introduced into Australia by a director of an engineering company based in the Pilbara. The company, Robil Engineering, was heavily involved in work for the mining industry in the region. As the work involved extensive re-engineering, with lengthy storage periods before installation, corrosion, both before and after the engineering work, was a major cost factor.

The ability to provide a dual purpose coating – providing both active and passive protection – to any object, no matter its size or complexity, was what attracted Robil to Enviropeel.

Robil began by applying Enviropeel to machined surfaces and components for storage. Soon, they were applying it to complete assemblies - and finding that all their previous problems with corrosion during storage had been eliminated.

Soon Enviropeel was being applied to all machined parts and steel assemblies – and achieving remarkable results. The gear shaft below typifies the results that Robil found –peeling away its protective coating after two years exposure in aggressive conditions, the gear shaft emerges in fantastic condition.

With such success with stored parts, the Company's thoughts turned to what could be achieved on operational equipment. One of the major components that Robil had to re-engineer was conveyor bearings. Hundreds of bearings from the many miles of conveyors operated by major customers BHPBilliton and Dampier Salt required constant replacement because of the high levels of iron-ore dust and salt in which they had to work.

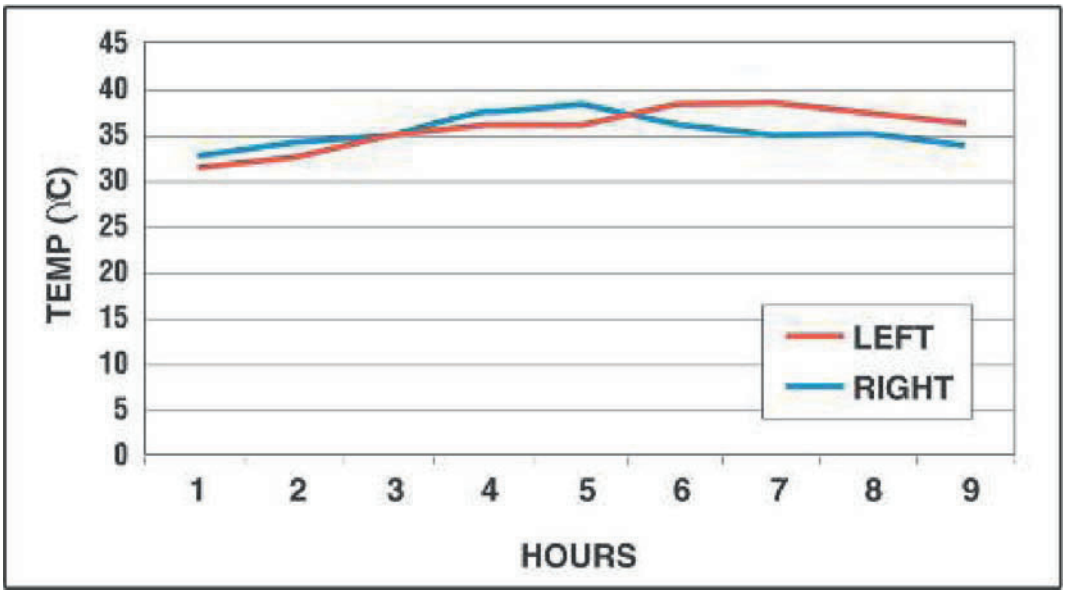


This bearing race on the right shows the wear patterns that produced failure

It's easy to see why Robil thought something needed to be done. The condition of these components is typical of what could be found in the most aggressively corrosive areas

Because of Enviropeel's ability to be sprayed even on to the rotating shaft of the pulley, it seemed to Robil that, not only would the material provide corrosion protection but that it might also prevent ingress of the dust and other contaminants that were so damaging to the bearings.

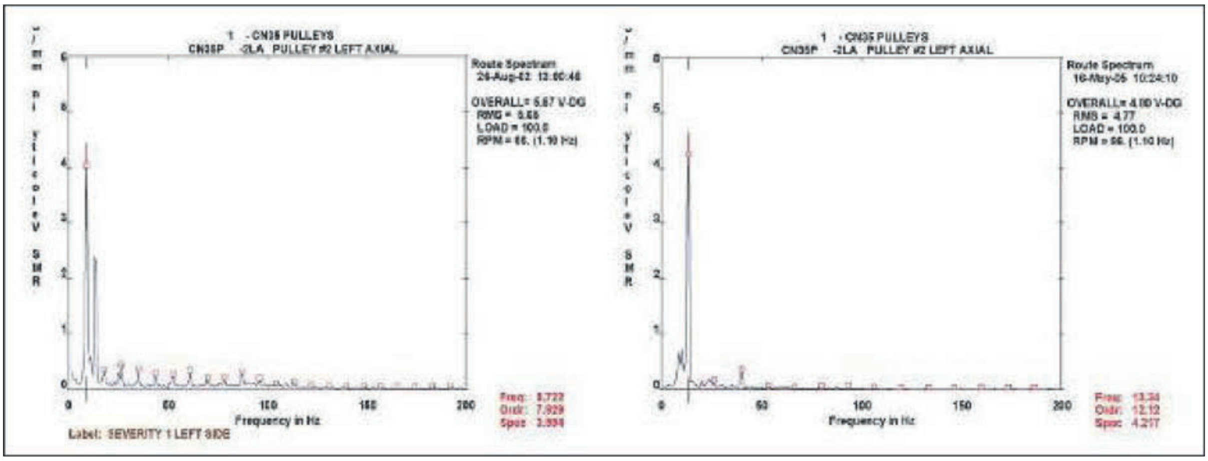
In the most severe areas, pulley bearings, which were costing $8000 to replace, were failing in an average of only nine months. If something could be done to increase their lifespan, the savings to the mining companies could be considerable.



Tests first had to be undertaken to see if the coating would have any adverse effect on bearings while in use – would the material increase operating temperature or prevent access for maintenance or inspection. Tests showed that the coating did not increase running temperature and access, where necessary, was easily achieved and the coating re-applied.

With cooperation from BHP Billiton and Dampier Salt, Robil installed test bearings with their housings still encapsulated in Enviropeel and the trial process began. It soon became evident that the system was a winner. Following the introduction of Enviropeel, warning indications from the bearing monitors ceased.

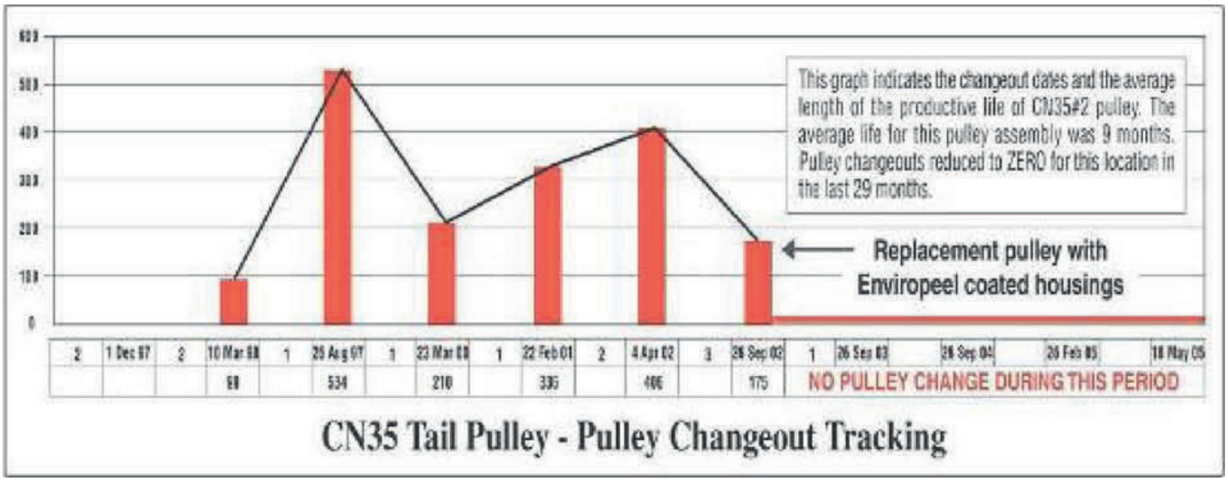
Conveyor operators monitor the state of the bearings for vibration and spectrum graphs, like these shown below, measure the vibrations recorded as wear occurs and bearing clearances increase. On the left-hand graph unprotected pulleys show typical large measurements as wear increases to the point of failure, whereas on the right the consistent low signals following the introduction in Sept 02 of a pulley coated with Enviropeel, during which time no further replacement of bearings has been required.



Note: The spike seen on the left of this particular graph is the lower frequency screen signal picked up during readings taken that particular day, and does not relate to wear factors. The earlier graph, on the left, shows a vibration level with a Severity 1 rating, indicating urgent change-out is needed to avoid a potentially dangerous failure.

Severity ratings commence at 4 (lowest) and progress through to 1. The more aggressive the environment, the quicker the wear rate and severity upgrades on unprotected pulleys.

This data shows what a difference Enviropeel makes – prior to September 2002 bearings were failing at an average rate of 9 months in the severest areas. Once Enviropeel was introduced, no further replacements were required – no excessive vibrations, no severity warnings. The graph shows up to May 2005 but in February 2006 there have still been no failures



The contrast between the corrosion on the roller in the top left of the picture and that of the bearing housing – both of which were refurbished at the same time - shows how effective Enviropeel can be.

4 COST SAVINGS

The potential for cost-savings is enormous. The system is currently showing an increased lifespan of over 400%. On one pulley alone, over 5 years, the saving will be over $50,000 and, although not all pulleys are in such severe areas, there are over 4500 pulleys in the Pilbara alone, with an estimate of at least 15,000 across Australia. Whatever the potential lifespan of the various bearings, it is obvious that millions of dollars could easily be saved if they were all using Enviropeel.

5 CONCLUSIVE RESULTS

An outline of the results from Robil makes it clear why their innovative approach won them a 2005 Engineering Excellence award.

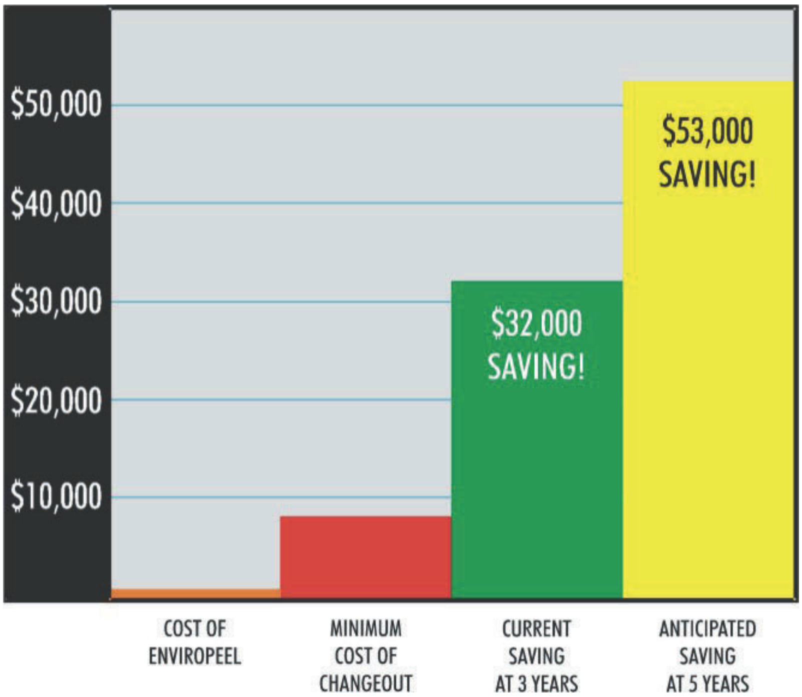
5.1 On stored conveyor pulleys

- Return for replacement without Enviropeel 44.5%
- Failure rate with full Enviropeel protection 0%

5.2 On operational pulleys

No bearing has failed since Enviropeel applied, previous average only 9 months!

Cost saving per bearing



Average bearing life in original trial location	**9 months**
Current bearing life in original trial location with Enviropeel applied	**36+ months**
Resulting component life increase	**400+%**
Resulting saving in pulley change out costs	**$32,000+**
Reduction in maintenance costs	**95 %**
Percentage of Enviropeel costs to rebuild costs	**10-15 %**
Percentage of Enviropeel costs to pulley change out costs	**5-7 %**
Resulting percentage reduction in risk exposure	**63+ %**
Anticipated increase in component lifetime	**670 %**
Average reduction in greasing regime	**75%**

6 CONCLUSION

Enviropeel is environmentally friendly. Reusable and recyclable it saves waste and contains no VOCs or other toxic materials.

It is easy to remove, when access is required and can as easily be reapplied – even using the same material!

We have already seen what cost savings can be made but the system, by reducing the amount of maintenance and risk involved in such complex renewals, also brings significant safety benefits.

Already specified by BHPBilliton and Rio Tinto for use on their equipment, Enviropeel is also being used or assessed by a number of other companies in all parts of Australia.

Enviropeel is a simple product with a huge market for overcoming ingress and corrosion of critcal spares and equipment.

The savings to date have been calculated to be in the thousands of dollars. What hasn't been mentioned is the LTI's or injuries prevented due to the reduction in the number of change outs required, which would be well over 75%!

MEASURING SAFETY IN GAS DISTRIBUTION NETWORKS

Ype C. Wijnia [a,b] and René J.M. Hermkens [c]

Abstract: In the Netherlands, the safety of the gas distribution system is a hot issue. The public perception is that the safety of the system is decreasing, whilst the industry thinks that it is business as usual and that neither the number of incidents nor the consequences of incidents are larger than they used to be. Which of the claims is true? To this question there is no objective answer. First of all, no accessible database exists that contains records of all relevant incidents. Secondly, there is no agreed upon method to combine all those incidents into a simple, easy to understand indicator of safety. In this paper we first explore the theoretical framework for such an indicator. Combining this framework with actual incident data will result in a quantitative model. Finally, we present the results of the quantitative model. The paper ends with an outlook for the application of the indicator in the quality regulation of the Dutch gas distribution companies.

Key Words: Safety, measurement, indicator, gas distribution,

1 INTRODUCTION

The gas distribution industry in the Netherlands claims that the system is safe. To support this claim, they refer to countless numbers of NEN/EN/ISO standards, which are applied in the design and maintenance of the system. Phrased differently, they state that gas distribution is highly technical, that experts have thought about the details thoroughly, and that those experts should be trusted. As both the standards and the experts are from within the industry, the basic message is: "You can trust us, we are the experts, we know and we care", a message that worked well for a long time.

In the current society, however, this asked for trust does not come naturally, as Shell, for example, experienced with the Brent Spar. In short, the Brent Spar was an oil storage rig in the North Sea that had to be decommissioned because its function had been replaced by pipelines. A Best Practicable Environmental Option study showed that the best way forward was a deep sea disposal. Greenpeace, however, did not agree with this study. They stated the volumes of toxic materials were much higher than Shell claimed and possessed the rig to prevent the disposal. The public assumed Greenpeace was more trustworthy than Shell and boycotted the Shell gas stations, an act which forced Shell to change course. In the aftermath, Greenpeace had to admit that they were wrong and Shell was right about the toxic content of the Brent Spar, but that did not help Shell anymore. The option of deep sea disposal was definitively out of question.

In the debate on the safety of the gas distribution system, some parallels can be drawn to this Brent Spar example. First of all, the liberalization of the Dutch energy markets in the period 1999-2004 resulted in lots of faulty invoices from the energy companies, destroying the image of a trustworthy industry. The large 3 energy companies ranked high in customer dissatisfaction (top3), according to consumer watchdog television programmes like Kassa and Radar. Secondly, because of this bad press, every gas related incident was connected to the liberalization, even if it had nothing to do with the gas distribution system. An example can be found in the explosion in The Hague (June 28, 2003), which according to the first reports was caused by gas leakage from a gas pipeline, where in fact it was caused by a leaking propane tank in the cellar. As a bonus, the public awareness of incidents was further enhanced by the rise of numerous reality TV shows and local human interest programs on the increasing number of nation wide television stations. The odds of an incident drawing attention of one of such shows were further enhanced by new technologies like the internet and cellular phones, speeding up the propagation of news. Furthermore, the Dutch safety board has published a few reports with some very alarming conclusions. As a result it seems as if the number of incidents is increasing.

In this light, it is not very surprising that the public did not take the industries claim of safety for granted and demanded additional measures. The awareness of incidents increased, and awareness drives the perception by the availability bias (Tversky and Kahnemann, 197x). But is there any truth in the perception? Is the gas grid really becoming unsafe?

Embarrassingly, to this question no objective answer existed. Beside the statistics on leakage and the standards, the industry did not have any facts supporting the claim of safety. On the other hand, there was no evidence for an increase in the number of incidents either, but the industry did have to prove its claim as perception was the public truth.

To issues revolving about the public perception, the best approach is not to claim expertise and declare safety, as the industry was used to (and Shell did initially with the Brent Spar), but to share knowledge and data (Shells reprise). This created an interesting challenge for the gas industry, as they did not have very much knowledge and data to share. First of all, they did not have an easy accessible database on all incidents and accidents related to the gas network. Secondly, they did not have any methods to translate such a list of incidents into an easy to understand measure of safety.

Fortunately, some experience on quality issues existed. Most gas distribution companies in the Netherlands also distribute electricity, and for the electricity grid, the major quality indicator is Customer Minutes Lost, which had been recorded for some 25 years in the so called "Nestor Enquete". If such an instrument could be developed for the safety of the gas grid, it might prove helpful in the public debate. However, discussions on safety issues are always difficult, as extensive research on this subject has shown (Slovic, 2002). Furthermore, even the existence of an objective metric for safety does not guarantee the right perception, as the reliability indicator for the electricity grid shows. The perception is that electricity is interrupted once every year for about 2 hours, where in fact it is only once every 4 years according to the 25 year statistics (SEO, 2004).

Despite these potential barriers for acceptance, just knowing for sure was tempting enough for the industry. Both authors were asked to take part in the development of the safety indicator. In this paper, we present the results of this development process. We first address the issues surrounding the concept of safety, like actual figures versus disaster potential, adding different types of accidents, the value of a human life and so on. This is the value judgment section. The next step is building a conceptual model for the indicator which translates the measured inputs into a single metric. As we shall see, a direct assessment of the safety consequences is not a reliable indicator for the safety of the gas distribution system. A deeper understanding of the underlying mechanism is needed. This is the conceptual part. Finally, we will fill this conceptual model with actual incident data, resulting in a quantitative estimation of the safety risk in the gas distribution system. We will end the paper with conclusions on the usefulness of the indicator.

2 THEORETICAL FRAMEWORK

In this section we address the issues surrounding the debate on safety. As we will see, much of the issues require some kind of value judgement on a certain aspect of the total safety abstraction. To structure the discussion, we will first focus on the different concepts of safety. Bases on the characteristics of the safety risk and the uncertainty involved, we will choose a concept for the indicator. Next, we will address the issue how to count safety incidents. Safety incidents can have quite different consequences, like personal injuries or fatalities, but also property damage. Adding those consequences is not trivial. This non triviality holds within a consequence level (is every fatality equal), between different consequence levels (how much worse is a fatality than a serious injury) and between different values (how should a fatality be compared with financial losses, or customer minutes lost). We will end up with a valuation scheme for the different types of consequences.

2.1 The concept of safety

Safety can be used in a myriad of ways. Sometimes it refers to financials (this is a safe investment), sometimes to information (how safe is the internet), but in many cases it refers to personal injuries (road safety figures). Furthermore, safety can be about the actual figures (the annual fatalities on the road) or about the expected figures, the so called safety risk (e.g. nuclear power). Discussions on actual figures revolve around the definitions. For example, does the road safety figure only count the victims at the crash site, or are the ones in hospital afterwards included? Until how many days after the accident should those be counted? Those issues are solved relatively easy.

Discussions on safety risks are much more difficult. This is because different views exist about the essence of risk. In the first conceptual approach, risk is seen as an entity that can be objectively measured or calculated. In this view, risks are typically expressed as a product of consequence and likelihood. This objective risk is used by financial managers, safety engineers, decision analysts and so on.

The second approach, challenges the assumption of objectivity, as it is not this objective risk that determines if a risk is acceptable. Some people smoke (high objective health risk) but worry in the same time about electromagnetic radiation from High Voltage Transmission Lines (health risk uncertain). Research by Slovic has shown that this acceptance level is driven by so called psychometric factors (figure below) and not by the objective risk level. Risk is therefore very subjective.

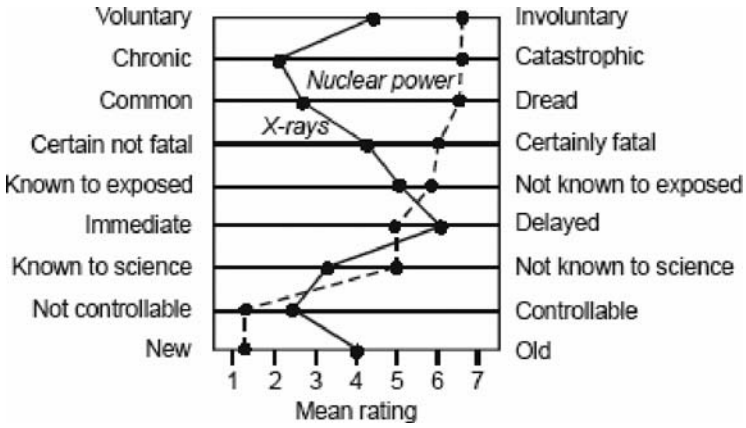

Figure 1: Psychometric factors for risk perception (source Slovic and Weber (2002)

Despite the usefulness of this subjective risk in risk communication, it does pose some problems for risk managers. For example, if the acceptance of a risk is determined solely by its disaster potential (like it was the case for nuclear power), no amount of risk measures can make it acceptable, as the disaster will always be thinkable. However, stopping all activities with a disaster potential might reduce the standard of living by a considerable amount, a sacrifice that few citizens are willing to make.

The constructive approach tries to bridge the gap between the objective and the subjective concepts, by stating that a risk is a social construction that human beings have "invented" to deal with the dangers and uncertainties of life. The dangers and uncertainties are real, as is the response to the risk (Thomas Theorem), but the risk itself does not need to be real. This approach is advocated by the USA's National Research Council (NRC, 1996). A risk can therefore be defined as *a potential problem that needs to be decided about*. This view is further supported by the value judgements needed to arrive at a risk figure (as mentioned in the introduction to this section).

Which of those concepts should be used for the safety indicator? For answering this question the classification scheme of Klinke and Renn (Klinke and Renn, 2002) could be used. They propose 4 different kinds of decision approaches for different risks, being rule based, risk based, discourse based and the precautionary principle. The drivers in this classification scheme are uncertainty, disaster potential and the social mobilization factor. As the uncertainty is pretty low (over 50 years of experience), the key issue is whether or not the gas distribution system has disaster potential. Natural gas can cause large explosions (e.g. Alpha Piper) but this is only possible at pressures well above the ones used in the gas distribution system (EGIG 2004). Therefore, a risk based approach could be used, even though some value judgement is needed. To manage the potential for social mobilization it is best to make it a collaborative effort by the industry and the regulating bodies.

2.2 Comparing incident types

In order to be able to add different types of accidents into a single number, some kind of a valuation scheme is needed. This valuation scheme should answer three questions: Which are the affected values that will be taken into account? What levels of severity will be distinguished? What are the equivalent values for the different levels of severity?

Those questions are not unique for a safety indicator. On the contrary, most companies familiar with risk management use a valuation scheme in their risk matrices. What we are looking for would be a risk matrix without a probability axis, being a consequence matrix. In case of the safety indicator, the only question left to answer would be what affected values would be taken into account. The use of personal safety would be trivial, but was any other value needed? The obvious candidate would be property damage, a well known consequence of gas explosion. Property damage could be assessed objectively. Therefore its inclusion would not threaten the objectivity of the indicator. In the table below the severity of different consequences for those values is shown.

Table 1: Severity levels of personal injuries and damages

Severity level	Personal injury	Damage
6	Multiple fatalities	> 10 million euro
5	Fatality	1-10 million euro
4	Serious injury	100k-1M euro
3	Lost time incident	10k-100k euro
2	Near miss/first aid	1-10 k euro
1	Unsafe situation	< 1k euro

In this matrix the logarithmic character of the severity classes is very clear for the value “property damage”. Quite surprisingly, this logarithmic character also holds for the personal injuries. Research has shown (iceberg theory) that for every fatality about 10000 unsafe situations, 1000 near misses, 100 lost time incidents and 10 serious injuries occur. Even though adding injuries is quite different from adding damage (financial damage can be transferred, personal injuries cannot), if used with the mentioned scaling factors it makes sense statistically. It allows us to express any combination of safety incidents in the equivalent fatalities. The scaling factor between the values seems to be an industry standard (Shell 2002). By expressing even the injuries in the monetary equivalent, all incidents can be expressed on a single scale, although this does in no way mean that a human life can be replaced by a certain amount of money. After all, no markets exist in which people sell their own lives.

3 DIRECT ASSESSMENT OF THE SAFETY INCIDENTS

Now that we have defined what we mean by safety, we can start counting. For this we used the Kiwa/Gastec accident database, which holds records of all network related accidents in The Netherlands dating back until 1993. In addition we used the reportable incidents of the Dutch safety board, although they only kept records for 2004 and 2005. The distinction between accidents and incidents is not meaningless. An accident is an event in which someone got hurt or third parties property was severely damaged (> € 500,000) as a direct result of the event, whereas an incident is an event in which this might have happened. The cost of the measures taken to prevent an incident becoming an accident (like evacuation costs) are not included. The total number of real accidents was 39 over the period 1993-2003, which averages 3-4 accidents per year. However, the variance is very large, as shown in the figure below. The number of accidents varies between 2 and 5, but the equivalent value ranges from almost zero (1996) to over 10 million (2002). Clearly, no correlation exists between the number of accidents and the equivalent value. Besides, it is highly unlikely that the outcome is correlated to the quality of the grid. This means a metric based on a direct assessment of the accidents does not produce a robust outcome if it is to be used for investment decisions.

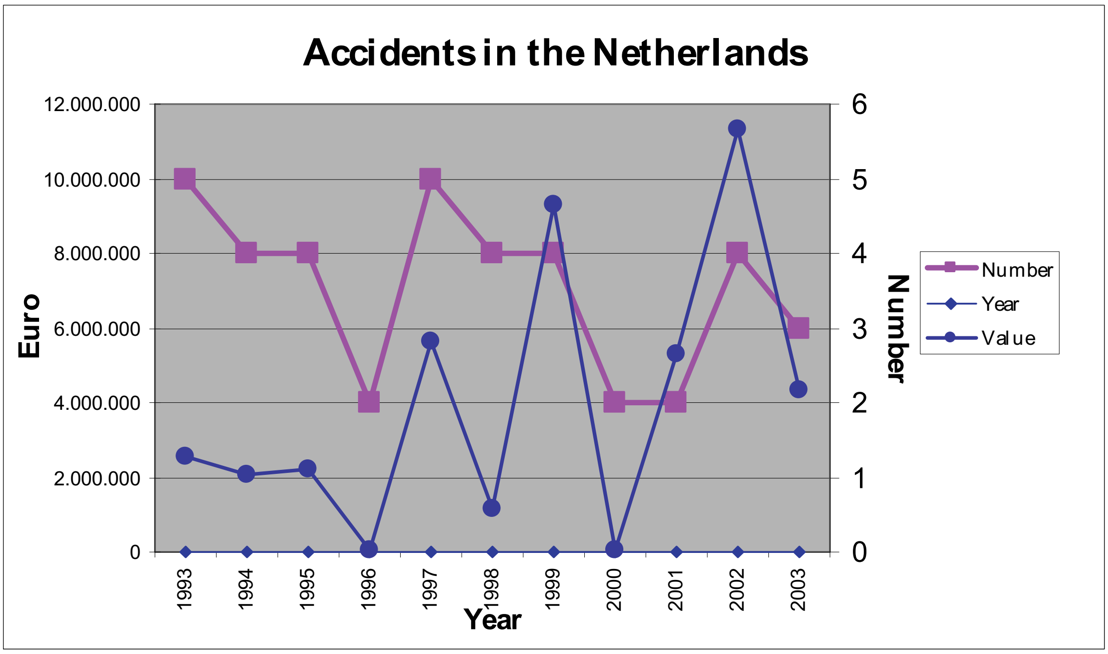

Figure 2: Gas related accidents in The Netherlands, number and equivalent value

This lack of robustness is a result of the low number of accidents, on average about 3 per year. As the indicator is meant to help in investment decisions, lack of robustness would be a fatal flaw. To overcome this problem, the data used to calculate the safety has to be extended. We will use the incident process (based on Wijnia and Herder 2004) to get a better understanding what those data should be.

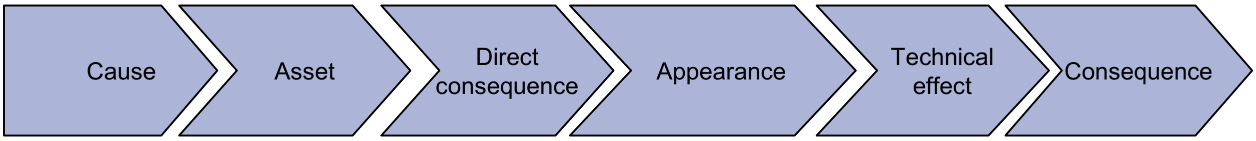

Figure 3: Incident process

The incident process states that value consequences do not appear out of nothing, but are a result of a chain of cause and effect. For example, excavation works (cause) can damage a service line (asset), resulting in leakage (direct consequence). The escaping gas might accumulate (appearance) in a closed space. If the gas explodes (technical effect), it might destroy property and injure people (value consequence). Barriers might exist between the different phases in the incident process. Not all excavation works damage pipelines, not all damaged pipelines leak and so on. This means that if we can reconstruct the processes that led to the mentioned 39 accidents, we might be able to measure safety based on situations occurring earlier in the process. As the number of those situations is much higher than that of real accidents, it is more likely to produce a statistically sound figure.

This incident process based approach also matches the concept of safety as a risk, as it addresses not only the real accidents, but also the potential accident. Applying the incident process to the recorded accidents led to the conclusion that only a few combinations of causes and assets, of the thousands possible ever led to a safety accident. The causes and assets are shown in the incident triangle below.

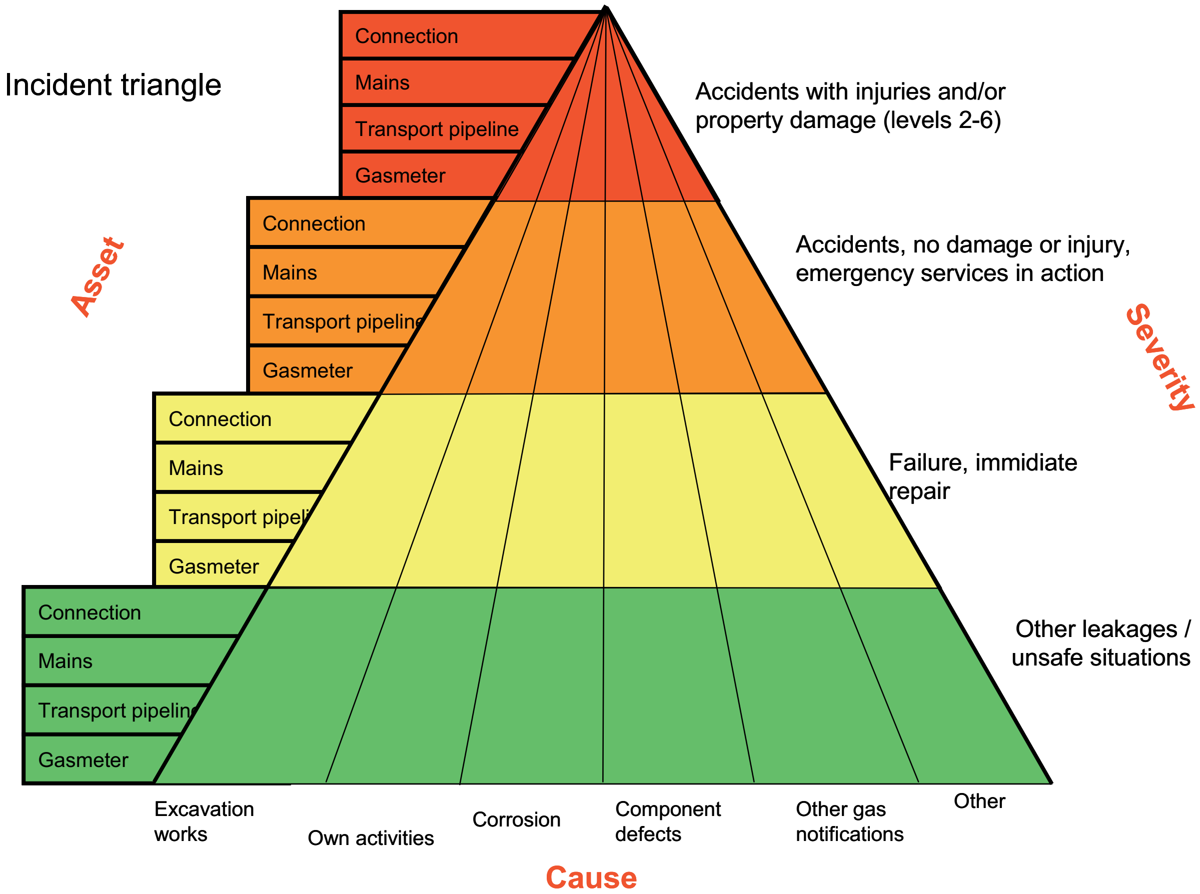

Figure 4: Incident triangle

A direct link exists between the incident process and the triangle. For each combination of asset and cause, four levels exist on which an incident can end, corresponding to the phases 3 to 6 of the incident process. The top level (red) accidents are those incidents that completed the incident process and had a value consequence. The second level (orange) represents the incidents that showed technical effects, but did not create heavy value losses. The third level incidents (yellow) are the ones that did have a public appearance, but no immediate dangers. Finally, the bottom level (green) represents those incidents in which a cause had a direct effect on an asset. Situations in which the asset was not damaged by the cause are not considered to be incidents.

In the incident process, a limited likelihood of propagation exists. Only a fraction of the assets will be exposed, only a fraction of causes acting on assets will create damage, only a fraction of the damage will reveal itself by escaping gas, only a fraction of the gas clouds will be within the explosion limits, and finally, not all dangerous situations will actually damage property or hurt people. Therefore, the number of incidents in the green level is much higher than the red level. This is in line with the iceberg model as described by Heinrich (1931). An indicator based on green level incidents should in theory be more reliable than an indicator that measures top level accidents. In practice, however, this does not hold, as the reliability of the indicator also depends on the quality of the incident registration, which is far better at the top level than at the bottom level. Fortunately, in the Netherlands we have Nestor-Gas, a database which holds records of incidents that required immediate action (yellow). This satisfies both the need for a robust number of incidents as the need for a reliable data source, and therefore will be used as the basis for the indicator.

With the framework presented above it is possible to calculate the total risk of a group of assets. However, absolute figures often do not mean much, as it does not tell about the size of the population from which the figures were derived. For example, road safety is always expressed as the number of fatalities per 1000 inhabitants, or per million miles. This makes it possible to compare different years within a country, or to compare different countries. Which metric is the correct one, however, depends on the question to be answered. The inhabitant based metric tells about the likelihood of an average person to die from a road accident. If the question is about the safety of road design, it is better to use the mileage based figure. For the safety indicator, both an inhabitant related metric and a network length related metric can be used. Because the issue is public safety, it seems logical to use the inhabitant based figure. So, to calculate the safety indicator for a group of assets, we have to count the number of different types of incidents, multiply those numbers with the average incident risk, add the risks and divide the total by the number of connections in the asset group.

This concludes the theoretical framework of the safety indicator. We have defined what we mean by safety, and specified a methodology to add all accidents into a single figure. In short, the safety indicator is a metric that is proportional to the likelihood of an individual to die from an accident in the gas distribution network. In the next section we will look at the quantitative properties of the indicator.

4 THE QUANTITATIVE MODEL

In the previous section we have explained the methodology of the safety indicator. Now it is time to use the concept and apply it on the incident data. We first will show the list of cause-asset combinations that led to an accident in the past 11 years. Next, we will explain how to calculate the expected effect of a single cause-asset combination. We end the chapter with the average effects of the relevant incidents.

4.1 Relevant cause and asset combinations

In our mapping of the accidents on the incident process we found that only a few combinations of assets and causes ever resulted in an accident. These combinations are presented in the table below.

Table 2: Accidents per cause/asset combination for the period 1993-2004

ID	Asset	Cause	Personal injury	Damage (=total number)
1	Service line	Excavation	4	47
2	Service line	Own activities	2	3
3	Service line	Soil settlement	1	1
4	Service line	Component defects	2	4
5	Service line	Corrosion	2	9
6	Service line	Other leakage	5	1
7	Mains LP	Other	0	25
8	Mains LP	Component defects	5	6
9	Mains LP	Own activities	18	23
10	Mains LP	Excavation	4	164
11	Mains LP	Soil settlement	0	41
12	Mains LP	Other	2	4

13	Mains LP	Other leakage	1	12
14	Mains HP	Component defects	0	1
15	Mains HP	Corrosion	0	8
16	Mains HP	Excavation	2	68
17	Mains HP	Soil settlement	0	9
18	Gas Meter Installation	Component defects	4	2
19	Gas Meter Installation	Own activities	0	8
		Totals	52	436

Note that the total number of accidents is higher than presented in the previous section. This is due to the extrapolation of the reportable incidents from a 2 year period to an 12½ year period, to match the other accident data.

4.2 Calculating the average incident value

We will demonstrate the calculating principles for the LP mains-excavation combination. This is the combination with the highest number of reported incidents.

Table 3: Average incident value for excavation and LP mains

	Severity levels						
	6	5	4	3	2	1	totaal
Number of incidents	0	0	2	44	94	28	164
Value per incident	1E+08	10000000	1000000	100000	10000	1000	
Value per level	0	0	2000000	4400000	940000	28000	7368000
Average value							44927

In the calculation we determine the number of accidents per severity class. We then multiply the number of incidents per class with the value of an incident in that class and sum those results over the levels, to get the total value of this asset- cause combination. If we divide this total by the number of accidents, we get an average value per reportable incident.

However, this is not the total number of incidents on this asset-cause combination, as most of the incidents do not qualify as reportable. However, for the non-reportable incidents, the available data spans an even shorter period. The incident data is recorded in Nestor Gas from Kiwa Gastec Technology, but it only started in 2003. We took all incidents relating to the combination Mains LP – excavation (some filtering within the database) and extrapolated those results to match a twelve and a half year period. For this, we assumed that the quality of the grid and thus the number of incidents did not change significantly. The results are shown in the table below.

Table 4: Accident probability for incidents

			Incident numbers		Reportable incidents	Probability
ID	Asset	Cause	2004	1993-2004	12½ year period	
10	Mains LP	Excavation	781	9763	164	0.0168

Finally, we have combined the average value and the incident probability into a incident risk figure.

Table 5: Average incident risk

ID	Asset	Cause	Incident value	Incident probability	Incident risk
10	Mains LP	Excavation	44927	0.0168	755

4.3 Results for all combinations

In the table below we show the results for all combinations

Table 6: Risk figures for all cause/asset combinations

ID	Asset	Cause	Value/inc	Probability/inc	Risk/inc
1	Service line	Excavation	172,660	0.00158	272
2	Service line	Own activities	1,066,667	0.00049	527
3	Service line	Soil settlement	1,010,000	0.00006	62
4	Service line	Component defects	3,052,500	0.00178	5,427
5	Service line	Corrosion	1,334,222	0.00104	1,394
6	Service line	Other leakage	60,000	0,00008	5
7	Mains LP	Other	71,200	0.00741	527
8	Mains LP	Component defects	2,538,333	0.00828	21,007
9	Mains LP	Own activities	701,435	0.01172	8,221
10	Mains LP	Excavation	44927	0.01680	755
11	Mains LP	Soil settlement	8,244	0.00576	48
12	Mains LP	Other	282,750	0.00041	116
13	Mains LP	Other leakage	102,333	0.00173	177
14	Mains HP	Component defects	1,000	0.01600	16
15	Mains HP	Corrosion	1,000	0.02286	23
16	Mains HP	Excavation works	51,721	0.15543	8,039
17	Mains HP	Soil settlement	100,000	0.01469	1,469
18	Gas Meter Installation	Component defects	2,050,500	0.00001	23
19	Gas Meter Installation	Own activities	100000	0.00137	137

Multiplying the number of incidents with the associated risk of the incidents and summing over all incident types gives the total safety risk. This is shown in the table below.

Table 7: Total risk, connection risk and individual risk

ID	Asset	Cause	Risk/inc	# incidents	Total risk
1	Service line	Excavation	272	2,384	649,200
2	Service line	Own activities	527	486	256,000
3	Service line	Soil settlement	62	1,313	80,800
4	Service line	Component defects	5,427	180	976,800
5	Service line	Corrosion	1,394	689	960,640
6	Service line	Other leakage	5	1,010	4,800
7	Mains LP	Other	527	270	142,400
8	Mains LP	Component defects	21,007	58	1,218,400
9	Mains LP	Own activities	8,221	157	1,290,640
10	Mains LP	Excavation	755	781	589,440

11	Mains LP	Soil settlement	48	569	27,040
12	Mains LP	Other	116	780	90,480
13	Mains LP	Other leakage	177	555	98,240
14	Mains HP	Component defects	16	5	80
15	Mains HP	Corrosion	23	28	640
16	Mains HP	Excavation	8,039	35	281,360
17	Mains HP	Soil settlement	1,469	49	72,000
18	Gas Meter Installation	Component defects	23	14,077	328,080
19	Gas Meter Installation	Own activities	137	467	64,000
	Total				7,131,040
	Per connection	**7,031,000**			**1,014**
	Per inhabitant	**16,000,000**			**0.445**

In this table we see that the risk per connection is about 1 euro per year, or 45 eurocents per inhabitant. In terms of equivalent fatality risk this is about once every 20 million years per inhabitant. Equivalent risk means that any financial damage is translated into a fatality risk. In the last 12½ years only one fatality occurred, so the actual fatality risk was about once every 200 million years. Both figures are well below the once per million year limit for individual fatality risks.

5 CONCLUSIONS

As we have seen, it is possible to predict the safety of a system based on the number of occurrences of minor incidents. However, there is a point, beyond which the benefit of more data is balanced by the diminishing quality of the data. The data we use in our paper are somewhere in between, being incidents that are serious enough to make a phonecall about. Furthermore, we have seen that only a small number of cause/asset combinations ever became dangerous. Monitoring the numbers on those incidents gives a reasonable feel for the safety of the grid. In total, the gas distribution system is very safe. In terms of direct fatalities it is roughly once every 200million years for an individual, in terms of equivalent damage it is about once every 20 million years.

However, we have also seen that the current data used in the safety indicator is not of a very high quality; Essent scored sometimes almost none of the risks, sometimes almost all. It is more likely this is caused by misinterpretations of data than because of differences in the grid. To make the indicator a really effective regulatory instrument this has to be sorted.

ASSESSMENT OF ROAD SIGNS FOR RETROREFLECTIVITY

Stephen J. Howe [a]

[a] *Stephen J. Howe, Senior Manager Infrastructure Operations, Latrobe City Council, P.O. Box 264, Morwell,Victoria 3840 Australia.*

Abstract: Road Authorities in Australia provide a range of road signs, the type, size, placement and manufacture of which is covered by a range of Australian Standards, Design Manuals, and Codes of Practice associated with legislation. However the in-service performance is not currently mandated. Within their Road Asset Management plans, road authorities must describe their road-related services and intervention levels for service provision, as the basis for budgeting, community acceptance and defence of liability claims. Signs must remain visible and legible at distances assumed by design engineers when initially installed, by day and by night. The quantification of in-service night-time visibility and legibility standards applicable to individual signs or even classes of signs is particularly difficult, with multiple, varying factors to take into account in any given circumstance. However, research has determined rules of thumb that can be applied (albeit simplistically) as *de facto* performance standards, and in-service performance can be assessed against the resulting criteria. A key component of the assessment process is determining a sign's 'retroreflectivity' (or reflective luminance). The issues associated with measuring retroreflectivity against objective service standards is discussed in detail, as well as presentation of a regional municipal road authority's recently adopted approach.

Key Words: Signs, Retroreflectivity, assessment, standards.

1 BACKGROUND

Road signs perform a wide variety of tasks on the road network – from guidance on tourist destinations through to statutory control. Regulatory, warning and hazard signs in particular are crucial parts of the designed road safety system, working in conjunction with delineation (centreline and edge marking), road geometry, public lighting and traffic signals to form the overall system of control within which vehicle drivers, cyclists and pedestrians operate.

A large body of research exists which has led to the various state or federal documents that advise road designers on what type of sign to place and where. These typically account for the message or outcome required, vehicle speed, environment (including weather, terrain and complexity of infrastructure) human response factors such as reaction time, and vehicle response factors such as braking distance.

There is an implied assumption in the standard texts that the signs installed will remain fit for purpose throughout their service life, and will be replaced when that service life has expired. However, other than for catastrophic failure (such as occurs with vehicle impacts or extreme acts of vandalism), quantifying when a sign is no longer fit for purpose can be problematic. Standard condition survey approaches do not typically account for the complex design intent, and are often conducted statically, with an observer up close to the sign, i.e. not in a vehicle, at the design speed. In addition to daytime visual condition, the night-time performance of a sign must be considered and evaluated objectively.

Night-time performance is, if anything, more critical, as it is subject to a range of complicating factors not evident in the daytime. The main physical property that contributes to a sign performing at night is its "retroreflectivity". This relates to its degree of luminance when subjected to an external light source, and is a property which can be measured objectively. The sheeting from which Australian road signage is made is manufactured to the Australian/New Zealand Standard AS/NZS 1906.1 "*Retroreflective materials and devices for road traffic control purposes – part 1: Retroreflective sheeting*" (with road edge and centre delineators and high visibility clothing manufactured to other standards in the same series), with different sheeting grades and colours having different associated retroreflectivity properties. The standard is currently under review, with a review draft being made available for comment in late 2005.

2 STANDARDS – COMPULSORY OR VOLUNTARY?

Since the much-discussed 2001 High Court repeal of the so-called "highway immunity"defence against public liability claims, the risk management context in which this subject is set is one whereby Australian road authorities have had to put in place more proactive and better documented road patrol and response systems, set within the context of formally adopted Road

Asset Management Plans – essentially public domain documents. Such plans must document what assets road authorities have, and to what standards they will maintain them.

However, a road authority may still remain open to public liability claims if it can be shown that its standards or systems are 'unreasonable'. Reasonableness will be determined by a Court comparing a 'defendant' road authority's standards with those of its counterparts, and/or with adopted industry standards (as expressed by peak body guidelines, specifications, Codes of Practice and the like). Few standards are mandated by law, and in that sense, road systems differ markedly from say, Buildings, in terms of mandatory minimum standards of design, construction and maintenance.

Road signs are a good case in point. Whilst *temporary* road works signs in Victoria have been prescribed as to the applicable AS/NZS 1906.1 sheeting class since mid 2005 (under Codes of Practice subordinate to the Road Management Act 2004 and its associated Regulations), *fixed* road signs have not. And even the temporary road works signs, which are required by the Victorian Code to be "*constructed of retroreflective material meeting or exceeding the performance standard for Class 1 material*", do not have their long term performance described or even discussed by such legislation…just their initial 'construction' (i.e. installation).

It is impractical and unsustainable (as well as unjustified by any research) to simply require all signs to perform to the 'as new' retroreflectivity standard of a given class of sign sheeting. The problem is that <u>no in-service retroreflectivity performance standard exists</u>. Appendix J of the current standard contains decay curves for most (but not all) sheeting types and colours, but the Appendix is only "advisory", and therefore does not even form part of the notional official framework provided by the standard. And even with the decay curves available (which are based on Jenkins and Gennaoui, [1]), the threshold for minimum performance is not defined, making the road asset managers' task seemingly impossible. How one Victorian municipal road authority is dealing with this dilemma is discussed further later in the paper.

In the United States of America, considerable effort has been focussed on this issue by peak industry and research bodies as well as regulators, for a number of years. In 1991, the Intermodal Surface Transportation Efficiency Act required "*the Secretary of Transportation…*(to)*…revise the manual of Uniform Traffic Control devices to include…a standard for a minimum level of retroreflectivity that must be maintained for pavement markings and signs, which shall apply to all roads open to public travel*" (as cited in Kalchbrenner, [2]). This focus is subtly, but importantly different to the current Australian approach - which is only about the standard of initial manufacture, and (except in the case of workzone temporary signs), not even mandated by legislation anyway.

Since this legislative imprematur, the relevant bodies in the U.S.A. have been busy, with the Federal Highway Administration issuing minimum retroreflectivity guidelines in 1997, and updating them in 2003 (see Carlson and Hawkins, [3]). Road authorities and road-research bodies have trialled various technologies in their quest to comply with the resulting (mandated) industry standards, and as a result the industry is more rigorous and mature in its approach than the average Australian counterpart.

However, momentum would appear to be building in Australia for mandated minimum standards, as the 2004 Inquiry into National Road Safety [4] included the following recommendation – "*that design and maintenance standards on the national highway system conform with world's best practice*", and a statement that "*minimum design and maintenance standards should be created and enforced*". Though these statements appear limited in intent to state and federal highways, it could (via the 'reasonableness' test Courts will apply) ultimately be broadened to include <u>all</u> public roads over time. The issue of what standards could 'reasonably' be applied is discussed further below, in the conrtext of having first considered the multiplicity of issues that add complexity to the matter.

3 ISSUES ASSOCIATED WITH SIGN PERFORMANCE (INCLUDING RETROREFLECTIVITY)

There are multiple, overlapping factors that apply to the issue of in-service performance of road signs, with retroreflectivity being merely one (albeit an important one). Some relate equally to day or night situations, while others are more critical only at night. These include:

1. **"Visual Clutter**". Signs are only one of the many visual signals being interpreted by drivers, which they need to process in order to react appropriately. In addition to the environmental and driver capacity factors discussed below, the level of visual clutter is a factor that significantly affects whether a sign can practically communicate its message. Other signs, advertising billboards (some of which can be very attention grabbing!), traffic signals, linemarking and the proximity and behaviour of other traffic all contribute to the visual clutter phenomenon. Adams et al [5] found when testing drivers in a driving simulator with eye-tracking capacity that "*the density of traffic has a profound effect on their behaviour in relation to signs….subjects who were exposed to more traffic were more likely to have accidents, were more likely to exceed the speed limit, and were less likely to stop at traffic lights, thus demonstrating what can only be described as a frustration effect*".
2. **Vehicles**. These can vary enormously - headlights can be mounted at different heights on vehicles, and the distance between headlamp height and driver eye height also varies. These affect the degree of sign luminance perceived by the driver (e.g. compare a sedan with a truck), as light is reflected within a limited 'cone' back towards the light source. Also, due to the changes in vehicle headlamp manufacture that occur over time and on different continents, the quality of light

being delivered for reflection can vary with the date and country of vehicle manufacture, making the concept of the "standard design vehicle" hard to sustain. Fortunately, it would appear that recently developed headlamps - which use gas discharge instead of tungsten filament or quartz halogen technology - whilst adversely affecting the reflected luminance of *certain* sign colours, have not made a significant difference overall, with Venkatachalam and Smith [6] concluding that "*new gas discharge lamps will not decrease the visibility of coloured road signs, compared to conventional tungsten halogen lamp*". However, in contrast to the quality of light, the strength of the the light beam can vary by as much as 25%-300% depending on headlight type and whether high or low beam is in use, just within the vehicles manufactured in the U.S.A.

3. **Environmental conditions** – issues such as rain, fog, and topography will affect a signs effectiveness, both directly (in terms of reduced visibility) and indirectly (in terms of diverting the driver's concentration from the sign recognition task). Topography is important to account for when first installing signs, as vehicle headlights will tend to over or undershoot a sign (until closer than the equivalent distance on flat terrain), depending on whether going up hill or down, and whether or not the curve of terrain is concave or convex. Excessively winding roads can have a similar 'masking' effect. These factors point to careful use of 'standard' height mounting poles (as one size may not fit all), and advance warning signs. The issues of rain and fog are even more complex. Rainfall performance is at least nominally covered by a 30% maximum allowable degradation in performance allowed in newly manufactured sheeting (as per the Standard), but whether this is adequate has not been proven, and in any case every rain storm will differ in intensity and direction. The issue of performance in fog has been studied in recently in Japan (Munehiro et al, [7]), but although it was determined that daytime fog has a greater effect on sign visibility than night time fog, no specific minimum performance criteria has emerged as yet. It is perhaps best to remember that road rules require that drivers adjust their speed to account for all relevant conditions, and that road engineers cannot be expected to cover all contingencies.

4. **Ambient light levels**. While street lighting is helpful for some aspects of navigating (e.g. being able to perceive general surrounds without being limited to the vehicle headlights capacity to light up the vicinity), it can actually hinder sign visibility, by reducing the visual impact of the reflected sign luminance on the driver. Sign sheeting is not manufactured to intentionally reflect anything other than headlight luminance, so the degree to which the street lighting itself 'lights up' the sign may not compensate for the reduced impact of sign luminance on driver perceptions. It also appears that the dark 'surround' provided by low levels of ambient lighting assists with the overall conspicuity of the sign. Similarly, the prescence of oncoming traffic (and whether or not they have high or low beam on) complicates the issue even further, and <u>always</u> at the detriment of sign visibility. Conversely though, in certain situations it may be necessary to actually illuminate signs intentionally, as pointed out by the U.S.A.'s Federal Highway Administration [8], "*auxillary illumination may be required on curved roads, areas of high and spotted illumination, conditions of frequent fog and dew, and at action situations such as at highway exits*". This compensatory measure recognises the inability of vehicle headlights to deal with extreme situations.

5. **Driver capacity factors**. Drivers can have a reduced capacity to respond to signs for a range of reasons – tiredness, drugs/alcohol, distraction on other matters (including stress and mobile phone use) and physical limitations such as colour blindness or extremes of light sensitivity. However the single most relevant factor studied is driver age. Advocates for older drivers (such as the Council for the Ageing, and various automobile associations, which often have a high proportion of older members) often point to the crash statistics on younger drivers, and the fact that the issues that face older drivers (such as hard-to-read signs) are issues for <u>all</u> drivers. These are valid points, but fail to recognise the uncomfortable realities revealed in the results of actual studies:

    i. Chrysler et al [9] commented that "*older drivers, in particular, often have trouble reading street name signs because of poor sign design and because of vision problems associated with ageing*", and found that drivers with a mean age of 71 needed brighter signs than other drivers in order to be able to read signs in complex traffic situations.

    ii. Pletan et al [10] have commented that "*a 70 year old person needs about four times more light to achieve the same visual acuity as a 25-year-old*".

    iii. Sivak and Olsen [11] found that "*the usually observed age-related performance decrement on nighttime legibility tasks is the result of visual-acuity deficits*". Whilst some of the deficits may be correctable with increasingly powerful glasses, this relies on the awareness of the aging driver of the issue and their willingness to act on that awareness. Whilst some older drivers exhibit compensatory behaviours (driving less, driving on known routes only, driving slower), this may not always be sufficient. King (2000) found that "*at some point, loss of judgement means that the compensatory efforts are no longer effective, and may even be counterproductive*".

    iv. King [12] also confirmed from a very detailed study of crashes and age, the simple fact that "*crash involvement …increases steadily with age*", and found that, in addition to visual acuity defects, that a jump in rural accident rates for drivers aged 80 and over may "*be due to a threshold of cognitive impairment being reached*".

6. **Sign orientation**. If not installed at the correct angle to the road, a sign will fail to reflect light at the angle assumed by sheeting manufacturers and traffic engineers, causing reduced or in some cases even excessive visibility. One (unsubstantiated) submission to the Australian Inquiry into National Road Safety [4] stated "*this is a management item that appears in all roads manuals yet in Victoria it is estimated that no better than 10% of signs are installed at the*

correct angle to avoid this "white out" problem…there is a plethora of signs (possibly as many as 80%) that are installed square to the road".

7. **Sign type** – it seems that, all other things being equal, drivers notice certain signs more than others. Charlton [13] reports in a study on hazard warning signs that "*of the signs tested, road works and school warning signs were most often detected, remembered and understood. Slippery surface warnings were associated with some of the lowest detection and comprehension rates*". Other studies have shown that the familiarity of the driver with the surroundings is also a factor. It seems that drivers almost 'don't want' to register certain signs as being important, particularly when repetition of exposure has occurred.

8. **Sign Cleanliness**. As road grime builds up on a sign, its daytime and nighttime performance invariably suffers. Jenkins and Gennaoui [1] cite that in regards to retroreflectivity, "*washing produced a 10-20% improvement, and could be much higher for particular sites that caused greater pollution*." Conversely, aggressive washing to remove grime or graffiti (using certain chemicals or abrasive rubbing) was found to reduce retroreflectivity. Sheeting manufacturers should be consulted before chemicals are used on particular contaminants resisting gentle cleaning methods.

9. **Sign retroreflectivity**. This is a physical property of the reflective sheeting, screen printing or multiple sheetings that make up a sign, and is dependant on the class designation to which it is manufactured (class 1, 1A, 2 etc), colour, and age. Extensive studies have documented the age-related decay that occurs in this material property in-service, which is slightly worse in industrial environments or those with extreme ultraviolet radiation levels (e.g. northern Queensland). Most real signs are made up of more than one colour, so this issue is in fact more complicated than it first appears. Not only must the *individual* colours have a sufficient level of luminance for their service life, but the *ratios* of luminance must be sufficiently different over the same period in order for the sign to remain effective. **Note**: the Australian Standard actually specifies minimum luminance contrast ratios, but fails to give comprehensive guidance, being based on research that did not account for the full range of colour combinations present in real signs.

The latter issue creates its own problems, as signs are visible as a function of their overall sign luminance, and legible as a function of the individual colour luminance levels and ratio – an issue discussed further below. Determining overall luminance requires the use of either detailed calculations based on weighted averages of area per colour, or simplistic approaches such as averaging the scores of the individual colours (which can be under or overconservative by a large degree). The test methods in the standard only really address the process of determining the retroreflectivity score for an individual sheeting colour, whereas in real life, assessors have to deal with (and decide the 'fate' of) an entire, multicoloured sign.

In the absence of performing detailed calculations or using results of specific research, the only 'safe' approach appears to be to assess the individual colours against a standard, and assess the luminance contrast ratio. Overly simplistic approaches, such as attempting to set a single standard level of retroreflectivity for a given sign type therefore currently appear to defy achievement, and should not be the expectation of practitioners.

Researchers typically talk about several aspects of 'seeing' a sign (and other traffic control devices). Firstly there is visibility – i.e. "can a sign be seen?" Then there is "conspicuity" - defined by the International Commission on Illumination as "*the attribute of an object within a visual context which ensures its prescence is noticed at the pre-attentive level of processing*". Put simply, a sign may be visible, but not 'conspicuous enough' to be noticed in certain contexts. Lastly, there is legibility. This is not so important for signs that communicate their message largely by their shape and colour, but critically important for signs that have to be read in order to serve their purpose. How drivers acquire and use all these cues is a very complex science, with different aspects being sensed and processed by different cognitive processes. Even legibility has both a static and dynamic aspect (as discussed by Schieber, [14]).

It should be understood that drivers progress through phases of 'seeing' a sign, some of which are subliminal, including recognition of a signs' shape and colour even before the written message becomes legible. Where there are too many competing or incapacitating factors, invariably a sign is not 'seen' at all, and is (not surprisingly) ignored, sometimes at the cost of an accident. Recent research using in-vehicle eye-tracking systems (Schieber and Burns, [15]) reports that "*reading a mission critical highway sign requires more attentional resources than expected*".

Jenkins and Gennaoui [1] summed up the core issues to be managed by road authorities as follows – "Locating the sign is likely to be more influenced by the sign luminance. Legibility of the sign will be influenced by internal contrast and luminance". However, they also noted that managing these issues is subject to an example of the law of diminishing returns; "a large change in luminance will result in a small change in legibility distance. This is shown explicitly in a paper by Colomb and Michaut (1986), where an increase in luminance by a factor of 3 results in a 15% increase in legibility distance".

It should not be considered appropriate for road management authorities to "punish" the society which funds its road infrastructure by assuming all possible worst-case scenario's should apply when designing the solution to a signage problem, as the resulting cost would be unaffordable and put no onus back on the individual. Thus it is not necessary to assume - as some researchers have done - that road signs must be designed and maintained so as to cater for older drivers, who have consumed alcohol, are driving in the rain, and have poorly maintained vehicles etc.

With regards to the legibility vs. visibility issue, it also seems unnecessary to require signs to be legible at the same distances they need to be visible and/or conspicuous, and it suggested that future research address establishing not only ready-reckoners for minimum sign retroreflectivity and luminance contrast, covering a range of situations (as the U.S. authorities have established), but also distance standards that differentiate between the legibility and visibility distance criteria, especially as these will have considerable impact on the resulting required retroreflectivity levels. In the meantime, the landmark Australian study by Jenkins and Gennaoui [1] gave numerous examples of sign scenarios over a range of speed limits and their resulting (dynamic) legibility distances were typically in the 40-70 meter range. This of course assumes that the engineering designer will use the appropriate size sign and lettering for the situation, chosen from predetermined standard templates.

However, it is important to note that much of the early research combined the use of *static* legibility distances (sometimes gained in laboratories rather than in the field) with research on human and vehicle response times to develop models for dynamic (at speed) sign legibility. It is only very recently that dynamic legibility has been able to be tested in the field, and even then only for a limited range of signs, at one speed (60 mph). Schieber [14], reporting on the findings of this research, found that dynamic (night time) legibility indexes declined below static distances by around 30%, falling even below the required standard. The study also found that dynamic night time legibility fell by around 12% for an 85% drop in sign retroreflectivity, which corresponded to the "*new end-of-service-life reflective minimums recently proposed by the Federal Highway Administration*", and commented that "*under most conditions, a life cycle reduction in performance of this magnitude would probably be acceptable*". If true, this would indicate that retroreflectivity is less important a factor for true driver sign legibility (though not visibility and conspicuity) than sign and lettering size, and may lead to a need in future to upgrade the standard approaches to sign sizing. Clearly more dynamic, field test-based research would be required in order to justify such a change and the resulting cost increases.

It is also noteworthy that the retroreflectivity minimums *seemingly* allowed by the U.S. authorities (presumably for all sign needs, not just legibility) fall way below both the warranty standards being offered by sheeting manufacturers in Australia and the 'as new' levels required by the standard. Road authorities will therefore need to decide whether the residual retroreflectivity standards they adopt and enforce in specifications are the mandated minimums (if set, which has yet to occur in Australia) or the considerably higher sheeting warranty levels. They could of course adopt both, which infers keeping signs for considerably longer than the warranty period so as to maximise useful life and minimise life cycle cost.

4 APPROACHES TO TESTING FOR RETROREFLECTIVITY

Figure 1 – Portable Retroreflectometer

There are various ways of testing for retroreflectivity. The crudest, and most time consuming, is not to carry out a retroreflectivity test at all, but simply to carry out night time sign audits, whereby all signs are checked by a driver and the visibility and legibility distances measured and compared with specified distances – which should be those expected by design criteria relevant to the situation and design speed. Whilst fraught with an unavoidable degree of variability (in terms of the number of factors that can vary in a given measurement situation, including differences between observers), this method is at least compatible with real life. Results gained from scientific methods (though more objective) have to be seen in the broader context of the wide range of factors that determine actual sign performance anyway, *many of which are unrelated to the sign's observable physical properties*. Unless all sign testers are required to be accredited road safety auditors (which would in most cases not be feasible for cost reasons), approximate methods using 'reasonable but not excessive' levels of conservatism should be seen as appropriate.

The most commonly available scientific method (though not in apparent use in Australia) is the use of a portable Retroreflectometer, also known colloquially as a 'Photometer', shown in Figure 1 above.

The studies that led to the current Australian Standard were based on the results of using these devices in the field across Australia. They are available with time saving attachments for reaching high-up signs, barcode scanning and GPS integration. They are commercially available via import and can be used to test signs according to the Australian or ASTM standard ASTM E 1709 – 00 [16]. The test methods vary little qualitatively, principally on the number of sample readings taken (the American standard specifies four readings per colour, whereas the Australian makes no mention of number of readings). The observation angle (α) in the American standard is the reverse of that in the Australian Standard [17], but that can be presumably be attributed to the fact that most road signs in the U.S.A. are on the right hand road side, not the left (as that is the side of the road Americans drive on).

The European standards (EN 12899-1/DIN 67 520) use wider illumination and observation angles in tests, so equipment configured for those standards should not be used unless they are also adjustable to the AS/NZS or ASTM methods. An example of a portable retroreflectometer in use can be seen in Figure 2 below:

Once a sign is tested, its retroreflectivity score can be compared with a designated standard, so as to evaluate the need for replacement. It is unrealistic to apply the 'as new' standard, and not justified by any studies. Alternatives could include the performance standard contained within manufacturers warranties, which are typically 80% of the 'as new' standard after 10 years for class 1 sheeting, or 50% of 'as new' standard for class 2 sheeting after 7 years, something the draft revision to AS/NZS 1906.1 (1993) alludes to. This contains an in-built margin of safety, as the 'as new' retroreflectivity levels which sheeting manufacturers are obligated to provide if required by clients to manufacture to the standard are themselves lower than results typically gained from field observations on new signs. For example, if a class 1 white sheeting material is to meet the standard, it must have a Coefficient of Luminous Intensity (CIL/m2) of 250 cd/lx.m2, yet the decay curve formula has been found by research to be:

Figure 2 – Portable Retroreflectometer in field use

CIL/m2 = 294 – 4.1 y (where 'y' is time in years).

Thus a new class 1 sign placed in the field typically has an average CIL/m2 of 294 cd/lx.m2, a providing an initial 17.6% margin of safety, even before the sign starts dropping below the 'as new' standard. It is possible of course for a sheeting manufacturer to produce sheeting which only just meets the standards, in which case the usual safety margin will not exist - though as noted above, in the U.S.A., the in-service minimum values allowed appear to be considerably lower than the as-new standard anyway.

It is important to note that whatever the standard chosen as the notional replacement threshold, it may be prudent to carry out night time cross-checks on all signs with retroreflectivity scores either just above or just below the intervention threshold, so as to ensure only those signs that are genuinely not performing are replaced. It must be remembered that retroreflectivity scores are themselves only an *indicator* of luminance, and it is actual luminance and its value to a real driver in a real traffic situation that ultimately counts.

Some road authorities may even conservatively decide not to even test signs at all, but simply replace them when they reach either a predetermined age, or the warranty date, though these apporaches require either date stamping to exist on all signs (rare) or comprehensive records on when individual signs were installed (rarer). Signs are generally meant to be date stamped, but errors in manufacturing and quality checking mean that most road authorities will have a large number of signs for which they have no idea regarding sign age. Thus they will need to either qualitatively test such signs after all, or simply act conservatively and replace them (possibly needlessly). Whilst there is a cost associated with performance based in-service testing, at least it takes a 'just in time maintenance" approach, and is not overconservative. Studies on which method provides the lowest life cycle cost do not appear to have been done yet.

In the United States, where imposition of standards and concerted research efforts have created a dual impetus for best practice, various alternate approaches have been tried. Maerz [18] reports on a prototype digital video image analysis system in Missouri, stating "*the results show the feasibility of developing a mobile vision-based system to classify and measure the visibility of road signs. The results also showed a rather poor correlation between retroreflectivity and visibility. Retroreflectivity was found to be a poor predictor of visibility of white, yellow and..orange signs…a relatively good predictor of the visibility of red, and to a lesser extent of green and blue signs. Brown signs were found to be of low retroreflectivity and visibility*". Maerz also claimed that "*the method …is the closest possible analog to what the eye sees when looking at signs under the normal illumination provided by the headlights*", but also reported limitations, such as "*the method should be used at night and may be limited to use with high beams*". The latter would be problematic, as road rules typically require drivers to dip headlights when in the prescence of oncoming traffic.

Long [19], cites another, similar technology being used at the Michigan Department of Transportation, the Mobile Evaluation of Traffic Signs (METS) project, which combines video cameras, a calibrated light source, laser range finder and computers, on board a specially configured van. The METS system is a good high-volume, safe method, but has the shortcomings associated with all approaches based solely on retroreflectivity, in that the relationship to actual luminance and thus sign visibility is only an *implied* relationship, without a direct correlation that takes in the many minor variations in sites and signs. The very recent work by Schieber [14] is similar, and also combines in-vehicle digital video capture and GPS, but is not a sign replacement assessment methodology, rather being aimed at testing research assumptions about legibility of signs.

The approaches to standards and testing for sign retroreflectivity of the various Australian state road authorities (based mainly on internet-based research) appear to vary considerably. Whilst it was normal practice for such authorities to have initial manufacture supply specifications that link to the current Australian Standard, few seemed to address the residual performance issue:

- In Victoria, the approach seems to be to use an older driver (55 plus) and visually assess visibility at night, apparently at a standardised distance (though this does not appear to address the issue of design speed affecting the required visibility distance). Oddly enough, by way of contrast, detailed test procedures using portable retroreflectometers are used for pavement markings;
- The approach in the Northern Territory, New South Wales also seems limited at present to testing pavement markings using portable retroreflectometers. Procedures on testing of signs was not able to be located in lists of test procedures related to infrastructure maintenance ;
- In Queensland, sign maintenance procedures discuss both night time visual assessments and use of retroreflectometers, without giving further specifics or residual performance standards;
- In South Australia, the only references discoverable related to warranties on residual performance in supply specifications.
- In Western Australia, there was both expected warranty performance, and a table specifying minimum retroreflectivity values per colour for different signs, and minimum luminance contrast ratios, maximum luminance factors for certain colours and a reference to the Australian Standards test procedures.

The Western Australia approach was therefore the most sophisticated approach able to be found. The Luminance contrast ratios listed were lower than those in Appendix B of the standard, but higher than the absolute minimum of one stated by Jenkins and Gennaoui [1] and coincided with the recommended limit suggested by the same authors. The minimum retroreflectivity scores were far lower than the 'as new' and warranty values in some cases, and therefore would appear to borrow heavily from the approach being taken by U.S.A. highway authorities. The maximum luminance factors stated were not justified, as the Australian Standard does not in fact set maximums for the specific colours listed.

In regard to those authorities requiring performance warranties from sign suppliers, it was not demonstrated how such warranties would ever be qualitatively tested - if there is in fact no measures put in place to either test all signs or at least those signs being replaced for perceived non-performance. In such cases the sign sheeting suppliers will never have to practically honour their warranty statements, which defeats the purpose of requiring them in the first place in a contract.

In summary, the Australian approaches to this issue – as evidenced by the State Road authorities published frameworks - appear to be inconsistent and lacking a genuine 'in-service' performance standard in almost all cases. There also appears to be no evidence of sophisticated, automated (typically vehicle-based) approaches to performance testing being used, such as the METS or digital video analysis techniques used in the U.S.A. This is odd, as such advanced technologies are being used in Australia for other aspects of road infrastructure assessment, such as road pavement condition rating.

One issue which has emerged recently (and could cause problems for authorities seeking to use retroreflectometer-based approaches) is that of the newer 'flourescent' sign colours. The draft revised standard includes performance information on the manufacture of the flourescent colours which have come into use in recent years, yet portable retroreflectometers may not configured to test for them, if they are configured and calibrated to assess standard colours only. In such cases, night time visual assessments against acceptable visibility/legibility distance standards may be the only means of testing performance.

5 COMPARISON OF APPROACHES, COMMENTARY AND RECOMMENDATIONS

In terms of testing cost alone, of the two *scientific* methods known to the author to have a quantified cost, use of a retroreflectometer is more cost-effective. In the initial trial project at Latrobe City (a regional municipal Council in Victoria), which included the initial purchase of a Trimble datalogger/GPS and related software, the Retroreflectometer purchase, and labour over a three month period, the cost per sign was approximately $2.70-$3.30AUD. This cost assumes the amortising of start-up capital costs over 3 years, and excludes the cost of transport, as the assessor either travelled on patrol maintenance trucks which were doing regular cyclic inspections (in rural areas), or used existing organisational fleet cars for township-based data collection. This cost also included capture of the initial management data for the signs, not merely the condition/retroreflectivity assessment, so in fact would go down slightly for future inspections focussing solely on sign retroreflectivity. The actual cost for another authority would of course vary, depending on the number and density of signs managed by it, and whether or not they already possessed portable data entry/GPS devices.

This cost compares well with the "METS" method cost per sign of around $4.55 AUD (which also excludes transport costs, and uses a three year capital amortisation), which would be higher if CPI effects were taken into account since the METS approach was first reported….though it is also possible that the associated technologies may have matured and/or reduced in price since METS was first implemented.

The cost of applying other testing/replacement methods (such as simple installation date-based replacement, or night time subjective visual assessment) is unknown, as no published data is available - though could no doubt be available from those road authorities which use such approaches. As discussed earlier, the approach with the lowest life cycle cost is as yet unknown, as a degree of overconservatism may exist with the less scientific methods, that results in unnecessary sign replacements and thus a higher cost - that may or may not exceed the savings made in not using in-field performance assessment methods.

Given the complexity of the issues and likely variance in capacity of different road authorities, it is perhaps worthwhile to note the comment made by Carlson and Hawkins [3], "*Agencies should have the option to select the methods or combination of methods best suited to their needs and resources*", and "*should have a 6-year period to implement methods*". What should <u>not</u> be acceptable is for road authorities to simply ignore the issue and do nothing – a crude approach is after all better than no approach at all. It is the author's opinion that many road authorities in Australia have yet to grapple with this issue in any comprehensive way, and are probably exposed in terms of public liability, given that signs play a crucial role in road safety. Compared to the many bodies actively researching and implementing rigorous approaches in the U.S.A, Australia would appear to be well behind in terms of world's best practice.

Latrobe City's emerging approach is one of combining the K.I.S.S. principle with a reasonable degree of sophistication, and has been based on the lessons learnt during an initial three month trial, and attempts to deal with the complexities associated with real signs and the issue of balancing risk with cost, as well as the errors of omission of the past. The overall (recommended) approach is as follows:

- All signs to be captured initially, including GIS location. Regulatory signs also assessed for Retroreflectivity and management data (e.g. type, date stamp etc);
- Set minimum visibility and (separate) legibility distances for signs, recognising differences of road speed and location (rural vs. urban), and the results of emerging research on dynamic sign legibility;
- Set minimum retroreflectivity and luminance contrast ratios for common sign colours;
- Give highest priority – in terms of inspection effort - to <u>safety</u> related signs: Regulatory (other than parking control), Temporary Works, Warning and Hazard signs;
- Give second priority to street name blades (of importance to both residents and emergency services)
- Give lowest priority to tourist, guide/advisory and parking control signs;
- Assess all signs on a cyclic basis, with higher priority signs inspected more frequently;
- Assess all high priority signs that are close to 'intervention level' (i.e. replacement) annually, once they are close to the warranty limit (if date of manufacture known) or the luminance-based performance limits (where no date known);
- Only clean signs if found to be below required performance levels when tested, then test them again. This may lift cleaned signs back into the 'acceptable performance' range (or confirm the need for replacement), and saves needless expenditure on cleaning <u>all</u> signs when there is not sufficient cause;
- Perform the cyclic tests by day – if the signs do not pass the daytime criteria such as daytime visibility distance, there is no need to even test for the night time criteria.
- Night time criteria are assessed via portable retroreflectometer testing. Signs which fail marginally are double checked at night using distance criteria to confirm failure before replacing.

The latter recognises the difficulty in using a single numerical result from a scientific test to justify sign replacement, as the sheer number of complicating factors can mean that a sign may not have 'failed' after all when observed by a real driver at night. In that sense, the approach described above can be described as a 'fuzzy logic' system, in that it "*is a way of reasoning that can cope with uncertain or partial information; a characteristic of human thinking and some expert systems*" [27].

Latrobe City is now applying this procedure and is actively replacing failed signs as a result. Ultimately, when it has sufficient data to be able to correlate the legibility and visibility distances of failed signs with their retroreflectivity scores, it will be able to refine its process further, possibly to the point of dispensing altogether with the night time "cross check".

6 FUTURE DIRECTIONS

There is a general trend towards improving the standard of road infrastructure that is arising from greater levels of public awareness, better research, the trend towards increased litigation against road authorities on public liability grounds, and improved asset management awareness. Unfortunately, this is in a climate whereby many road authorities are faced with a funding gap (see Burns et al, [20]) due to the fact that their networks are approaching the renewal point in their life cycle, and have to operate with budgets that have been based on CPI-based increases rather than on a clear awareness of asset funding needs. This management problem has often been exacerbated by unsustainable decision-making by elected decision makers, who often expect road infrastructure renewal and maintenance to 'just happen', and have been known to favour politically popular new assets and services at the expense of sustaining existing infrastructure.

With ever-evolving intelligent transportation systems, some funding decision makers may argue that there is no great need to invest resources in maintaining signage networks to performance standards. But as Adams et al [5] noted as long ago as 1998, "*despite the advent of in-car information systems…and the dedicated road infrastructure for vehicle safety in Europe programme….road sign fixed warning signs will remain the primary hazard warning system for the forseeable future*".

That being the case, it is suggested that the Federal Government should make it mandatory (probably via State Road legislative frameworks) that minimum construction and maintenance standards are set for ensuring that the various aspects of sign luminance - and thus the resulting qualities of visibility, conspicuity and legibility - of road signs remain at reasonable levels, and that road authorities are required to demonstrate that they actually assess them proactively. However, this does not mean that the Federal Government needs to set the standards – road authorities should be given some leeway to decide their cycles of inspection and method of assessing and setting intervention levels, in keeping with their communities expectations and capacity to pay. A Federally funded project to develop maintenance guidelines (with guidance on the full range of approaches and issues) to establish benchmarks would greatly assist the road management industry, as would a more equitable distribution of road-related fuel taxes.

TOOLS FOR ANALYSING LARGE NUMBERS OF INSPECTION DATA, USED TO ASSESS REMNANT LIFE OF PIPEWORK

Abstract: Shell Global Solutions Statistical Consulting and the Materials & Inspection business groups deliver technical services, consultancy and R&D to both Shell and third party customers in the areas of manufacturing process solutions, non-intrusive inspection, maintenance planning and integrity quantification.

Last year a large project was started to upgrade pipework integrity on offshore platforms. To identify pipe sections that need replacement, extensive inspection was carried out, followed by analysis of the data to assess remnant life. Challenges faced during the project were the handling of vast quantities of wall thickness data containing various types of data errors, taking into account different corrosion degradation mechanisms and the sometimes limited inspection coverage typical for pipework inspection.

This paper focuses on the different data analysis methods that have been used during the course of this project, most of them had to be tailored for the purpose and have become part of the Shell Inspection Design Analysis and Plotting (S-IDAP) package. The paper particularly discusses the functionality of an advanced method for trending wall thickness data and various visualisation tools to help understand the distribution of corrosion in the circuits. Further tools were developed to optimise the inspection coverage and to estimate corrosion rates together with statistical confidence measures, providing input into the updating of remnant life parameters of the Risk Based Inspection scheme.

Key Words: pipework, risk based inspection, non destructive testing, non-intrusive inspection, ultrasonics, radiography, corrosion rate trending, inspection database

1 INTRODUCTION

Last year a large project was started concerning the upgrading of pipework integrity on offshore platforms in the North Sea. This project includes an extensive upgrade of the pipework that has been in service for anything up to 25 years. To upgrade the overall integrity, sections of pipework that are damaged as a result of internal or external wall loss have to be replaced. The criterion for replacement is that pipework is required to have a remnant life of at least 5 years, measured against a specified minimum required thickness well above the pressure containing thickness.

The pipework on a production platform is divided in some 15 functional groups and further divided in some 60-120 pipe circuits. Each circuit consists of 50-500 pipe features in the form of bends, straights, reducers, Tee's, etc. Depending on their size such features can be divided in one or more inspection locations. NDT measurements have been recorded in a pipework database since 5 years, with older data summarised as a starting thickness estimate. This has resulted in a volume of up to 10.000 inspection data points per platform.

Coverage of the pipework by inspection is influenced by several factors. Changes in the inspection philosophy over time have resulted in different types of data; older data represent so-called key points (RT-shot; UT-measurements at cardinal points; or scanning of a larger area), whereas more recent inspection procedures require scanning a 200 mm wide band every meter of pipe and full or extensive coverage of bends, Tee's etc. Working practices developed by inspector and corrosion engineer are the basis for selecting a certain proportion of the features within a pipe circuit. For the project a target for the initial level of coverage was set at: 60% of the features and 10% of the welds.

The inspection techniques used in this project are mainly ultrasonic normal beam scanning and gamma-radiography. For welds angle beam ultrasonics and radiography are used, while in a minor number of cases use was made of a Time of Flight Diffraction technique (welds) and MFL/SLOFEC inspection (for rapid scanning of straight sections).

Any discrepancy in the data used for a remnant life calculation will immediately translate in odd, extreme or missing corrosion rates or remnant life estimates, which disturb a clear view on the corrosion behaviour in the circuit, the level of inspection, etc. Therefore the data in the RBI-Pipework database have to be of very high quality. For the remnant life calculation the following data are critical: measured wall thickness, pipe diameter, nominal thickness, minimum required thickness, together with the piping class connecting these three items, and the commissioning date or the replacement date of sections of it. These data have to be connected, via unique numbers, to the features in an isometric drawing, and to the correct piping class and operational parameters as specified in P&ID drawings.

It soon became clear that the data from the routine, day-to-day, inspection program were good enough for a first indication, but insufficient to enable the calculation of remnant life estimates with the required accuracy. This can be explained by the fact that the first aim of day-to-day inspection is to detect damage close to the critical level, whereafter this particular damage is monitored until the replacement level is reached. A risk-based inspection plan, requiring an accurate medium-term remnant life estimate, on the other hand requires accurate wall loss measurements over a larger range to enable accurate estimation of the corrosion rate.

To fulfil both the short-term requirements and the longer-term requirements of the risk-based inspection plan, the following approach was chosen. The available inspection data were both used to find near-critical damage (the usual short term requirement) and to make a first pass assessment of remnant life. With these first estimates dedicated inspection plans could then be designed and carried out to firm up the initial remnant life estimates.

Other challenges to this approach became soon apparent:

- The quantity of data available from an offshore platform is far too large for manual processing
- Existing inspection databases are incapable of providing the required detailed overview of the condition of the pipework
- No reliable method to calculate 'optimal' inspection coverage was available. Particularly challenging in this respect is the fact that corrosion damage in pipework is often very local (bends, welds, low points, etc.)
- Inspection drawings (isometrics), indispensable for planning the execution of inspection, were available, but only in various different formats (e.g. hand-drawings, CAD drawings).
- Longer term historical data series, necessary for estimating corrosion rates, are often curtailed e.g. when pipe sections are replaced or inspection management databases are changed.
- Remnant life calculations are very sensitive to discrepancies in the data, necessitating extensive data quality testing.

It is clear from the above that a better, automated, way to analyse the data was the first requirement. A dedicated computer program was developed and called the Shell Inspection Design Analysis and Plotting (S-IDAP) package. This package can be easily linked both to Excel and to inspection databases. Its use in analysing inspection data will be described in this paper.

2 ANALYSIS OF INSPECTION DATA

After storing the measured wall thickness data in the database the following data processing and analysis steps have to be carried out:

- Estimate the corrosion rate per location, based on the historical wall thickness data.
- Analyse the corrosion rates for each corrosion circuit. The corrosion circuit initially is the smallest unit in the pipework for which similar type and level of corrosion damage is expected.
- Check whether the corrosion circuit indeed is the smallest unit in the pipework. If corrosion damage is more severe, or of a different nature, in particular locations, the corrosion circuit has to be broken down in several parts. This process is called stratification, and the different parts are called (corrosion) strata.
- Decide whether enough measurements have been taken to achieve an adequate confidence level that the corrosion behaviour is represented reliably. If not, make a plan for additional inspections.
- Update the RBI corrosion rate and confidence rating.
- Calculate the remaining lifetime of each piece of pipework (or stratum).

These analysis steps and the use of the S-IDAP package are briefly described below.

2.1 Estimating the corrosion rate per location

Knowledge of the local corrosion rate at each inspection location is essential for the understanding of the corrosion behaviour in a pipe circuit. By looking at actual wall thickness readings over several years, one realises that relative large errors can occur in NDT data, that the corrosion rate is in general not constant over time and that the number of measurements in a series is very limited. These data are therefore not an ideal basis for forecasting using conventional linear regression techniques. Hence we used our statistical trending software tool (TST). This tool, based on Bayesian techniques, deals with anomalies in the data in a natural way, predicts wall thickness and corrosion rate over time and gives an estimate, with confidence bounds, of the remnant life of the pipeline, vessel or other structure under consideration.

The method consists of simultaneously fitting four different models. In the main model (1) the wall thickness and corrosion rate are allowed to vary slowly over time. Furthermore three alternative models (*Figure 1)* are fitted to cope with the following anomalies in the data:

- outliers, a wrong measurement (model 2);
- change in wall thickness, e.g. occurring due to a wrong instrument calibration or a change in paint thickness (model 3);
- change in corrosion rate, a genuine change, e.g. caused by a change in operating conditions, that need to be detected and taken into account as early as possible (model 4).

The posterior probabilities of the four models, given the data at a particular time instant, are calculated and a weighted mixture is used for prediction.

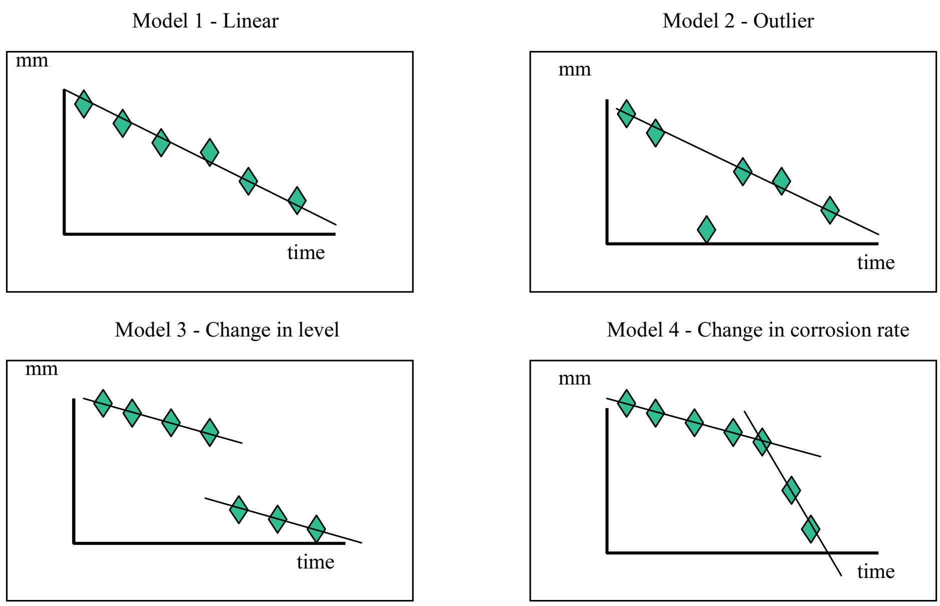

Figure 1, the four models applied in the trending software tool

With the trending software tool large numbers of data are processed automatically and only those locations where an anomaly in the data (model 2, 3 or 4 prevails) has been detected are selected for manual review. A replacement of a pipe spool, which is not documented in the inspection database, will show up as a discontinuity (change in level). An example of the trending graph is given in figure 2. In this example the dark blue line at 11.7 mm represents the minimum required wall thickness and the blue points are wall thickness measurements. The predictions are shown as purple points, the accompanying error band can be interpreted as a prediction interval for a single future measurement. It is based on the updated confidence in the model and the supplied accuracy of the UT wall thickness measurements. The red rectangle at February 2003 indicates that this measurement is detected as an anomaly. This has been confirmed by the inspector. The estimated corrosion rate of 0.14 mm/year is used to calculate the remnant life for this location (i.e. feature A12).

The TST package has been developed under the framework of Shell Risk Based Inspection (S-RBI) and is routinely used at a number of Shell refineries and upstream production sites.

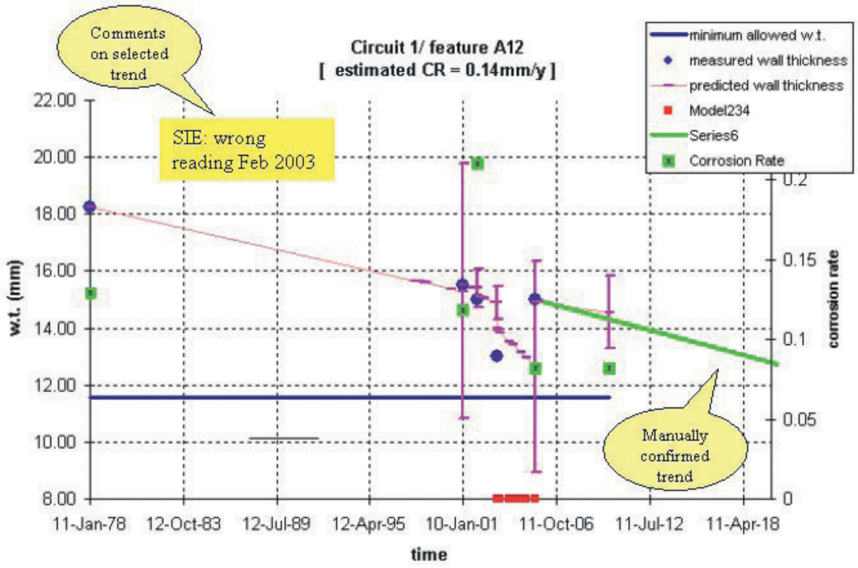

Figure 2 Graphical output of the TST package. A wrong measurement has been detected Feb 2003.

2.2 Analysing the corrosion rates for each corrosion circuit

After trending the wall thickness data at each location, we continue the analysis by displaying the corrosion rates in different plots per corrosion circuit, which is initially the smallest unit in the pipework for which a similar type and level of corrosion is expected. With the help of the plots the corrosion engineer can judge whether an update of the circuit corrosion rate (i.e. the RBI corrosion rate) should be made, to better represent the actual corrosion rate of the circuit. For some circuits a further breakdown of a corrosion circuit is necessary, this process is called stratification. In total about ten different plots can be produced in S-IDAP. Examples given in the following figures are the histogram plot, the box-plot and the overview plot.

In Figure 3 the histograms for two circuits, 14 and 12 are given. The first histogram shows a low corrosion rate for the whole circuit, while the second shows that higher corrosion rates are also present. Circuit 12, for instance, needs to be further analysed to decide whether further stratification within this circuit is necessary. In Figure 4 a categorised box plot is shown. From this plot it is clear that corrosion rates in bends on average are considerably higher than those in the other features, requiring a split up of this circuit into 2 corrosion strata.

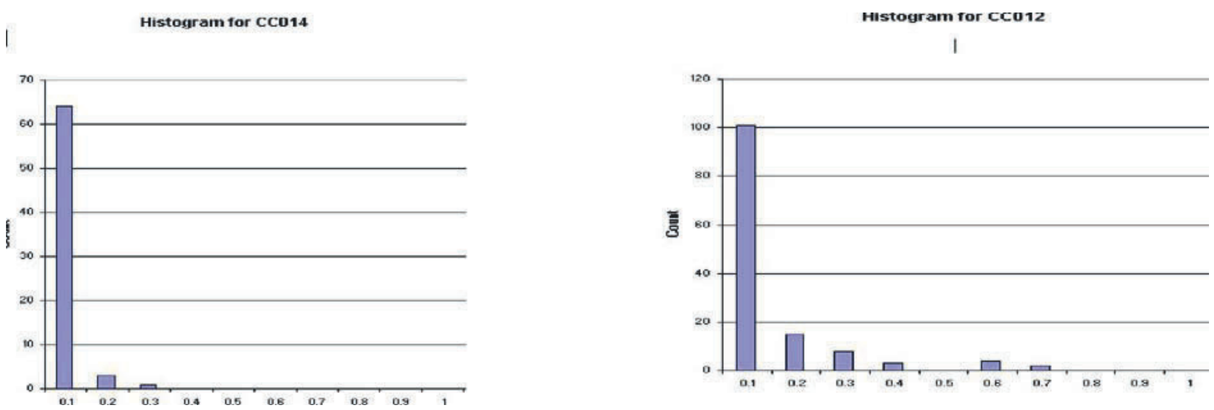

Figure 3 Histograms of corrosion rates from 2 circuits

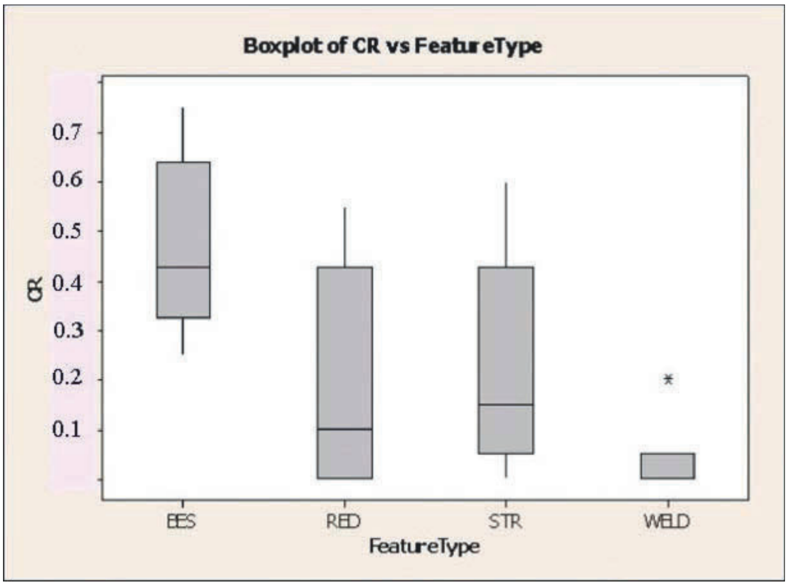

Figure 4 Categorised (per feature type bend, reducer, straight, weld) box plot of corrosion rates

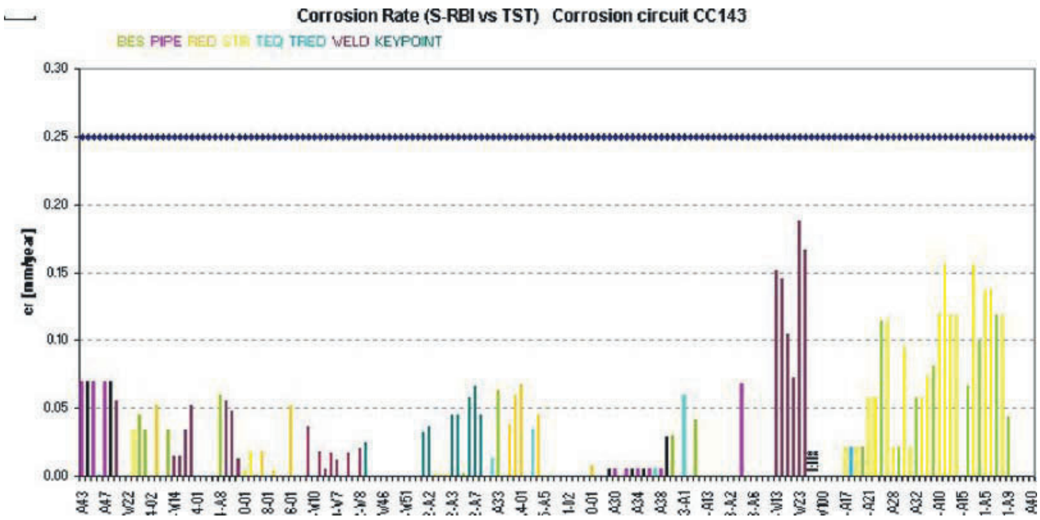

Figure 5 Circuit overview plot. Corrosion rates of adjacent features are shown, colour-coded per feature type

Figure 5 shows a circuit overview plot. The corrosion rates of all features in the circuit are shown, colour-coded per feature type. The dotted line is the RBI-selected corrosion rate for the circuit. From this plot it can be easily seen whether certain features show different corrosion behaviour or whether corrosion is more severe in certain parts of the circuit. From this overview of measured local corrosion rates the RBI-selected corrosion rate can easily be updated. The overview plots are automatically produced from data down-loaded from the pipework database into spreadsheets and calculations are carried out using the S-IDAP library and applying the Shell-Non-Intrusive Inspection methodology.

2.3 Colouring hand-sketched or autocad isometrics

Further understanding of the behaviour of the corrosion mechanism(s) can be obtained by marking up isometrics with the corrosion rate at each measured location (Figure 6). Such marked-up drawings provide an overview at a glance of the locations where high corrosion rates occur. This often supports the explanation for such extreme corrosion rates, for instance because a feature is a dead leg or a high-flow area. Data points that possibly contain an error are specially marked so as to avoid false interpretations because of data errors. The drawings are also used to display other information, such as remnant life, date of inspection, or wall loss. It can also give a good indication for the necessity of further stratification.

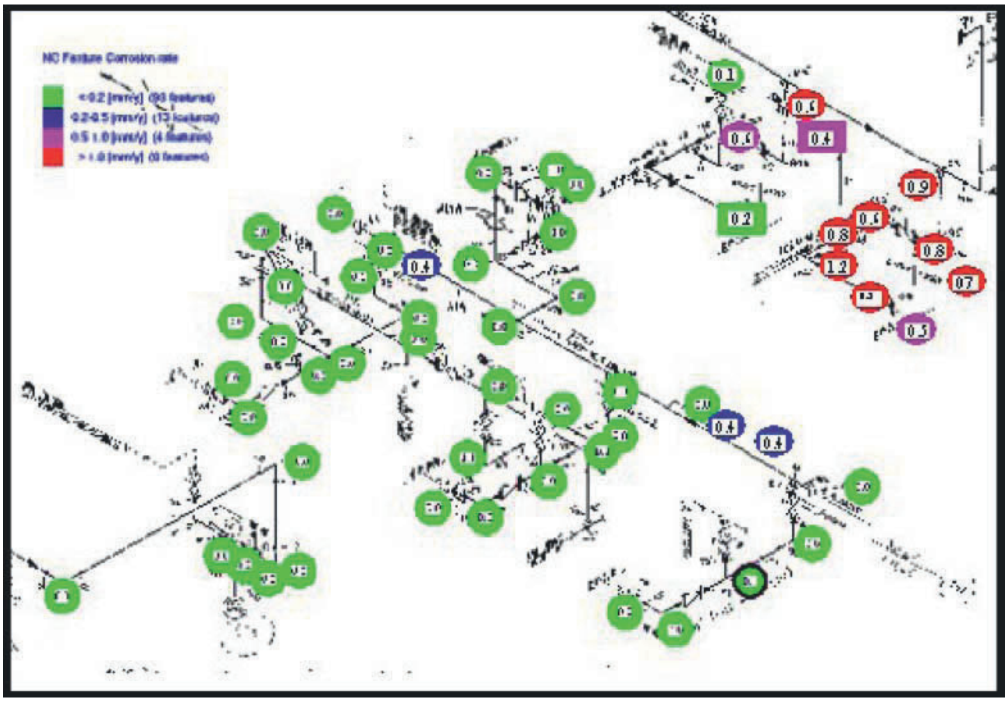

Figure 6. Isometric drawing of a circuit, marked up electronically with the inspection points, and displaying information about the corrosion rate, (by colour and number). The symbols identify locations at a dead leg (rectangle) and data anomalies as indicated by the trending package (black border).

2.4 Stratification of corrosion circuits

If preferred locations for corrosion occur in a circuit, this may result in an adverse effect on planning and effectiveness of the inspection. Firstly, when selecting the highest corrosion rate anywhere in the circuit for calculating the inspection interval, this will generate a large penalty in the form of unnecessary, premature inspection in a large part of the circuit. Secondly inspectors, with support of the corrosion engineer, often build up knowledge over time of the preferred locations for corrosion, so that inspection effort can be directed towards these locations. However, if the administration of this knowledge is not supported by proper functionality of the inspection database it may become subject to an individual's judgment, prone to human errors, and it may easily be lost over time due to staff changes. To make this process more objective and open for verification use can be made of sampling rules; as these rules are strongly driven by the estimate of the largest corrosion rate, they are very sensitive for proper "stratification" of a circuit, i.e. the subdivision in hot spots and the rest.

Stratification can be visualized using isometric drawings marked up with corrosion rates (as in Figure 6) and further analysed by splitting the circuit in corrosion strata and studying the corrosion rate histograms (Figure 2) or box plots (Figure 3).

2.5 Analysing inspection coverage requirements

In practice it is often impossible and normally undesirable to inspect 100% of a structure such as a piping system. Statistical sampling techniques allow the necessary inspection coverage to be defined and the results of a limited inspection to be extrapolated to the status of the total system. S-IDAP has functions that calculate either the sample size or the coverage that has to be inspected to achieve a certain confidence level. The required input consists of the RBI parameters (next inspection interval, confidence rating for the corrosion rate, criticality) and the expected corrosion morphology, general (uniform) corrosion or localised (pitting, grooving) corrosion.

This set of functions has also been developed under the framework of Shell Risk Based Inspection (S-RBI) and has been used at a number of Shell refineries and upstream production sites.

By its nature, pipework introduces complexity in the assessment of coverage: each circuit is made up of parts with a different corrosion allowance, whereas corrosion happens locally within the circuit but may be expected to occur anywhere. This requires that the components in pipework need to be organized along two dimensions: in groups of equal corrosion allowance, and in circuits subject to similar degradation.

2.6 Calculating the remnant life

After the calculation of the corrosion rate and the minimum allowable or required wall thickness the calculation of the remnant life is straight forward. By displaying the remnant life in the hand-sketch or autocad isometric one gets a good overview of the problem areas in the pipework.

3 SHELL-INSPECTION, DESIGN, ANALYSIS AND PLOTTING (S-IDAP) LIBRARY

The functions described in this paper are all present in the S-IDAP library. Furthermore, the package provides routines that can give an overview of many plots on one screen, see e.g. Figure 7 below. In this figure a histogram is displayed in the upper left part, an overview plot in the upper right part, a trending plot in the lower left part and the isometric in the lower right part. After an update by the user in the trending plot the other plots will automatically be updated. By selecting another feature in the isometric the corresponding trending plot will be selected. Further, a polygon can be drawn around a number of features to define a new corrosion stratum.

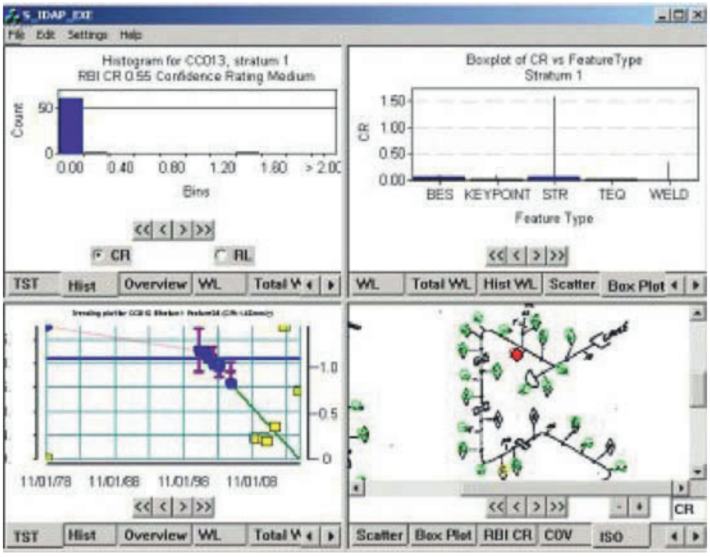

Figure 7. Overview of different plots in one go. The high corrosion rate showed in the histogram is the red dot in the isometric. The corresponding trend plot confirms that corrosion rate is really high !

4 CONCLUSIONS

During the course of performing a large-scale project to upgrade pipework on offshore production facilities a number of problem areas and learning points arose. The main conclusions can be summarised as follows:

- When the planning of inspection and repair activities assume long remnant life, a strong focus is required on obtaining accurate corrosion rate estimates, not just on finding near-critical defects.
- Pipework inspection databases have to be modified to support the analysis of corrosion rates more appropriately. For better inspection planning, combining sections with similar corrosion behaviour and pipe-sections with the same tolerance should be possible.
- New inspection data should be assessed and validated immediately following the inspection, enabling a better judgement of its consistency, enabling better planning of further inspections.
- Inspection staff should be trained to understand the methodologies of assessment and to operate the TST tool.

These findings, together with the fact that large amounts of data had to be analysed, lead to the development of the Shell Inspection Design Analysis and Plotting (S-IDAP) package. This package is composed of a combination of existing and newly-developed tools, brought together in a package that can be easily linked to Excel and to inspection databases. The package already showed its value during the course of this project. Its main functionality can be summarised as:

- A tool for trending wall thickness data (TST), which deals with data anomalies and changes in corrosion rates. With TST large amounts of data can be handled automatically, so that manual attention is only required for special cases.

- A comprehensive set of plotting routines, assisting the user with data validation and interpretation. Some of the plots are also valuable in helping the user with the difficult, but important, process of stratification of pipe-sections.
- A tool to aid the user in designing 'optimal' inspections within a stratum, with respect to the required statistical confidence in remnant life estimates.

Abstract: This paper presents a system and methods for tracking and tracing inventory items in retail stores and manufacturing warehouses. The motivation is to provide businesses in retail and manufacturing industries with an effective technology using Radio Frequency Identification (RFID) to practice lean inventory management. The current focus in major RFID trials around the world is steered towards at pallet and case levels. Using RFID to track and trace inventory at item level is still at its infancy stage. The challenges of item level RFID implementation are more complex than at pallet level particularly in the area of data management and device management. This paper presents an architecture design of a networked RFID tracking and tracing system, and also proposes a data schema design for managing track and trace data.

Key Words: Radio Frequency Identification, Middleware, Track and Trace, Item-level Inventory Management, Data Management.

1 INTRODUCTION

Lean inventory management is important to many industries including manufacturing, retail, logistics and healthcare. This is more so in today economy in which companies compete to offer products and services at the best possible values at the lowest possible cost, and to be quick in adapting and responding to the dynamic change in market demands. To be lean in inventory management, there is a need to track every item in the inventory. This requires the capability of telling the current location of every item, how long in time each item has stayed in the store and the history of location and time for every location each item has moved to. Such requirements are difficult to achieve using the mature bar-code technology with manual stock taking process. The current approach is labor intensive, time consuming and highly prone to error. In many retail stores, inventory items are managed at stock keeping unit (SKU) level. The lack of item serialization presents another challenge to track the age of individual items.

RFID is widely accepted by industries to be the emerging technology for product identification [1]. In fact, multiple RFID trials for warehouse applications are already underway in various parts of the world. The well-known case is Wal-Mart RFID mandate of 2005. Other similar efforts are also reported in Carrefour in France, Marks and Spencer in United Kingdom, Metro AG in Germany. Most of these efforts focus at pallet level in warehouse applications. A study reported in [2] discussed about the use of RFID in air cargo tracking in which air cargo pallets were tagged and RFID readers were installed at material handling vehicles in the airfreight terminal for tracking the pallets within the warehouse.

The challenge in item level track and trace is to pinpoint the current location as well as the historical movement of every item in an environment. In many retail stores, this information is useful especially in stock taking and sales operations where finding stocks indicated as available in system is often a daunting task. A frequent reported problem in retail stores is inefficiency and inaccuracy in manual stock taking process [3]. Usually manual stock taking is carried out periodically from weekly to monthly or even half yearly. In every stock taking exercise, the aim is to close the gap between physical count and system count. The gap will tend to grow as the interval of stock taking is further apart. This has an effect on purchasing function which is often based on system count and not physical count. An undesired effect is to order more than necessary or order less than required. The problem with the former is excess stock and depreciation, and with the latter is loss of sales due to stock shortage. By tracking the location and time of every inventory item, the problem of instant stock counting is also solved. In fact, this paper shows that such a track and trace system can provide a more detailed stock count with location information.

The problem of aging inventory is another issue that can be solved by a track and trace system. An inventory age refers to the duration the item stays in a store from the time it is delivered from supplier. The current practice in some retail stores is to estimate the age of inventory based on delivery order records. Such estimation is good for indicating general inventory age. However it is not good enough to tell which item among a group is older. Tracking inventory age is important especially for perishable goods as well as goods with high depreciation. In retail industry, price competition is normal among retailers. Very often, items that are older are preferred to be sold at discounted price than new arrivals. This presents a requirement to identify and locate aging inventory items. With the proposed track and trace system, this requirement can also be met.

Pilferage detection is another important task in retail industry. A common approach is using the 1-bit electronic article surveillance (EAS) technology [4]. An EAS system comprises a tag and a gate reader. When a tag is not disabled, it will trigger a security alarm system when it passes through the gate. EAS is commonly used together with barcode technology. It is not uncommon to find two different labels on an item: one for EAS and another for barcode. The former provides security function while the latter provide identification. RFID can be used to provide the two functions in one system.

Read reliability and data scalability are two problems that make item level tracking and tracing more difficult to handle than pallet level. Read reliability refers to the ability of an RFID system to successfully interrogate every item without a miss. Perfect read reliability requires every item to be identified without any miss-read at all times. However, this is difficult to achieve in practice due to radio frequency blind spots and interference from external sources such as human crowd. One way to reduce miss-read is by deploying multiple layers of RFID interrogation zones with complementary reading functionality. In this area, the idea of networked RFID is discussed in this paper.

In item level tracking, each item has a RFID tag containing a unique identification code. As the size of inventory increases, the volume of data generated in an RFID system is expected to grow exponentially since a single tag can be read multiple times at various locations. Data scalability refers to the problem of managing large volume of data in the more efficient manner. Poor data management is undesirable since it can result in memory overflow, loss of data and slow data processing. One way to streamline data management is by designing a compact data model. In this area, a novel data schema is proposed in this paper.

The contributions of this paper include an architecture design of a networked RFID track and trace system and a data schema design for tracking inventory items. The rest of this paper is organized as follows: Section II describes the networked RFID track and trace system. Section III presents an approach for data schema design. Finally, Section IV concludes.

2 NETWORKED RFID TRACK AND TRACE SYSTEM

Every item to be tracked and traced requires a unique identity code. This is commonly known as product serialization. An emerging standard for product serialization is the Electronic Product Code (EPC) [5]. The standard specifies the use of 96 bits comprising manufacturer code, product type and serial number. A RFID tag stores the identity code. In the EPC standard, there are several classes of RFID tags. Each class differs in features and performance. Class 1 Generation 1 and Class 1 Generation 2 tags are two most widely mentioned tags now. Class 1 Generation 2 offers better features such as longer read range, better anti-collision and faster speed than Gen 1. Cost of tag is still fairly high ranging from US 30 cents. As such, the cost of tagging every item in an inventory can contribute a large running cost of the system.

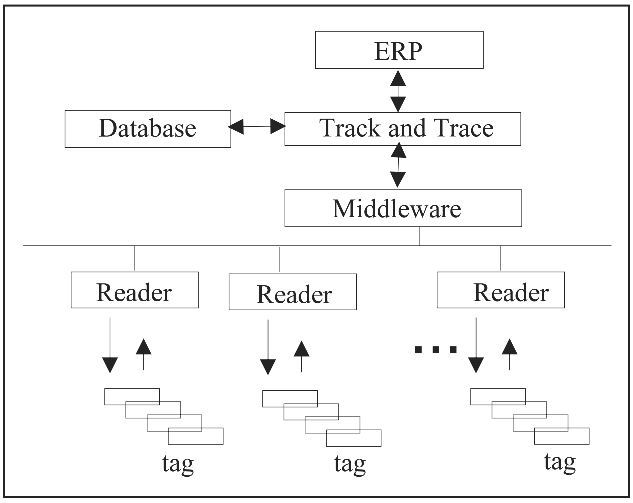

Figure 1: Track and Trace System Architecture

With every item given a RFID tag, a system is required to read the RFID tags in order to identify tagged objects and track its movement as they are moved from one location to another in an environment. The system should comprise a network of RFID readers deployed across the environment. Fig. 1 shows the networked RFID system architecture which comprises RFID tags, readers and middleware, database and track and trace application. RFID readers can be flexibly deployed in various strategic locations in the environment including exit and entrance points, checkout points, path, shelves and open areas. Three levels of granularity of RFID coverage can be considered: 1) Exit/Entrance coverage 2) Boundary coverage and 3) Point coverage. The choice of granularity depends on specific application needs. Exit/Entrance coverage is the basic option. It covers the exit and entrance points of an environment as well as check out stations. In a retail store, exit and entrance points can be found in the showroom as well as in the receiving store. Deploying RFID readers at exit and entrance points is sufficient to achieve stock counting, aging inventory monitoring, pilferage detection as well as limited location tracking and tracing.

Where it is useful to know the distribution and tracing of item movement across departments, boundary coverage should be considered. This concept involves the deployment of RFID readers along department boundary. It requires more reader investment than the basic option. The gain is additional information including stock counting by locations and tracking of items at department level. Point coverage offers the highest granularity among the three. This refers to the large scale deployment of RFID readers at strategic points in the environment where items are stacked or shelved. In retail stores, it is quite common to find stacks of products on the floor. With point coverage, a RFID reader is deployed above each stack as shown in Fig. 2 so that item taken out or placed on the stack can be tracked. This increases the investment on RFID readers.

The gain is pinpoint tracking of each item with higher resolution. Aging items within a stack can be identified and locating items is also much easier.

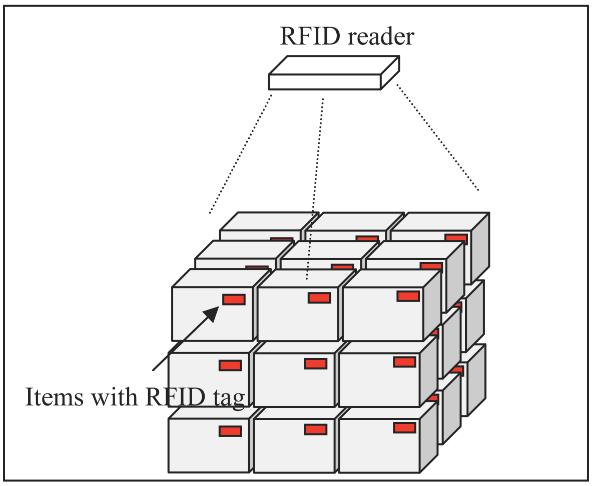

Figure 2: Stack Item RFID Readability

Read reliability is not 100% particularly for stack items. Referring to Fig. 2, the top row of stack items usually has no problem with readings. However, items in the middle and bottom rows may not be completely read at all times. These items can be read when they are removed from the stack.

Above the RFID readers and tags in the system of Fig. 1, is the RFID middleware layer and Track and Trace application. RFID middleware manages and controls RFID readers. Passive tags do not have battery. In order to power up its integrated circuit, a passive tag obtains energy from RF wave produced by a RFID reader. After power up, a tag proceeds to transmit data to reader. Data received at each reader is first stored in the reader memory and subsequently transferred to the middleware when a reader is polled. Data loss due to reader memory overflow is possible if a reader is not serviced in time by the middleware. This is possible to occur in two ways: a) new data is rejected b) old data is deleted to make room for new data. To avoid reader memory overflow, it becomes critical that the Middleware controls the polling of readers in an optimum way such that each reader will not be starved of data service opportunity. Some RFID readers in the ultra-high frequency band including that of Alien and Symbol are offering memory capacity about 1000 tag data. The network that links every reader to the middleware can be seen as a shared media. At any one time, only one reader is allowed to transmit data to the middleware in order to avoid data traffic collision. The reader allocation function in the middleware runs an assignment algorithm to decide the next reader to allow transmission. Reader assignment problem in RFID middleware is similar to the classic polling problem. Static allocation algorithm based on fixed time slice sharing is widely reported in literature [6]. The static algorithm is useful for the case with similar data traffic load condition in every reader. However, it is possible for cases with wide difference in data arrival rate at each reader to occur. For this situation, the static algorithm of reader assignment is not efficient. What is needed is an adaptive algorithm that assigns the right to transmit to the reader according to the data traffic load of each reader. The reader with the heaviest traffic loads should be served first to avoid memory overflow.

Large volume of data is collected by the RFID middleware from a network of readers and processed in the track and trace layer. According to Fig. 1, the track and trace layer lies above the middleware layer. Application specific customization is allowed in the track and trace layer and does not need to be in the middleware layer. In addition, the track and trace layer provides the graphics user interface for stock counting information and aging inventory information. Tracking and tracing information is presented in a graphical map window of the environment as shown in Fig. 3. Flashing circle represents the current location of an item. Filled circle represents historical locations visited by an item. Lines with arrow represent the path taken by an item. As an item is moved from one location to another, the graphical map will be updated with new circles. A listing of the historical locations and timestamps is also provided in a separate window. Another useful feature is the use of different color codes to display recent tag readings and old readings. Using a user defined time threshold e.g. 5 seconds, recent tag readings are displayed in green color and the older readings are displayed in red color.

By maintaining a set of track records and trace records for every item, the track and trace layer continuously updates the location of every item and also shows the route of movement for individual items. Additionally, the track and trace layer performs stock counting and monitoring functions. Items recorded in the database are retrieved for stock counting information by adding all items according to SKU and locations. The age of an inventory item starts from the time the item arrives at the store. The track and trace layer maintains a set of timestamps for every item. One of the timestamp is initialized with a time corresponding to the first moment the item is received and read in the receiving store. The age of an inventory item is computed as the different between current time and the timestamp. Monitoring stock levels is another key function of the track and trace layer. This refers to the task of highlighting specific stocks in which the current quantities are below the minimum quota required as well as stocks that are more than the maximum quota allowed. This information is useful to support purchase decision in enterprise purchasing department. In fact, the track and trace layer could feed stock counting and monitoring information directly to the enterprise resource planning (ERP) system (also shown in Fig. 1) to improve the efficiency of purchasing.

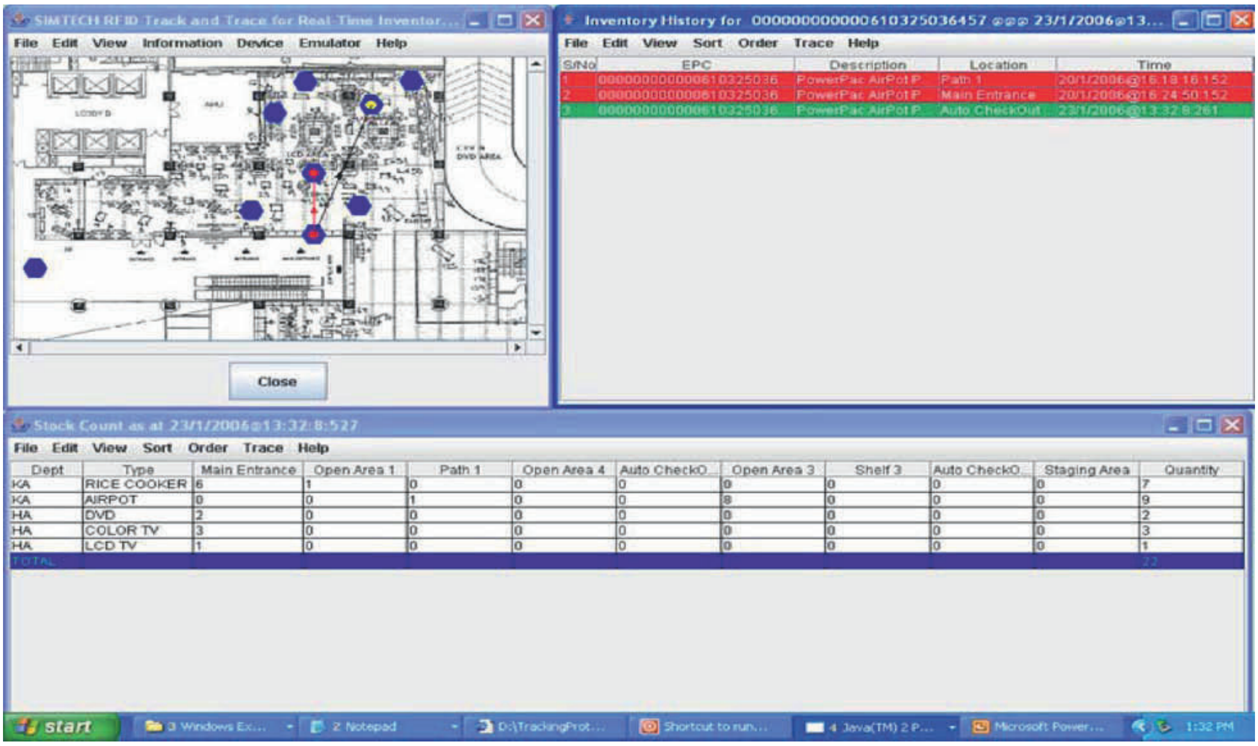

Figure 3: Stock counting, item tracking and tracing windows

Detecting and alerting pilferage is another function that the track and trace layer should provide. By maintaining a checkout status of every item, the system triggers an event to activate the enterprise security alarm system when an item without proper checkout code is identified at an exit location. In addition, the system provides a full detail of every occurrence of pilferage event including location, time and item identity. To provide the inventory related information stated above, an efficient data model customized for track and trace is needed. The next section gives a detail account of the proposed idea.

3 DATA MODELING AND UPDATING

Every item has a unique identity code encoded in the RFID tag. As item is moved from one interrogation zone to another within the network, the identity code from a tag is captured by RFID readers at both source and destination locations. A reader normally timestamps every reception of identity code based on its internal clock. The identity code and reader clock timestamp data are stored in the reader internal memory and subsequently sent to the middleware when the reader is polled. The middleware should also timestamp data from readers based on the middleware clock. In summary, item identity code, reader timestamp and middleware timestamp are data processed by the track and trace layer for every tag reading before storing in an item record in database.

Fig. 4 shows a schematic view of an item record in the database. Each item record includes an identity code field, a state field and a track record pointer and a trace record pointer. The state field includes several values including Available, Checkout, Pilferage, Check-in, Return and Servicing. The track and trace layer updates the state of each item according to the state transition diagram in Fig 4. When suppliers deliver items to a retail store, the state of each item is assigned with the value of Available. The state is marked Checkout in the state field when the items are sold. If items are detected at exit locations but not checkout, the item is marked pilferage in the state field. When customers return items, the items are marked Return. When items are sent for servicing, the state is changed to Servicing. After servicing, the items are ready for sales and marked Available.

Fig. 4 also shows a schematic view of the track record and trace record. Both types of record contain a plurality of location records. A location record contains several fields including location code, first timestamp and last timestamp, reader timestamp and middleware timestamp. The location code identifies every interrogation zone in the network. The first timestamp corresponds to the first RFID reader timestamp captured at the location for the specific item. This timestamp is not changed after it is created. The last timestamp is the most recent RFID reader timestamp captured at the location for the specific item. This timestamp is updated whenever there is a new timestamp from the RFID reader. The time clock in every RFID reader in the network should be synchronized with the RFID middleware.

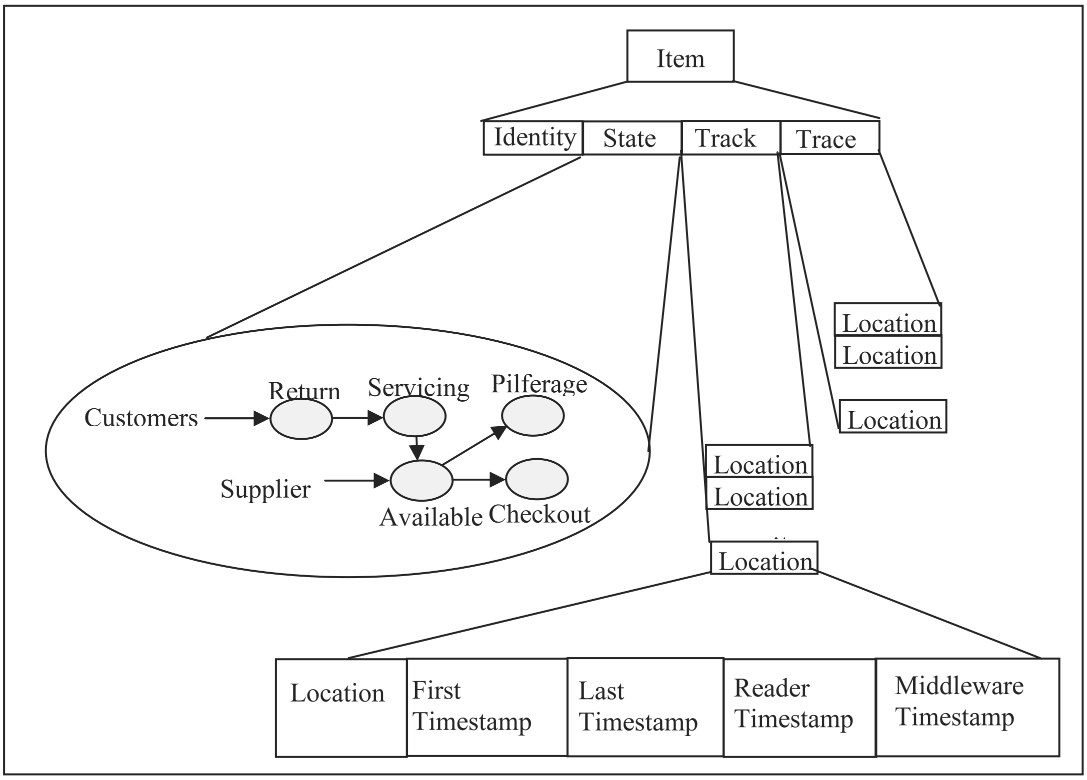

Figure 4: A schematic view of item record

The track record contains a unique set of location records such that one cannot find two or more location records with the same location code. When an item is moved to a new location for the first time, the track and trace layer adds a new location record to the track record. In subsequent visits to the same location, the track and trace server does not add new location records in the track record. Instead, it updates the timestamp fields of the specific location record with the most recent timestamps. The location records in the track record are also never deleted unless the item record is removed. With this arrangement, the track record of an item shows the most recent timestamps for all the locations visited by the item. The most recent location visited by an item corresponds to the location record with the most recent timestamp in the track record.

The trace record contains a set of unique location records such that it is possible to find multiple location records with the same location code but not the same last timestamp. The trace record is for the purpose of tracing the history locations of every item in the inventory. The track and trace layer stores every location visited by each item up to the present location, and adds a new location record in the trace record for every new location visited if the new location is different from the last recorded location in the trace record. It also updates the timestamps of the most recent location record if the item is identified to be at the same location as the most recent location record. This can happen when items are stationary at an interrogation zone and continuously being identified by the RFID reader. With exception to the most recent location record in the trace record, all other location records cannot be modified once added to the trace record. However, the old location records can be deleted when the number of location records grows beyond a user-defined limit. The location records in the trace record correspond to the location trace of the item.

It is possible for no read to occur due to radio blind spot and other environment interferences such as human crowd. In this case, items affected cannot be identified in the interrogation zones. This is particularly so for a stack of items in which items in the topmost layer can be identified but not those in the middle and bottom layers. Usually items at the middle and bottom layers cannot be removed unless those at the top layer are removed first. As such, those items in the hidden layers are likely to be identified. The track and trace system is designed to update the location records only if RFID readers can identify items in an interrogation zone. If no read occurs, the location records are not updated. This does not cause error in tracking if the item remains in its present location. An error occurs if the item is moved to another location without being identified. The system reduces this error by employing a network of interrogation zones such that items that fail to be identified at one interrogation zone is likely to be identified at other zones. As the granularity of the interrogation zone network grows, accuracy of tracking also increases.

4 CONCLUSIONS

Growth of interests in RFID application across many industries is ever increasing. Pallet level tracking is becoming mature soon. The next focus is steering towards item level tracking and tracing. This is especially useful in retail industry where inventory management is still a highly manual process. To close this gap, a system and data design for a RFID-based track and trace system are presented in this paper. The main contributions of this work includes a design of the track and trace layer above the middleware layer in the proposed architecture, as well as a design of an item record with track record pointer and trace record pointer. Each pointer is linked to a plurality of location records comprising of timestamps and location.

As part of future work, an adaptive reader assignment algorithm based on estimation of individual reader data traffic condition will be investigated. This is needed to ensure that all readers are serviced without loss of data. In addition, an information reliability model will be derived to study the accuracy of tracking information in view of uncertainty in RFID readability particularly in areas where RF blind spots are prevalent. Also, optimization of the RFID reader location with mobile readers will be explored to improve the track accuracy.

Abstract: This paper presents a method to determine optimum feature subset selection with a modified wrapper-based multi-criteria approach using genetic algorithms. We present details of the algorithm, design and implementation of feature subset selection using genetic algorithms. The best compound features found by genetic algorithms are verified by multiple regression models and are used to construct fault prediction models. A case study of machinery tool wear-out prediction is presented. The fairly good agreement between the prediction result and real tool wear-out data demonstrates the viability of the feature subset selection method for diagnosis applications.

Key Words: Genetic Algorithms, Feature subset selection, Fault Diagnosis

1 INTRODUCTION

In an era of intensive competition, where asset usage and plant operating efficiency must be maximized, unexpected downtime due to machinery failure has become more costly than before. Therefore predictive maintenance has been actively pursued in the manufacturing industry in recent years, where equipment outages are predicted and maintenance is carried out only when necessary. To ensure successful condition based maintenance, it is necessary to detect, identify and classify different kinds of failure modes in the manufacturing process. Sensing technology is necessary in implementing the detecting system. There are two major approaches using sensing technology: the direct method, which measures and evaluates the fault from a single direct sensor, and the indirect method that adopts different kinds of sensors at different positions to sense different failure modes. Features are then extracted and selected to analyse the signals from all these sensors to assess the condition of the system. In many applications, direct method is not possible for on-line realization. Indirect method may work as an on-line systematic technique as it measures the operating parameters during the manufacturing process. In the indirect method, amount of sensors could be large and determining failure could mean taking minutes or hours to analyse data from all the sensors and make a reasonably accurate deduction.

In many complicated applications, it is not unusual to find problems involving hundreds of features. However, it has been observed that, beyond a certain point, the inclusion of additional features leads to a worse performance. Moreover, the choice of features affects several aspects of the recognition process such as accuracy, learning time and necessary number of samples. Most importantly, this leads to an increase in time and computational space complexity of the recognition process. The main goal of feature subset selection is to reduce the number of features used in classification without compromising on accuracy.

Feature subset selection algorithms can be classified into two categories based on whether or not feature subset selection is performed independently of the learning algorithm used to construct the verifier. The filter approach to feature subset selection is done independently of the learning algorithm. Another technique, known as wrapper feature subset selection [1], uses the method of classification itself to measure the importance of a feature or feature set. The first one is computationally more efficient but its major drawback is that an optimal selection of features may not be independent of the inductive. On the other hand, the wrapper approach is more computationally expensive and tends to provide better results than the simpler filter methods [2].

Genetic Algorithms (GAs) [3] can be used for feature subset selection problems since they are generally effective for rapid global search of large, non-linear and poorly understood spaces [4, 5]. The power of GAs comes from the fact that the technique is robust and deals successfully with a wide range of problem areas, including those that cannot be solved by other methods. Over the recent years, many research works have been devoted to the feature subset selection using genetic algorithm for reducing feature numbers without accuracy reduction [6] [7] [8]. These works only study the feature subset selection without further study about their influence on the faults. Little work has been reported on the feature subset selection in the manufacturing equipment fault diagnosis.

The objective of this study focuses on feature subset selection for fault diagnosis through a modified wrapper-based multi-criteria approach using GAs. The feature subset selection results are verified using multiple regression models. The selected feature subset is used to build diagnosis models for fault diagnosis. Implementation issues of GAs on feature subset selection in equipment fault diagnosis are discussed in detail. The feature subset selection and diagnosis system has been tested experimentally with the prediction of tool wear-out on a high speed milling machine.

2 GENETIC ALGORITHMS FOR FEATURE SUBSET SELECTION

Feature subset selection refers to the selection of an optimum subset of features that are most responsible for a given outcome. Feature subset selection problems are found in all machine learning tasks (supervised or unsupervised), classification, regression and time series prediction. The objectives of feature subset selection are to improve the prediction accuracy and to provide a better understanding of the underlying concept that generated the data. GAs is one of the methods that used for feature subset selection [6] [7] [8].

2.1 Genetic algorithms

GAs are inspired by the Darwin theory of principles nature selection and survival of the fittest. The fundamental mechanisms derive the evolutionary process include selection, crossover and mutation within chromosomes. Selection occurs on the current population by choosing the highly fit individuals to reproduce. The selected individuals reproduce new individuals as offspring by crossover with other individuals in the population. Mutation may happen in the reproduction. In this way, over many generations, good characteristics spread in the population, mixing and exchanging with other good characteristics as they go. GAs are computer programs that create an environment where populations of data compete and only the fittest survive, sort of evolution using a computer. GA is well suited for feature subset selection when the number of feature set is large. Though robust, GA takes a high computation time [9]. If GAs is designed well, the population converges to an optimal solution for the problem in a reasonable time.

Generally, there are five steps to implement a GAs:

(1) Randomly generate an initial population.

$X(0) := (x_1, x_2, \ldots x_n)$ of chromosomes

In our case, $x_1, x_2, \ldots x_n$ represents the initial feature sets.

(2) Establish a method to evaluate the fitness $F(x_i)$ of each chromosome x_i in the current population $X(t)$.

(3) Create a new population by repeating the following steps until the new population is complete

i. Selection - Select from the population according to some fitness scheme.

ii. Crossover- New offspring formed by a crossover with the parents

iii. Mutation - With a mutation probability, mutate new offspring at each locus (position in chromosome).

(4) Retain the desired number of fittest individuals in order to maintain the size of the population.

(5) $t := t+1$, if not termination.

The major design components of the GAs include the initialisation process, the design of the evolutionary functions and an objective fitness function. Our GAs design and implementation refer to some of the work in [10].

2.2 Chromosomes creation

One form of encoding is the binary string. The chromosome may be encoded as shown in the Table 1 below:

Table 1

Chromosomes with binary encoding

Chromosome A	1011001010110010
Chromosome B	1111110000011001

Each bit in the string represents one feature. If the bit is 0, it means the feature not selected; otherwise, the feature is selected. To express feature subset selection problem using chromosomes, a number generator that returns 1 or 0 randomly can be used to generate chromosomes.

2.3 Fitness function

In the feature subset selection system, a fitness function is used to evaluate how "good" a feature and the level of association of that feature with the fault values [9][11].

To give a score to each set bit (recall that one set bit refers to a feature) of chromosome, Pearson Correlation Coefficient (PCC) is adopted. PCC is a statistical measure of interdependence of two or more random variables. The PCC correlation coefficient is defined as r

$$r = \frac{\sum_i (x_i - \overline{x})(y_i - \overline{y})}{\sqrt{\sum_i (x_i - \overline{x})^2}\sqrt{\sum_i (y_i - \overline{y})^2}} \tag{1}$$

The expression can be simplified into the following form:

$$r = \frac{S_{xy}}{S_x \bullet S_y} \tag{2}$$

where X (x_1, x_2, ….x_i)represents features and Y (y_1, y_2, ….y_i) represents the fault. Sxy is the standard deviation of $X \bullet Y$, and Sx and Sy refers to the standard deviation of X and Y respectively. This simplifies the implementation as only a few arrays to store intermediate results.

As the magnitude of r is needed for scoring of a particular bit of the chromosome, and its value can be negative, the absolute of r is returned as the score of that feature. To filter out low r value as zero association, a confidence level is introduced so that only r values above the confidence level are considered in the total score. Therefore, set bits that have a score less than the confidence level is given a score of 0 and the bit is reset to 0. In this way, the results only consist of selected features whose r values are higher than the confidence level.

2.4 Selection using roulette wheel

Simple reproduction allocates offspring strings using a roulette wheel with slots sized according to fitness [12]. This is one way of choosing members from the population of chromosomes that is proportional to their fitness. Parents are selected according to their fitness. The better the fitness of the chromosome, the higher the chance it will be selected. However, the fittest member is not guaranteed to go to the next generation.

Imagine a roulette wheel where all chromosomes in the population are placed according to fitness, as in Figure 1 below. The wheel is "spun" and the marble fallsinto one of the slots. The larger the slot, the higher the chance it will be selected.

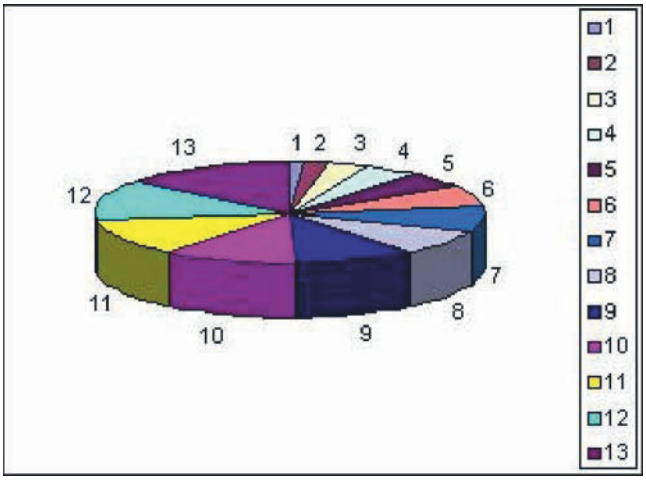

Figure 1. A roulette wheel with thirteen chromosomes

2.5 Crossover and mutation

One point crossover is implemented in our method by picking one position in the chromosomes at random and then exchanging the parent chromosomes to form children chromosomes as in Figure 2. Mutation is much easier to implement. To mutate a certain bit, we generate a number randomly and compare the number with the mutation rate. If the random number is smaller than the mutation rate, the bit is mutated; otherwise, the bit is maintained and next bit is considered. The mutation is shown in Figure 3.

3 CASE STUDY

A case study is carried out to verify the usability of the method. An application related to high speed machining tool condition is selected for the experiment. Tool condition is an important factor in the high speed machining process. Tool wear and tool failure may result in a loss in surface finish and dimensional accuracy of the finished parts, and even possible damage to the work piece and machine [13].

3.1 Experimental set up and features extraction

Most CNC machines are not able to detect machining tool's wear-out in an on-line manner. The cutting force signal is instead used to establish usable models due to its high sensitivity to tool wear, low noise, and good measurement accuracy [14]. Our experiment about the tool condition is shown in Figure 4.

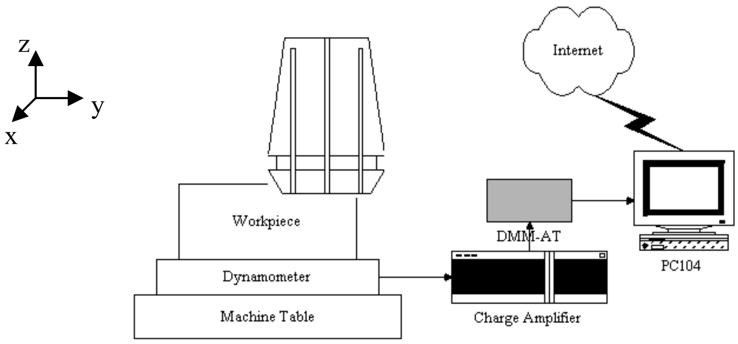

Figure 4. Tool Conditions Experiment in Machinery

The cutting force along the y-direction of the machining path was measured by a dynamometer in the form of charges, and converted to voltages by the Kistler charge amplifier. The voltage signal was sampled by the PCI 1200 board at 2000 Hz and directly streamed to the hard disk of a computer. The flank wear of each individual tooth of the cutting tool was measured using an Olympus microscope. Details of the experiment set up and feature extraction methodologies have been reported elsewhere [15]. Four experiments were used for our study and the cutting parameters are summarized in Table 2.

Table 2

Cutting Experiments

Test No	Spindle Speed (rpm)	Feed Rate (mm/min)	Depth of Cut (mm)	Insert Number
1	1000	100	1	4
2	1000	200	1	2
3	1200	150	1	2
4	1000	100	1	2

From these experiments, 16 main features are extracted and summarized in Table 3. The 16 features that have been shown to be effective for tool wear-out monitoring form the scope of the feature subset selection in this paper.

Table 3

Feature Extraction Methodologies

No	Feature	Notation
1	Residual Error	Re
2	First Order Differencing	Fod
3	Second Order Differencing	sod
4	Maximum Force Level	fm
5	Total Amplitude of Cutting Force	fa
6	Combined Incremental Force Changes	df
7	Amplitude Ratio	ra
8	Standard Deviation of the Force Components in Tool Breakage Zone	fstd
9	Sum of the Squares of Residual Errors	sre
10	Peak Rate of Cutting Forces	kpr

12	Average Force	Fa
13	Variable Force	vf
14	Standard Deviation	std
15	Skew	skew
16	Kurtosis	kts

3.2 Feature subset selection

Feature subset selection can be achieved following the steps mentioned in Section 2. Although the feature subset selection results do not depend on the input parameters, the performance of the feature subset selection depends largely on the setting of the starting parameters. Hence, an investigation of how each parameter affects the performance of the system was conducted.

3.2.1 Parameters used for GAs

The input parameters and their representation are summarized in Table 4.

Table 4

Parameters and their representation in GAs

Parameter	**Representation**
Population Size	The size of the population for every generation
Crossover points	The number of crossover points to be defined when performing crossover
Crossover rate	The chance of crossover being applied to a chromosome
Mutation rate	The chance of a chromosome being mutated
Confidence level	A limiting value on the required association *r* value.
Maximum Number of generation	The maximum number of generations the GA is allowed to evolve to. Also the terminating condition of the algorithm.
Number of test sets	The amount of data sets used for the calculation of *r*.

Since crossover rate and mutation rate only elevate the randomness of the system, their influence on the performance of the subset selection system is unnecessary [16]. Hence, these two parameters study are omitted. To investigate the influence of the other five input parameters on the performance of the feature subset selection, experiments were performed for 30 runs for each parameter. From our experiments, the parameters that have insignificant effect on the system's performance are number of crossover points, maximum number of generations, the number of test sets. These parameters produced similar results and a wrong setting may increase the run-time, hence leading to the degradation of the system performance. As for other two parameters (population size and confidence level), optimal values improved the system's accuracy. The optimal parameter setting from our experiments are shown in Table 5.

Table 5

Optimal parameters setting used in GAs

Parameter	**Value**
Population Size	20
Crossover points	1
Crossover rate	0.7
Mutation rate	0.001
Confidence level	0.9
Maximum Number of generation	200
Number of test sets	2000

3.2.2 Feature selection results using GAs

Experiments were conducted with different numbers of selected features at beginning. We found that the least number of features to build association model with fault is four. If feature numbers are less than four in the feature subset selection, the correlation between feature subset and fault can not be well established in our case. Fifty runs of each experiment data set on feature subset selection with four features were conducted according to the optimal parameter setting shown in Table 5. The feature selection results are shown in the following Table 6.

Table 6

Experiment Result

		Data Set (50 runs)			
		Test No 1	Test No 2	Test No 3	Test No 4
Features	re				
	fod				
	sod				
	fm	49	47	47	44
	fa	50	48	47	47
	df				
	ra				
	fstd				
	sre				
	kpr				
	thp				
	Fa	49	48	48	47
	vf				
	std	47	49	49	40
	skew				48
	kts				47

The results were labeled with the feature notation and for each data set, the number of times a feature is identified as relevant to tool wear is counted.

From the results, the features that were discovered to be most significant against tool wear were {fm, fa, Fa, std}. Each of these features has an r (fitness) value of at least 0.95. The average time taken for 50 runs of each of the data sets was about 230 seconds.

3.3 Evaluation of the feature selection

The selected features were used to build a multiple regression model to evaluate selected feature subset. Four-variable regressions are used to generate the relation model between wear-out and the features. Wear-out prediction is calculated based on the regression model. Four runs of experiments with different compound features are conducted and the results are discussed below.

The experiment condition and parameters of Test No. 1 are described in Table 2. Totally 65,536 sets of data are captured in Test No. 1. We used half of the data to conduct the training and another half to test our prediction model. Through data processing, the experiment data are separated into two sets, odd numbers of the data (1, 3, 5, ...) are used for training and the even numbers (2, 4, 6, ...) of data for the testing.

We first used the selected feature subset from GAs {fm, fa, Fa, std}, The regression equation obtained from the training data is as in equation (3). The prediction and real tool wear-out comparison diagram is shown in Figure 5 (a).

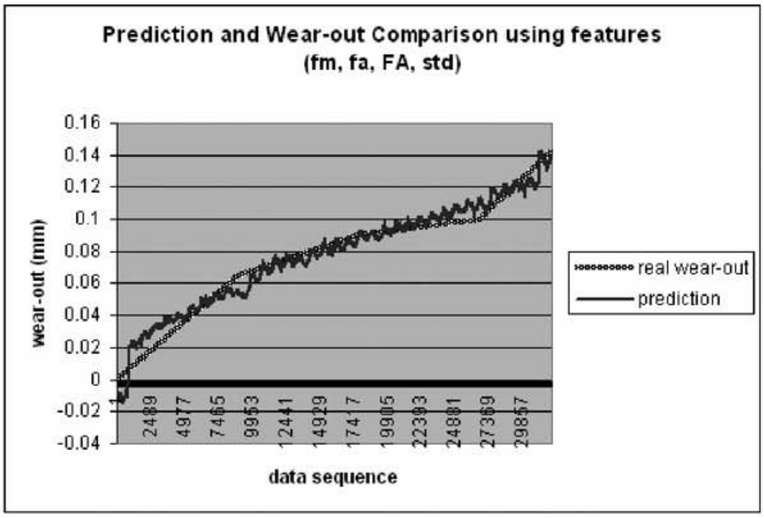
$$W_{ear\text{-}out} = -0.187+0.238f_m - 0.004f_a - 0.0129F_a + 0.054std \quad (3)$$

We second used some randomly selected feature subset {fm, fod, sod, vf}, The regression equation obtained from the training data is as in equation (4). The prediction and real tool wear-out comparison diagram is shown in Figure 5 (b).

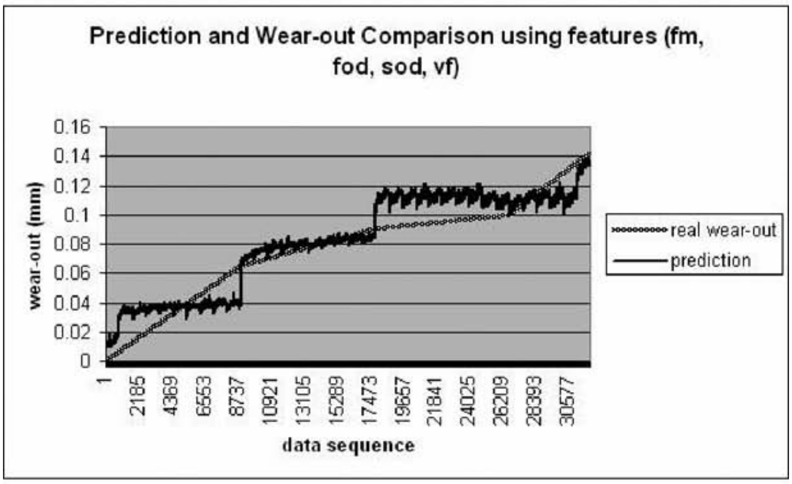
$$W_{ear\text{-}out} = -0.127+0.220\,f_m+0.543\text{ fod} - 0.0353\text{ sod} + 7.795\text{ vf} \quad (4)$$

We third used some other randomly selected feature subset {sre, std, thp, vf}, The regression equation obtained from the training data is as in equation (5). The prediction and real tool wear-out comparison diagram is shown in Figure 5 (c).

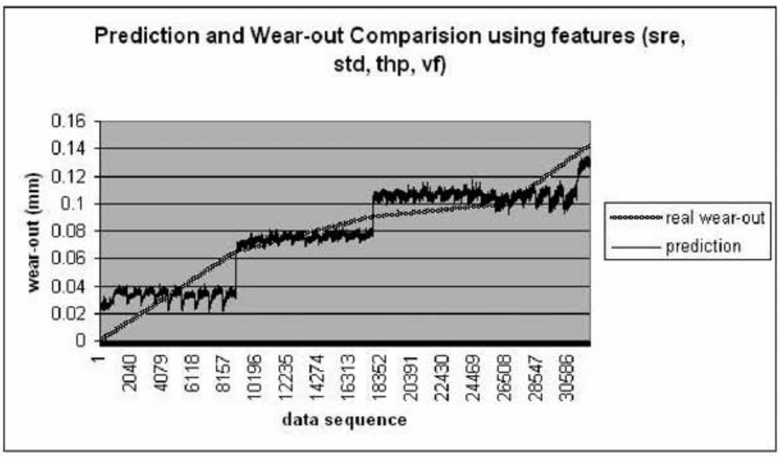
$$W_{ear\text{-}out} = -0.104 + 6.439\text{sre}+0.199\text{ std}+0.003\text{ thp} - 0.578\text{ vf} \quad (5)$$



(a)



(b)



(c)

Figure 5. Prediction and Wear-out Comparison

The prediction and wear-out comparison using different feature subset are shown in Figure 5. The prediction mean error, average relative error and estimation of variance between the prediction and real wear-out for different feature subsets are summarized in Table 7. The selected feature subset from GAs gives the best prediction result for tool wear-out.

Table 7

Comparison results of prediction accuracy for different features subsets

	features (fm, fa, FA, std)	features (fm, fod, sod, vf)	features (sre, std, thp, vf)
Prediction mean error (mm)	0.005	0.012	0.011
Average relative error	11.89%	22.70%	22.50%
Estimation of variance	0.237	0.445	0.425

To conduct further study, we used other three sets of experiments data to evaluate the feature subset selection. R^2 of the multiple regression models is used for evaluation in this study. R^2 is usually used to test the degree of association between output variable Y and all the explanatory variables X_i. R^2 lies between 0 and 1. When R^2 equals 1, the fitted regression line explains 100 percent of the variation in Y. On the other hand, when R^2 equals 0, the model does not explain any of the variation in Y. The closer R^2 to 1, the better the fit of the model [17]. The comparison results of R^2 from different features subsets are shown in Table 8. The R^2 value from selected four features {fm, fa, Fa, std} are much closer to 1 than other randomly selected features and this verifies that the selected features from GAs has the most correlation to tool's wear-out.

Table 8

Comparison results of R^2 for different feature subsets

Test No	R^2 for 16 features	R^2 for four selected features (fm, fa, FA, std)	R^2 for four randomly selected features (fm, fod, sod, vf)	R^2 for four randomly selected features (sre, std, thp, vf)
1	0.979	0.964	0.843	0.873
2	0.971	0.953	0.80	0.846
3	0.985	0.969	0.856	0.887
4	0.972	0.950	0.82	0.841

Our experiments also found that use original 16 features to build multiple regression models takes about 5 times of computational time than to build the models with four selected features. Therefore, use the four selected features subset from GAs has the advantage to implement on-line prediction as it saves computational time without loss of accuracy.

4 CONCLUSION

In the present work, a modified wrapper-based multi-criterion approach using genetic algorithms has been designed for solving feature discovery problem. The best compound feature subset by GAs is verified by using multiple regression models and used to build fault prediction models. The method has been tested experimentally with the prediction of tool wear-out on a high speed milling machine. An acceptable prediction of the tool wear-out has been achieved, which can be viewed as a demonstration of the usability of feature selection method in the manufacturing environment.

EFFECT OF INFORMATION ON THE RISK OF UNEXPECTED FAILURE

D Chaschin

ABB Performance Service Centres. Automation Technologies Division, ABB Australia

Abstract: Condition monitoring (CM,) as part of the Reliability Based Maintenance, is getting more and more popular. With the right systematic approach, this method is proven to increase the productivity of the most manufacturing processes. There is no doubt that when CM helps to find the developing fault and prevents the unexpected failure, it proves to be a good investment. What happens, if the fault doesn't exist? Is this information still useful? How do we estimate the value of this information? How can we use this information in development of the maintenance strategy? This paper has some answers to these questions. Although all these issues are important for any technical objects, the author is investigating the relations between the information and reliability in electrical machines and in induction motors in particular, because they are currently the most popular drives in the industry. The examples are given to demonstrate the approach.

Key Words: Reliability, Condition Monitoring, Information

1 INTRODUCTION

The failure of any mechanism is the result of many possible causes. Unexpected failure of any mechanism is always a result of one reason - insufficient information. This statement determines the easiest solution for reliability improvement: instead of trying to prevent the failure we can try to predict it and undertake all necessary action to prevent or minimise the losses that the failure may cause. This strategy has two important advantages: it is achievable and it is cheaper.

This strategy also has limitations. In most cases gathering all off the information about the mechanism is impossible, sometimes it is very expensive. The attempt to gather the exhaustive information about your equipment can simply deplete your maintenance funds. To assess the amount of information we need, we have to know how to assess the effect of information on the risk of unexpected failure.

Information, by Claude Shannon's definition, is the measure of uncertainty. This definition automatically gives us the answer to the question about the use of information. The value of information can be assessed by the degree of the uncertainty reduction.

The most important question about the equipment involved in the production process is: "How long is it going to last?" Three corner stones are needed to answer this question:

- adequate model, that contains all the parameters affecting the process;
- knowing that all the parameters, used in the model have correct values;
- knowing that the parameters are not changing in time or knowing how they are changing.

Unfortunately there is very limited number of mechanisms that have accurate answers to those questions. That is why we have to acknowledge that the time to failure is a random value.

The other question worth considering is: What equipment we would call more reliable:

- the one that operates 100 hours before failure?
- the one that operates 1000 hours before failure?
- the one that operates 10000 hours before failure?

Subconsciously most of us would pick the last one, but in fact all of the above equipment is equally unreliable if it fails UNEXPECTEDLY. This brings us back to the importance of the information as a tool to prevent the unexpected failure.

2 RELATION BETWEEN RELIABILITY AND INFORMATION

"The development of this program is towards the control of reliability through an analysis of the factors that affect reliability and provide a system of actions to improve low reliability levels when they exist." [1]

"Developments in the automation and electronics in last decades caused the problem of the reliability of the complex multi-element systems which still remains unresolved." [2]

"The problem of reliability is becoming more important with every year". [3]

"…Reliability is such a critical parameter of most modern engineering product" [4]

All the above quotes have one common feature: they are underlining the importance of the reliability problem for manufacturing. But they also have a difference: the first three quoted books were published in 1961 and the last one was published in 2004.

Why the reliability remains the problem for the last 50 years? The following diagram may help to find the answer.

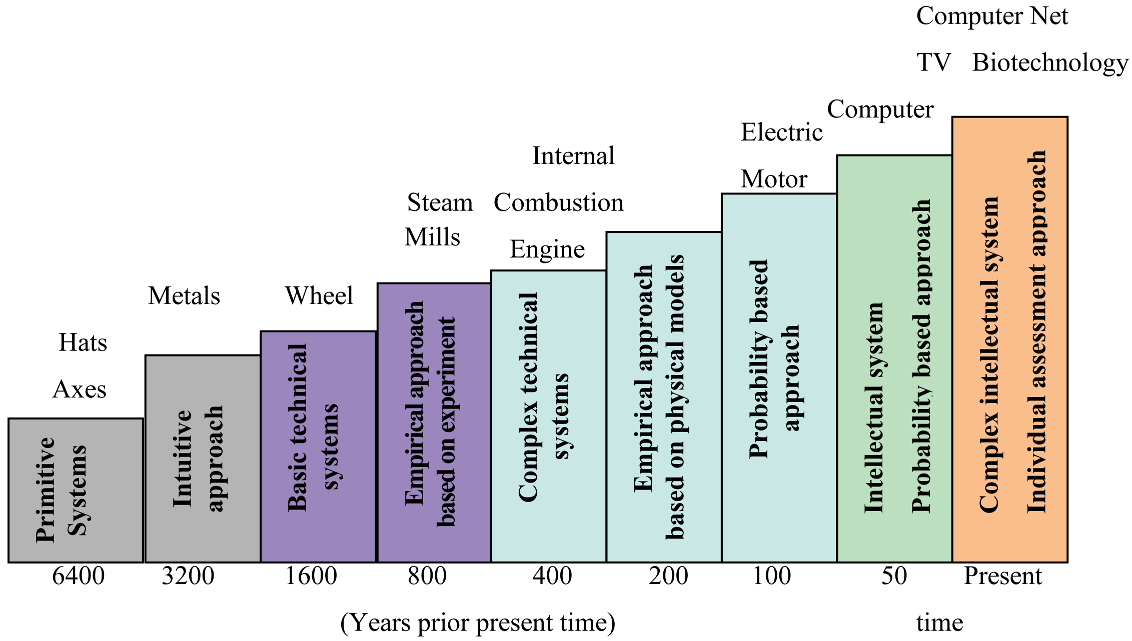

Figure 1 Relation between the complexity of the systems and approach to reliability.

The diagram shows that as long as there were primitive systems and very little knowledge about them, there was an intuitive approach to the reliability by "go/no go" tests. The failure could happen any time with the same probability.

Development of basic technical system such as the carriage, mill, hat etc required some basic knowledge that was mainly gained from experience with some simple empirical modelling. That was better than nothing, but didn't do much for the improvement of reliability.

The next period contains complex technical systems that required complex physical models. The calculations were more accurate, the modelling was more sophisticated and as a result the reliability could be controlled to a certain degree. But the knowledge was still not refined and to achieve higher reliability the reserve factors were widely used. It was working well before the complex mobile systems were developed.

It is understood that one can improve the reliability of the shaft simply by increasing its diameter. But it will increase its weight as well. And if you can afford it for some stationary equipment, it is always in contradiction with weight restriction of mobile systems, which always mean to be lighter. This contradiction initiated the probability-based approach to reliability problems. This approach is in fact a compromise between the level of knowledge we have about the system and reserve factor we can afford. So instead of a simple guess we could have an educated guess.

As a result of the technical evolution, more complex technical systems were involved in operation without the methods of accurate control of their reliability. In 1952 reliability problems in electronic equipment forced the US Department of Defence and the electronics industry to jointly set up the Advisory Group on Reliability of Electronic Equipment. The recommendations of this group later became the US Military Standard 781, Reliability Qualification and Production Approval Tests. This can be considered as the beginning of the systematic approach to reliability problems.

In 1965 the principles of the above standards were developed further and lead to the integration of the reliability engineering approach into the common engineering approach. These new principles were put into the new standard MIL-STD-785-Reliability Programs for Systems and Equipment. This approach was used by NASA for their space program.

The next level in reliability development was reached in 1980s, when a new Japanese approach took the western world by surprise. This approach emphasised the total quality management role in reliability improvement and it lead to considerable increase in reliability with reduction in price.

The outcome of the above historical issue is that the level of reliability development was lagging behind the development of technical systems. Only in industries such as defence and space exploration, where reliability is absolutely crucial, the new methods were implemented. Other industries considered such approaches too expensive and preferred to stick to the good old "repair when fail" methods. That is why the cost of maintenance of the equipment sometimes reaches 40% of the manufacturing expenses. Considering that manufacturing expenses are counted in hundreds of billions, this 40% extra cost really reaching cosmic proportions. It is time to understand that the lack of information causes low reliability. The lack of information is not necessary caused by our negligence; in most cases we simply don't know that this particular factor will affect the reliability of our system. No matter how well designed the system could be, there will be always some factors that are not considered in the design. Here is simple example from electric motors. European manufacturer receives an order from Africa for several motors. The motors were specially designed for protection from excessive heat and moisture. After some time of operation the motors started to fail. The investigation showed that local ants liked the insulating materials used in the motors. This example proves that it is impossible to provide high reliability only by good design. Although it is a very important part of the equipment life cycle, there are also manufacturing and operations that will inevitably bring their corrections to the initial design.

Let us see how the above principles reflect on the electrical machines. Induction motors are the most popular and reliable electrical machine.

3 ANALYSIS OF THE INDUCTION MOTOR FAILURE

What is causing the uncertainty in the life expectancy of the induction motor? The diagram on the figure 2 would help us to understand it. It shows the most important parameters that affect induction motor characteristics through its lifetime and also subject to variation. As you can see, the first stage of the motor life cycle is its design and the outcome of the design can be affected by the specifications such as required power, voltage, character of the load, ambient temperature etc. The more detailed the provided specifications can be, the more adequacy the motor design will have. If the motor with open air circuit is working in an aggressive environment, like high concentration of SO_3, then no matter how well it is maintained, it will fail quickly. Another factor that affects the design is the model that the designer is using. How accurate is the model? How accurate is the loss calculation, because this will determine the efficiency of the motor and the temperature rise. How accurate are the starting characteristics? This will determine how quick the starting process will be, and the starting process is the most stressful for the most of the motors.

Next step in the life cycle is manufacturing, and the outcome of this process depends on two factors as well. There are materials that are usually supplied by subcontractors and the manufacturing process itself, which includes coil manufacturing and insertion, lamination stamping and core assembly etc. All the factors shown as "Manufacturing" can vary and, as a result, change the motor characteristics. Unfortunately there are not many parameters in the manufacturing process, deviation from which would improve the reliability of the electric motor. The problem is that the electric motor was invented more than 150 years ago and most of the manufacturers already reached maximum possible outcome from the motors of a particular design. It requires new materials or new energy transformation principles to be discovered in order to improve the electric motors any further. That is why variations of the manufacturing parameters from their designated values can only degrade the motor characteristics including the reliability.

The transport and set up steps have the same effect. All the impacts of the transportation as well as misalignment during the setup can severely damage the bearings and cause unexpected failure.

A lot of variations happen to the motor operation conditions. Only the most critical are shown on the diagram below. It is important to understand, when assessing the factors affecting motor reliability in operation, that it is not only the motor features that affect its reliability, but also supply, load and ambient conditions. It is also important that most of the factors listed in the diagram are mutually connected. For example quality of the core manufacturing will affect the flux density, which in turn will affect the starting characteristics and the temperature of the motor. What is interesting, is that the load conditions will determine wether the temperature will rise or fall.

As it can be seen from the diagram and also confirmed by experience, there are a lot of factors which affect the motor life and make it very uncertain. The diagram also shows that neither of the life cycle steps is able to improve the reliability. Only a complex approach including all steps of the motor life cycle will bring positive results.

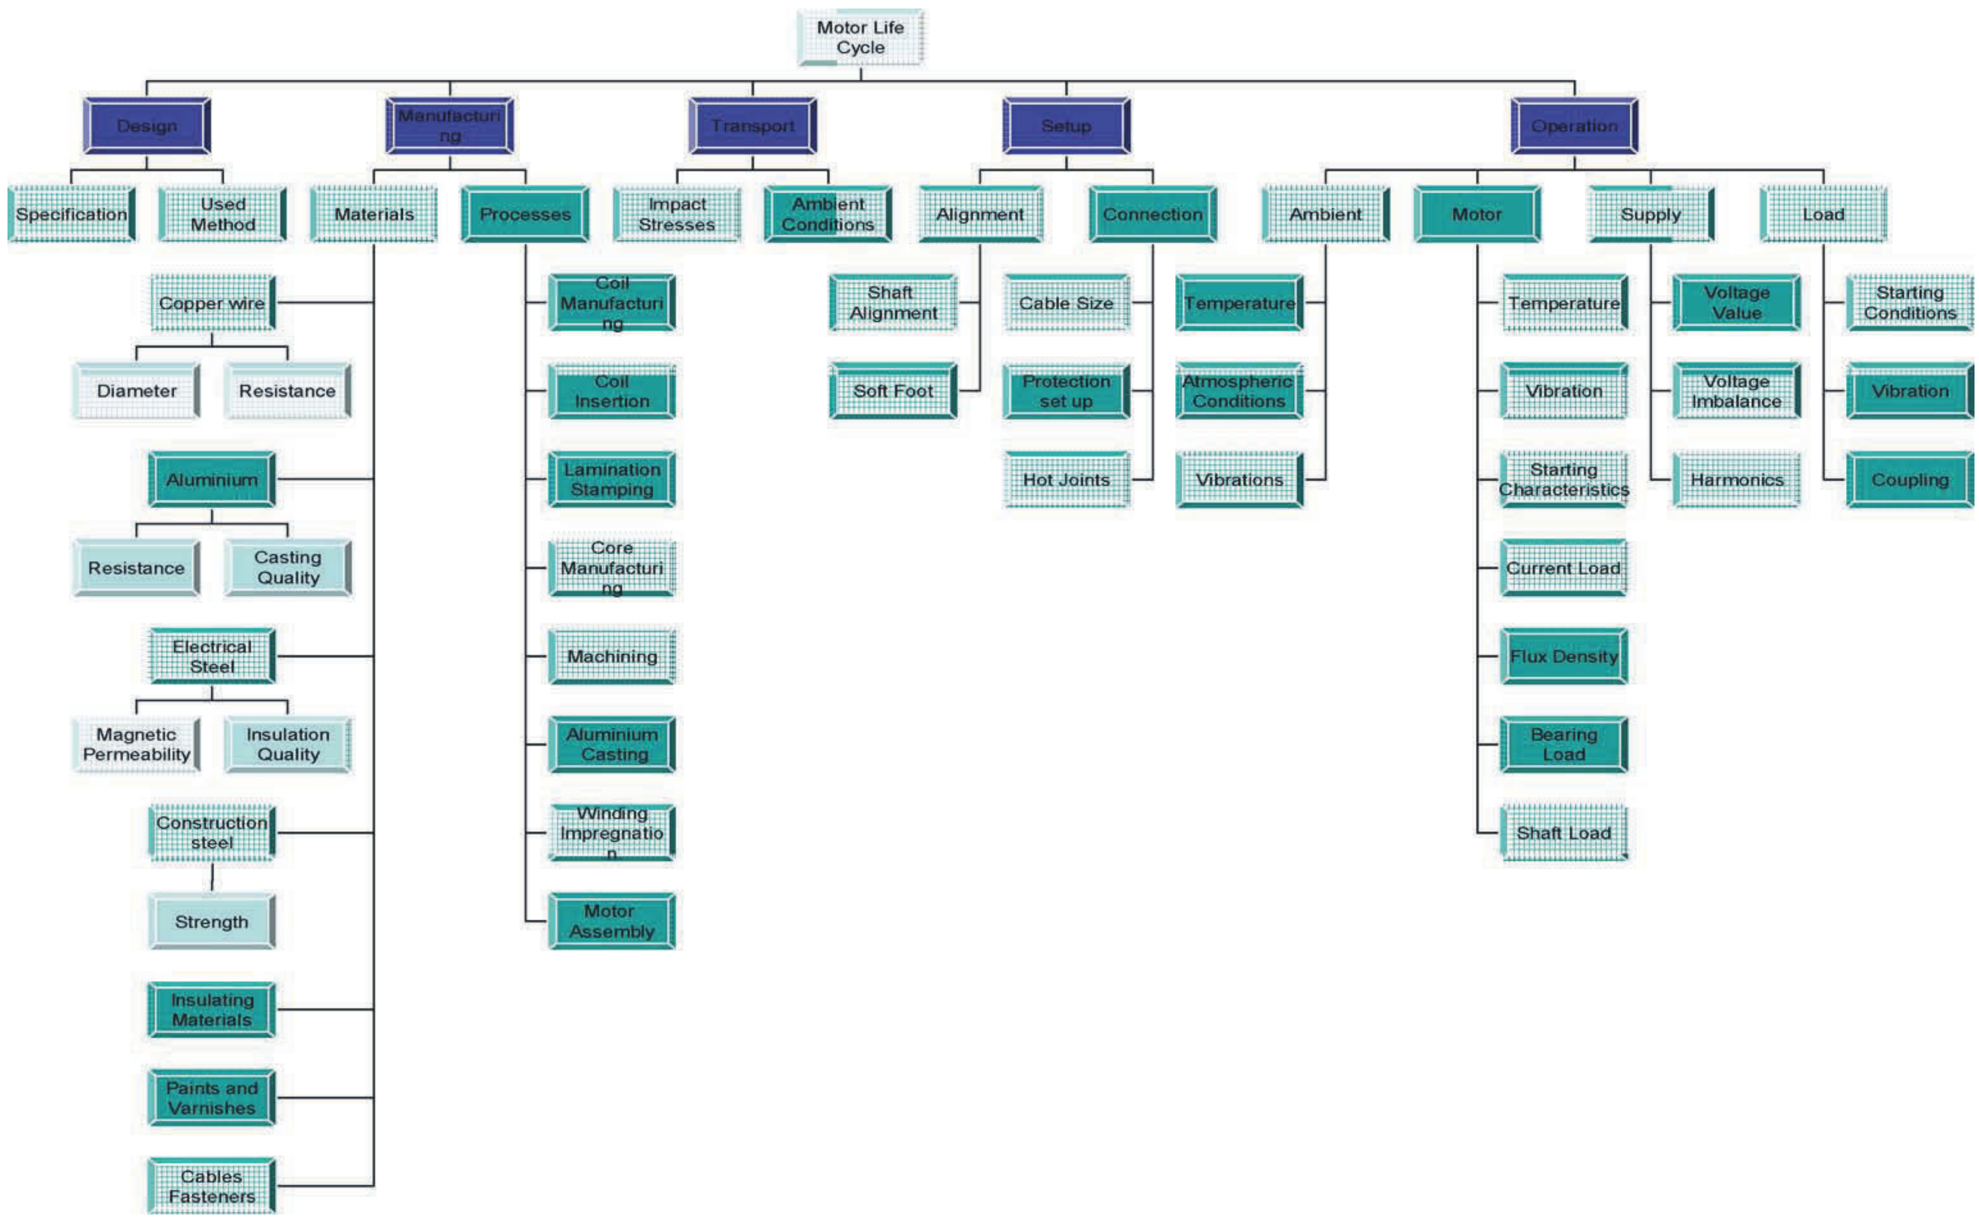

Figure 2. Electric Motor life cycle.

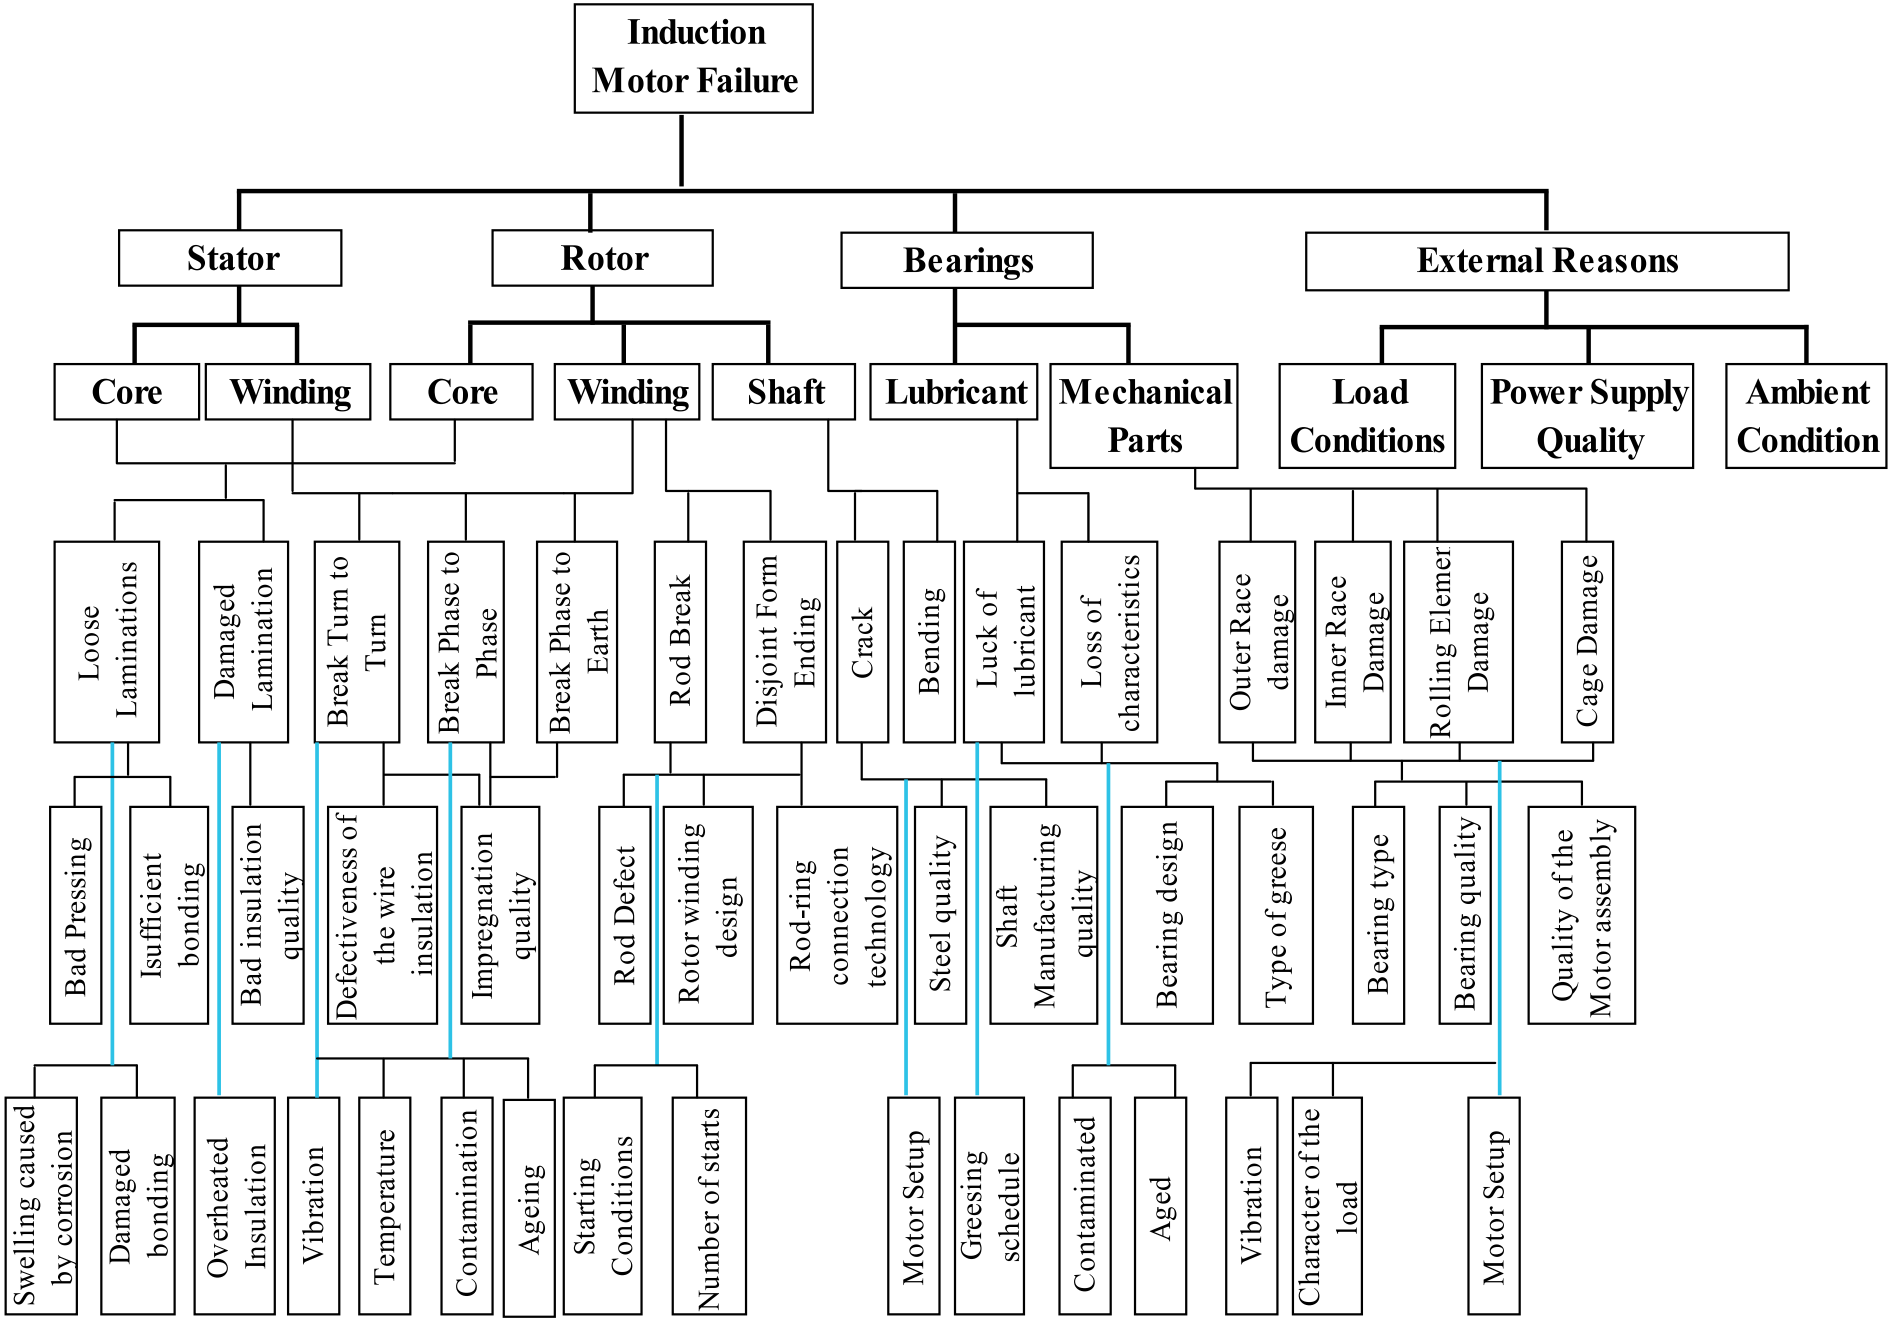

Figure 3. Failure diagram of the Induction Motor

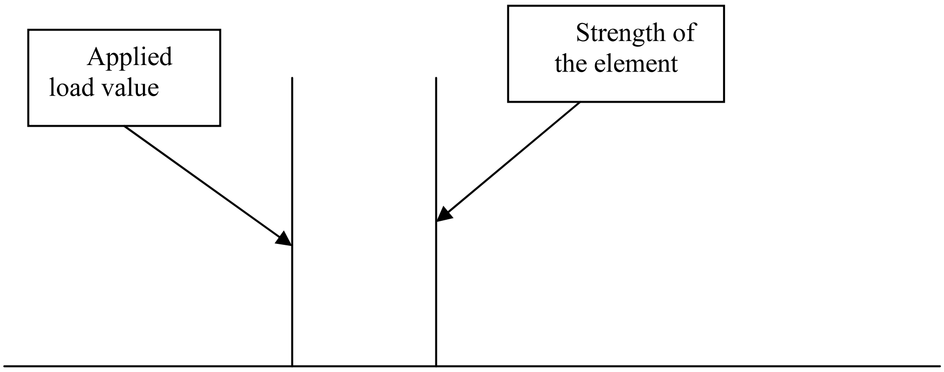
Diagram on the Fig 3 shows possible failure types of the induction motors. There are many common blocks in those diagrams. The significance of the diagram on the Fig 3 is that it shows the connections between particular life cycle parameters and type of faults. Analysis of these diagrams shows the possible ways of the prevention of the unexpected failures. The diagrams show the most important elements of the Induction motor reliability system and connections between them. Let us have a look at this problem from the statistical point of view.

4 STATISTICAL PRESENTATION OF THE RELIABILITY

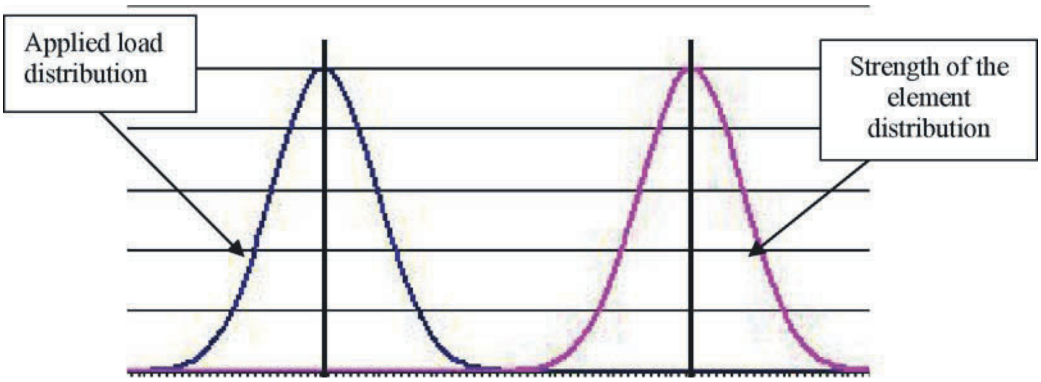
It is well known that the failure of the technical system happens when the applied load exceeds the strength of the element it is applied on. If all the principles of absolute reliability that were laid down in the introduction to this paper would be fulfilled, then we would have the following model:



Load-Strength

Figure 4 Load-Strength discrete values

When we have the adequate models of the load and strength and know that all the parameters are accurate, we will have the discrete values of the load and strength and it will provide absolute 100% reliable product. We have to change the word “know” in the above sentence to the words “have enough information” to bring it closer to the subject of this article. And this is the problem. As we discussed before, most of the time, by different reasons, we don’t have enough information. In this case we are facing another option, presented on Figure 5 below.



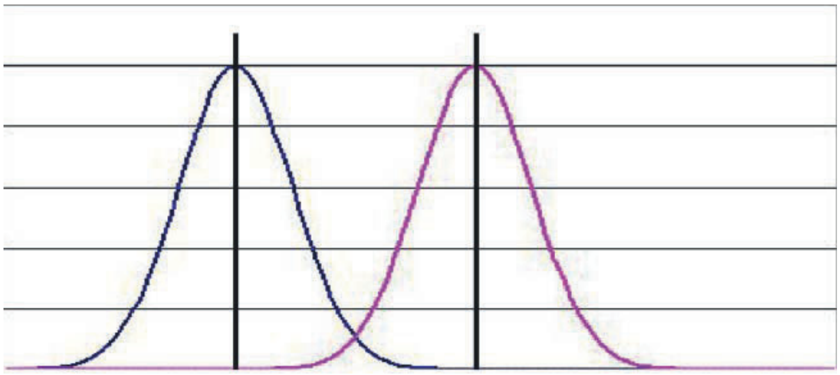
Load-Strength

Figure 5 Load Strength distributed values

The distributed values simply represent the lack of knowledge. It means that both load and strength are affected by some parameters that are included neither in the model nor in the measured values. In other words we don’t have enough information to accurately determine load and strength. Imagine how accurate the results of your electric current calculation would be if you would measure only resistance of the circuit, but not the voltage.

But in this case the reliability is again very close to 100% because the distribution curves are not interfering, which means that even the highest possible load doesn’t reach the value of the lowest possible strength. Obviously the mean value of the strength in this case should be substantially higher than the mean value of the load, represented by the according straight lines.

Now if we decided to reduce the strength of the element, for example reduce the shaft diameter, then we will have the situation presented on the Figure 6, the most common case in engineering reliability.



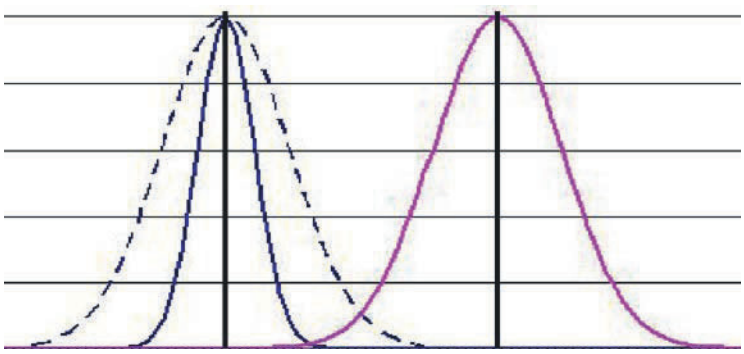
Load-Strength

Figure 6 Load-Strength interfering distributions

In this case because of the lowered mean value of strength we have the interference of the distributions. This means that in some cases the applied load will be higher than the strength of the element and there will be a chance that the element will fail.

And here we have our critical moment. There are two ways of fixing the problem:

- increase the mean value of the element strength, so we will have the case presented on the Figure 5
- reduce the variation of the load or strength or both and have the new case presented on the figure 7.



Load-Strength

Figure 7 Load strength reduced load variation

As you can see, the mean values of the load and strength didn't change, but the probability of the load exceeding the strength practically disappeared.

Now the only question is how to reduce the variation of the load or of any parameter for that matter. This is where the information comes on stage. Modifying the design model by including new parameters that were not considered before, analysing the manufacturing process trying to find the parameter that creates the most uncertainty in the final product and offcourse monitoring the operating conditions of the equipment will reduce the variations of load and strength and by doing that, increase the reliability of the equipment. That is where diagrams 2 and 3 can be very useful when talking about electric motors.

From this chapter we can conclude that it is not the mean values that create the problems with reliability. The mean values are usually analysed all the way through the life cycle. It is the variations that create the problems and it is the variations that should be considered as the main target in the reliability improvement process.

5 THE METHOD OF THE SENSITIVITY ASSESSMENT

As it was written in the introduction, and concluded from the previous chapter, it is important to know which parameter is the most influential in respect to reduction of the uncertainly. The method of the sensitivity assessment can help in this case. As it was mentioned before, it is the variation of the parameters not their designated values, that affect the reliability most. Mathematically we can use the following equation:

$$Y_{jo} = f(x_1, x_2, \ldots x_i, \ldots x_n) \tag{1}$$

Here Y_{jo} - designed value of the j^{th} characteristic from the upper level of the diagram Fig.2;

x_i - i^{th} designed parameter from the lower level of the same diagram,

The actual value of the characteristic after the motor was manufactured and installed can be described as:

$$Y_{jo} + \Delta Y_{j\Sigma} = f(x_1 + \Delta x_1, \ldots x_i + \Delta x_i, \ldots x_n + \Delta x_n) \tag{2}$$

Here $\Delta Y_{j\Sigma}$ - deviation of the j^{th} characteristic caused by the deviations Δx_1 of the parameters from the lower level.

There are following assumptions made:

the deviations of the characteristics and parameters are small, i.e.

$$\Delta Y_{j\Sigma} << Y_{jo} \text{ and } \Delta x_i << x_i \tag{3}$$

- because of (3) the relations between the deviations of characteristics and deviations of the technological parameters are linear or can be presented as linear;
- the distribution of the technological parameters is close to the Gauss distribution.

Then, using Taylor series we can write:

$$f(x) = f(x_0) + f'(x_0)(x - x_0) + \frac{1}{2!} f''(x_0)(x - x_0)^2 + \frac{1}{3!} f^{(3)}(x_0)(x - x_0)^3 + \ldots + \frac{1}{n!} f^{(n)}(x_0)(x - x_0)^n \ldots \tag{4}$$

Based on the assumption about the linearity of the function $f(x)$, we can ignore all the derivatives higher than first order and rewrite (4) as:

$$f(x) - f(x_0) = f'(x_0)(x - x_0) \tag{5}$$

With some alterations we can rewrite (5) as follows:

$$\frac{f(x) - f(x_0)}{f(x_0)} = f'(x_0) \frac{x - x_0}{x_0} \frac{x_0}{f(x_0)} \tag{6}$$

Here $\frac{f(x) - f(x_0)}{f(x_0)}$ - relative function variation;

$\frac{x - x_0}{x_0}$ - relative argument variation.

For several variables (6) looks like this:

$$\frac{\Delta f(x)}{f(x_0)} = \sum_1^n \left[\frac{\partial f(x_1, x_2, \cdots x_i, \cdots x_n)}{\partial x_i} \bullet \frac{x_i}{f(x_1, x_2, \cdots x_i, \cdots x_n)} \right] \frac{\Delta x_i}{x_i} \tag{7}$$

Or in terms of the characteristics presented on the diagrams 2 and 3:

$$\frac{\Delta Y_{j\Sigma}}{Y_{jo}} = \sum_1^n \left[\frac{\partial f(x_1, x_2, \cdots x_i, \cdots x_n)}{\partial x_i} \bullet \frac{x_i}{f(x_1, x_2, \cdots x_i, \cdots x_n)} \right] \frac{\Delta x_i}{x_i} \tag{8}$$

The coefficients in square brackets are called sensitivity coefficients C_{ij} .

This equation allows investigation of the sensitivity of variation of each parameter from upper level to the variation of each parameter from lower level.

If we consider changing only one parameter x_i , then the derivatives of the other parameters of the sum in square brackets will be equal to zero and (8) can be presented as:

$$\frac{\Delta Y_{ji}}{Y_{jo}} = C_{ji} \frac{\Delta x_i}{x_i} \tag{9}$$

To explain this process in more details, let us go through the example.

6 EFFECT OF THE INFORMATION ABOUT THE BELT TENSION ON THE RISK OF THE BEARING FAILURE

To analyse this issue we need to know the model that connects the load on the bearing with its life expectancy. The most popular model is the one developed by Palmgren and Lundberg and it is as follows:

$$L_h = K_\lambda K_t \frac{10^6}{60n} \left(\frac{C_h}{Q} \right)^m \tag{10}$$

Here Lh – basic rating life, hours; n – motor RPM; Ch – basic dynamic load rating, N;

Q – dynamic load, applied to the bearing during the operation time, N;

$K_{\lambda,} Kt$ - corrective coefficients depending on the lubrication conditions and temperature, m – bearing type factor equal to 3 for ball bearings and 10/3 for roller bearings.

. It is known that the time before failure for rolling bearings is described by Weibull distribution:

$$F(t) = \begin{cases} 1 - e^{-\frac{(t-a)^k}{b}} & if (t \geq a) \\ 0 & \text{if t< a} \end{cases} \tag{11}$$

Here a – location parameter; b – scale parameter and k – shape parameter.

For ball bearings shape parameter k = 1.5. Then scale parameter for 90% probability can be calculated as:

$$b = \frac{t_\gamma}{\sqrt[k]{-\ln(\gamma/100)}} = \frac{t_{90}}{\sqrt[1.5]{-\ln(90/100)}} = 4.48 t_{90} = 4.48 L_{10} \qquad (12)$$

Here L_{10} - basic rating life of the bearing used in the most of the bearing hand books.

Now the Reliability function of the ball bearing can be presented as:

$$R(t) = \exp\left[-\left(\frac{t}{4.48 L_{10}}\right)^{1.5}\right] \qquad (13)$$

Here t- time of operation, hours; L_{10} – basic rating life of the ball bearing, hours.

Now we can have a look at the example:

Induction motor is driving a fan through the pulley and set of v-belts.

The DE bearing is 6305. The other parameters are as follows:

Basic dynamic load rating	C = 22500 N
Mean value of the dynamic load	P = 1000 N
Rotation speed	n = 1500 RPM
Expected belt tension force	Pb = 400 N; force variation from 100 to 700 N
Expected magnetic pull force	Pm = 150 N; force variation from 0 to 300 N

All other components (fan load, contact angle of the bearing, temperature, lubrication characteristics etc.) are presumed stable.

1	Variation of the belt tension force	700-100 = 600 N
2	Estimation of the standard deviation	600/6 = 100 N
3	Variation of the magnetic pull:	300-0 = 300 N
4	Estimation of standard deviation	300/6 = 50 N
5	Resultant variation	$\sqrt{100^2 + 50^2}$ = 111.8 N
6	Estimated mean life expectancy according to Lundberg/Palmgren bearing equation (10)	$L_{10} = K_\lambda K t \frac{10^6}{60 n} \cdot \left(\frac{C}{P}\right)^3$ = 1*1*10^6/60/1500*(22500/1000)^3 = 12656 h
7	Standard deviation in per load units	111.8/1000 = 0.1118
8	Sensitivity of the time to failure to the variation of the load according to (8)	K_Q = -3
9	Deviation of the time to failure because of the load variation	3*0.1118 = 0.3354
10	Deviation of the time to failure in hours:	12656*0.3354 = 4245 h
11	Shape parameter of the Weibull distribution for	σ_L / M_L=0.3354 is approximately 1.85
12	Scale parameter for γ=90 using (12),	b=3.375L_{10}

13 Probability of failure before 10000 hours according to (13):

$$R(t) = 1 - \exp\left[-\left(\frac{t}{3.375L_{10}}\right)^{1.85}\right] = 0.066$$

If we monitored the belt tension and keep it at 400N, the variation of the Pb would be 0.

Substitute 0 in the above calculation will give us probability of failure:

R(T) = 0.054

This example shows that information about only one parameter can reduce the risk of failure by more than 20%. Note that the mean values of the load levels are remaining the same for both cases. We also can name such parameters, related to the bearing reliability, as vibration, eccentricity of the air gap, rotor imbalance. Modern testing methods allow measuring these parameters as well as the belt tension and this additional information will reduce the risk of the unexpected failure even more.

Presented paper explains the reasons of uncertainty in estimation of life expectancy in rotating machines and shows that additional information can reduce this uncertainty. Presented diagrams and the method of sensitivity assessment help to establish the most efficient information sources.

Abstract: This paper provides an overview of the Australian Government's Facilities Management (FM) Action Agenda as announced in 2004 as a key policy plank designed to facilitate growth of the FM industry. The resulting consultation with industry leaders has seen the creation and release in April 2005 of the FM Action Agenda's strategic plan entitled *'Managing the Built Environment'*. This framework, representing a collaboration between the Australian Government, public and private sector stakeholders and Facility Management Association of Australia (FMA Australia) and other allied bodies, sets out to achieve the vision of a more "*…productive and sustainable built environment…*" through improved innovation, education and standards. The 36 month implementation phase is now underway and will take a multi-pronged approach to enhancing the recognition of the FM industry and removing impediments to its growth with a 20 point action plan. Additional information is available at www.fmactionagenda.com.au

Keywords: facilities management, recognition, innovation, education and training, regulatory reform, sustainability, built environment

1 INTRODUCTION

Facilities Management (FM) is "a business practice that optimises people, process, assets and the work environment to support delivery of the organisation's business objectives" (Glossary of Facility Management Terms, 1998).

According to Access Economics' 2004 statistical profile of the industry, FM is a significant contributor to the Australian economy. The combined direct and indirect contribution of the FM industry in 2002-03 was A$12.2 billion of value added, A$12.4 billion in GDP terms, and (full time equivalent) employment of 172,000 persons. The combined contributions represented 1.80%, 1.65% and 2.10% share of the corresponding Australian GDP and employment totals.

In 2004 the Australian Government announced their support of the FM Action Agenda as a key policy plank designed to facilitate growth of the FM industry. The resulting consultation with industry leaders and collaboration between the Australian Government, public and private sector stakeholders, and industry bodies saw the release in April 2005 of the FM Action Agenda's strategic plan entitled '*Managing the Built Environment'*.

The FM Action Agenda sets out to achieve the vision of a more "*…productive and sustainable built environment…*" through improved innovation, education and standards.

This paper provides an overview of the process thus far, its strategic directions and the current implementation phase.

2 ABOUT ACTION AGENDAS

Action Agendas are a key policy plank of the Australian Government under the Department of Industry, Tourism and Resources (DITR). Action Agendas represent an opportunity for collaboration between Industry and Government, with both working together to identify impediments to growth, harness sustainable competitive advantage and to facilitate growth of specific sectors.

Action Agendas also provide industry direction for a whole-of-government approach on key issues such as innovation, investment, the environment, market access, regional development, education and training, workplace relations and regulatory reforms.

In October 2003 the Facility Management Association of Australia (FMA Australia) successfully made application to the DITR. On 19th January 2004 the federal Industry Minister, Hon. Ian Macfarlane MP announced the development of a Facilities Management (FM) Action Agenda.

There are currently 36 Action Agendas at various stages (4 under development, 15 being implemented through the adoption of recommendations, and 17 completed, as at December 2005). The industries covered by these Action Agendas accounted for about a third of Australia's gross domestic product (GDP) and employment, about 46 per cent of Australia's export earnings, and contributed more than 75 per cent of Australia's business investment in research and development (R&D).

Action Agendas provide a flexible model for industry to consider in developing sectoral priorities, and planning for the future in partnership with government.

3 STRATEGY FOR CHANGE

"It seems appropriate that in the Year of the Built Environment, we will create the opportunity for this growing industry .... it is industry commitment combined with the support of the Australian Government that Action Agendas require to be a success. This sector is positively positioning itself to deliver improved productivity on a whole range of work fronts."

Hon. Ian Macfarlane MP, Minister for the Department of Industry, Tourism and Resources (January, 2004)

3.1 Providing Leadership

Announced on the 19th January 2004, the FM Action Agenda saw FMA Australia work with DITR representatives to form a Strategic Industry Leaders Group (SILG) for the strategic phase. Nominations from a broad spectrum of industry participants were received and during February - March 2004 ministerial appointments were made of individuals drawn from the following organisations, representing a mix of private and public sector facility users, FM service providers and consultants.

- AEH Property
- ANZ Banking Group
- Coles Myer
- Connell Mott MacDonald
- Department of Industry, Tourism and Resources
- Hames Sharley
- CSIRO Corporate Property
- Investa Property Group
- Multiplex Facilities Management
- Rider Hunt
- Resolve FM
- Spotless Group
- Stockland Corporation
- Telstra Corporation
- Tungsten Group

The SILG comprised 15 industry leaders appointed by the Hon Ian Macfarlane MP, Minister for Industry, Tourism and Resources, and chaired by John McCarthy.

3.2 Formulating our Agenda

The SILG met several times to develop the focus areas, it was recognised from early on that a lack of an agreed definition of FM and recognition of its significant contribution was a core issue. Without identity and recognition any group of partitioners will struggle to attract quality candidates, access resources, achieve professionalism, develop standardisation and ultimately sustainability.

Practical objectives identified by the SILG included;

- Recognition by all levels of Government and corporate sectors of the value of FM in terms of environmental performance, economic contribution, immigration, innovation and research, education and training, etc;
- Provision of a national focus for the FM innovation and compliance to maximise efficiencies and effectiveness;
- Ensuring that procurement and management decisions are made on the basis of whole-life costs, cultural fit and not solely short term financial criteria;
- Providing leadership, building capability and sharing knowledge;
- Improving partnering and collaboration between service providers and contractors;
- Creating clearer career paths and specific tertiary education courses;
- Support of professional, dynamic, moral and ethical attitudes;
- Improved productivity and sustainability on a whole range of fronts;
- Justification of the business case for FM investment; and
- Value for money.

"Whole-of-government support through the acceptance of our Action Agenda proposal is an exciting and critical step forward in the development of the facility management industry."

Steven Gladwin, Chairman, FMA Australia (January, 2004)

3.3 Providing Focus

At the SILG's first meeting on 31st March 2004 five (5) core themes identified and agreed, including;

- Recognition
- Innovation
- Education and Training
- Regulatory Reform
- Sustainability

Working groups were established to develop the themes.

Each of the five (5) Working Groups was chaired by a member of the SILG. Many had more than one SILG member actively participating. In all the Working Groups involved some 50 volunteers from some of Australia's leading organisations, who gave not only of their time and energy, but also covered their own expenses. The task of the Working Groups was to identify, according to their respective themes, key issues affecting competitiveness and future growth for the industry.

The findings for each Working Group, along with recommendations were presented to the SILG for consideration as part of developing the FM Action Agenda.

The SILG met on the 26th May and 21st July 2004 to review the progress of the Working Groups. The SILG also met on the 13th October 2004 to agree and prioritise actions, and to consider draft action agenda report. The drafting process continued until the 1st December 2004 when the SILG signed off the FM Action Agenda report for submission to the Minister and to consider the implementation strategy.

When launched at Sydney Opera House by Parliamentary Secretary, the Hon. Warren Entsch, MP, on 28th April 2005 the FM Action Agenda was acknowledged as "… the best ever Action Agenda …" with a clear and concise vision of the future.

3.4 Statistics for the Future

FM is not formally recognised in Government policy or an identified industry by the Australian Bureau of Statistics (ABS) or the Department of Immigration, Migration and Indigenous Affairs (DIMIA). This is reflective of the prevailing lack of recognition of the distinctive nature and importance of FM.

As part of the FM Action Agenda strategic phase Access Economic were commissioned to conduct an independent and credible analysis of the Facilities Management industry size and contribution to the Australian economy and compile a statistical profile.

Good quality statistics are essential to any industry, and especially to an emerging one industry such as Facilities Management, which is at a critical stage in its development. Statistics can provide information on production and employment trends, inter-industry relationships, market opportunities, potential threats and a range of other matters that point to the industry's future and influence decision-making.

The Access Economics 2004 study has provided a starting point for collecting statistics on the industry. In the short-term, the industry can build upon this methodology to update current statistics. Over the longer term the industry could look to the Australian Bureau of Statistics to provide improved data.

For the purposes of the Access Economics report, FM activities are concerned only with servicing of buildings. The services include services provided by both FM management and FM service suppliers such as tradesmen and cleaners. The business-specific operating costs of occupants of the facilities were excluded. This means that FM costs consist mainly of building-related repairs and maintenance, servicing and energy for lifts and air conditioning, gardening / landscaping, cleaning, lighting, security, and management fees, whether actually paid to FM firms or imputed (ie. carried out 'in-house' by building owners or tenants). Occupant costs for all other energy uses are excluded, as are any costs of production and processing within a facility.

The analysis was not restricted to businesses formally designated as FM firms. It was intended to include all activities that have the potential to be undertaken by FM firms, regardless of whether or not these activities may be undertaken 'in-house'. Access Economics found boundaries of the industry are not defined precisely. For example, while all servicing of buildings used by educational and hospital facilities have the potential to be covered by FM contacts, there is some arbitrariness in deciding where to draw the boundaries on the sizes of office buildings, retail centres and multi-unit residential buildings that are to be included.

As a general rule, where Access Economics had to make a judgement on these matters, it generally erred on the side of understating the size of the FM industry.

Table 1

Facilities Management Contribution to the Australian Economy (2002-03)

	Value Added ($mil)	GDP ($mil)	Employment ('000)
Direct management component	1,958	1,982	16
Direct service supplier component	6,583	6,662	119
Total direct	8,451	8,644	135
Total indirect	3,689	3,753	37
Combined direct and indirect	12,230	12,397	172
Combined share of Australian economy	1.80%	1.65%	2.10%

Source: Access Economics (2004)

4 MANAGING THE BUILT ENVIRONMENT

4.1 FM in Australia

The Facilities Management industry evolved during the 1980's as a consequence of more widespread outsourcing by business of activities, such as the management and maintenance of buildings. The industry plays a significant role in planning and managing the built environment throughout its life cycle, which has three linked stages: facility creation, operation and disposal.

The industry's primary function is providing strategic management advice on the efficient operation of buildings and reducing operational life cycle costs. The industry is also responsible for ensuring that services are delivered in a way which contributes to the productivity and profitability of building occupants, as well as improved returns for owners and investors.

The range of services provided include traditional building services such as repairs and maintenance, security and cleaning, as well as more highly technical services requiring skilled personnel. The FM industry contributes $12.4 billion to Australia's gross domestic product (GDP). This is equivalent to 1.65 per cent of Australia's GDP. It includes a direct GDP contribution of $8.6 billion or around 1.15 per cent of Australia's GDP, and an indirect contribution of a further $3.8 billion or about 0.50 per cent of Australia's GDP. Total employment by the FM industry was 172,000 persons in 2002-03. This is equivalent to about 2.1 per cent of Australia's workforce.

The FM Action Agenda aims to develop a strategic framework for the growth of a sustainable and internationally competitive Australian Facilities Management sector.

The SILG examined five main strategic areas which constitute the main areas of focus for the FM Action Agenda. The areas identified were: facilities management in the Australian economy, innovation, education and training, regulatory reform, and sustainability. The SILG also examined issues associated with implementing the FM Action Agenda and raising awareness about the facilities management industry more generally.

4.2 Innovation

Success in achieving growth in the FM industry will depend on the promotion of an innovative culture and bringing innovations into the market place.

The actions proposed promote the benefits of innovation through greater industry collaboration and research and development, and to highlight the contribution that facilities management makes to workplace productivity. An FM Innovation Forum will be established to facilitate the exchange of information and ideas, and a web portal designed and built to disseminate this information, 31st May 2006 saw the launch of www.fmactionagenda.com.au

4.3 Education and Training

Education and training is essential to creating a skilled FM workforce which is recognised by clients as professional and capable of delivering a valuable service.

It has been proposed that industry work with the vocational education and training (VET) sector to support the provision of VET, and with universities to increase the availability of facilities management courses at the undergraduate level. Greater collaboration between the VET and higher education sectors is also proposed, along with an awareness campaign to increase recognition of Facilities Management as a career of choice by school leavers.

4.4 Regulatory Reform

An awareness campaign has been proposed focusing on three important regulatory areas asbestos, emergency evacuation plans and cooling towers with five further identified areas (dangerous goods; fall prevention; confined spaces; plant safety, and electrical inspections testing and residual current devices) to follow. It is recommended that the industry undertake initiatives to further the cause of regulatory reform in these and other areas. Industry should seek to participate in the various regulatory consultative mechanisms to promote conformity of requirements and contribute to key areas impacting on the efficiency of Facility Managers.

4.5 Sustainability

The FM industry is in a strong position to influence decisions made by government and corporate entities to lower environmental impacts through business practices.

The industry should actively promote its contribution to the sustainability challenge for business and the community. Further, FM should be aware of the role it can play in key industry and government forums on promoting sustainability. The new FM Action Agenda web portal should also be used to disseminate information and develop a business case model highlighting the costs and benefits of sustainable practices.

4.6 Implementation

The SILG proposed that an Implementation Group be formed comprising leading people drawn from within the FM industry to follow through on the 20 actions incorporated in the FM Action Agenda strategic plan.

Such an Implementation Group would need to work closely with all industry stakeholders and meet regularly for a period of up to three years after the launch of the FM Action Agenda. The SILG also proposed an awareness campaign designed to communicate clear messages about the contribution and multiplier that FM represents to Australia's Built Environment.

The key objective of the FM Action Agenda is to support the future growth and sustainability of Australia's facilities management industry by successfully developing and promoting its competitive advantages.

5 IDEAS INTO ACTIONS

FM Action Agenda industry vision being that Facilities Management should be; "the foremost contributor to a productive and sustainable built environment through excellent and innovative management of facility services."

The following is the 20 point action plan as developed by the FM Action Agenda and as published in *'Managing the Built Environment'* (2005), and now being followed though in the Implementation Phase;

5.1 Facilities Management in the Australian Economy

Action 1	Annually update data on the facilities management industry's contribution to the Australian economy
Action 2	Consult with the Australian Bureau of Statistics with a view to obtaining improved data for the facilities management industry.

5.2 Innovation

Action 3	Establish a Facilities Management Innovation Forum for the facilities management industry.
Action 4	Establish a web portal for the facilities management industry to disseminate information and provide feedback on innovation, education and training, regulatory issues, and sustainability.
Action 5	Promote the benefits of innovation and encourage greater industry collaboration and investment in research and development.
Action 6	Highlight the contribution that facilities management makes to productivity by establishing performance measures and 'best practice' benchmarks, incorporating client input, with a specific focus on improving workplace productivity.

5.3 Education and Training

Action 7	Work with the Construction and Property Services Industry Skills Council to support the provision of vocational education and training (VET) for the facilities management industry.
Action 8	Work with Australian universities to increase the availability of facilities management courses at the undergraduate level.
Action 9	Develop an innovative project that will encourage greater collaboration between the VET and higher education sectors in the provision of facilities management education.
Action 10	Undertake an awareness campaign directed at those who influence career choice – including school counsellors, career advisors, educators, parents and students – to increase understanding of facilities management as a career.

5.4 Regulatory Reform

Action 11	Promote awareness within the facilities management industry of the regulatory requirements applying in three selected areas (asbestos; emergency evacuation plans; and cooling towers).
Action 12	Identify the regulatory requirements for a further five identified areas (dangerous goods; fall prevention; confined spaces; plant safety; electrical inspection and testing and residual current devices).
Action 13	Promote conformity of regulatory requirements and contribute to key areas of regulatory reform.

5.5 Sustainability

Action 14	Promote the role of facilities management in responding to increased demand for corporate accountability associated with sustainability performance.
Action 15	Promote the role of the facilities management industry in key industry and government forums addressing sustainability.
Action 16	Use the data web portal proposed in Action 4 to disseminate sustainability information.
Action 17	Develop a 'business case' model that highlights the costs and benefits of embracing sustainable practices in the use and management of materials; energy; water; waste; and indoor environmental quality; with a particular focus on workplace productivity.

5.6 Implementation

Action 18	Establish an Implementation Group comprising leaders of the facilities management industry to manage the implementation of the Action Agenda.
Action 19	Develop a communications strategy to increase recognition of the contribution of facilities management as an industry.
Action 20	Work with relevant government departments and agencies to identify opportunities to raise awareness of the facilities management industry and to consult on relevant government policies and programs.

5.7 FM Exemplar Project

Additionally the SILG resolved to commission an FM Exemplar Project for the Implementation Phase as a demonstrator of best practice to act as a base for industry technology transfer and up-skilling. Several facilities at various stages of their life cycle were considered, however Sydney Opera House was ultimately selected on 13th October 2004 based on its ability to cover a range of the 20 action areas and its iconic status.

6 IMPLEMENTATION PHASE BEGINS

"The FM Action Agenda puts our profession on the map and provides all industry participants and stakeholders with the opportunity contribute to delivering a productive and sustainable built environment through improved innovation, education and standards."

Stephen Ballesty, Chairman, FMA Australia (September, 2005)

Following the launch of the FM Action Agenda publication entitled *"Managing the Built Environment",* which is the output of the strategic phase conducted throughout 2004 in consultation with industry, again saw FMA Australia and DITR representatives working form a Strategic Industry Leaders Implementation Group (SILIG). Again nominations from a broad spectrum of industry participants were received and during August 2005 ministerial appointments were made of individuals drawn from the following organisations, representing a mix of private and public sector facility users, FM service providers and consultants.

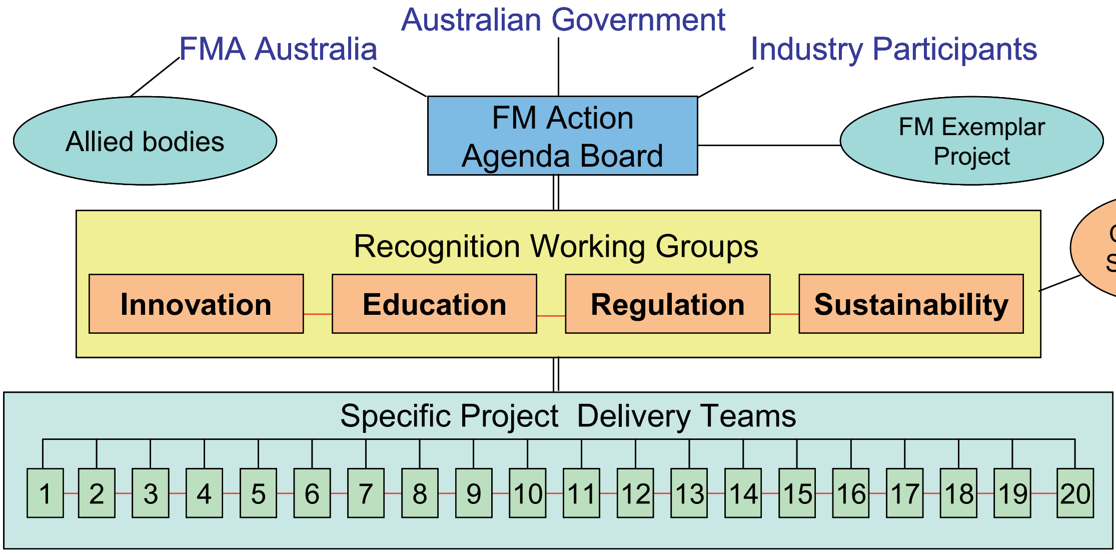
- AEH Group
- Australian Department of Parliamentary Services
- Balance Corporate Property (from July 2006)
- Investa Property Group
- Macquarie Bank
- Mirvac Group (until November 2005)
- Multiplex Facilities Management
- Myer
- Queensland Department of Public Works
- Resolve FM (until March 2006)
- Rider Hunt Terotech
- Spotless Group (until February 2006)
- Transfield Services
- Tungsten Group
- University of New England

This voluntary body comprising 14 industry leaders with an *ex officio* member from the Department of Industry, Tourism and Resources, again chaired by John McCarthy has now been officially designated the FM Action Agenda Implementation Board. The Board at their first meeting reviewed the FM Action Agenda strategy and the 20 action items for the 36 month Implementation phase, and resolved;

- its structure and responsibilities around the focus areas of Innovation, Education & Training, Regulatory Reform and Sustainability;
- that FMA Australia would act as facilitation and provide support for the process;
- allocated specific responsibilities for the formation of Recognition Working Groups for each of the four focus areas; the formulation of a Communications Strategy and liaison with the FM Exemplar Project – Sydney Opera House in order to progress the 20 action items;
- to appoint a Board Secretary and seek funding for a scoping study to identify the requirements for Project Delivery Teams; and
- a meeting and reporting cycle for the future.

Figure 1

Implementation Phase Structure (diagrammatic only)



Source: Stephen Ballesty

"This is a defining moment for the Facilities Management and I am delighted to be part of such a dedicated team which represents a mix of experience gained during the strategic phase and new talent that would contribute to important industry transformation".

John McCarthy, Chairman, FM Action Agenda Implementation Board (September, 2005)

The 36 month implementation phase is now underway and will take a multi-pronged approach to developing the FM industry and removing impediments to growth with a 20 point action plan across the following platforms:

- *Innovation* – Improved appreciation of facility life cycles, and greater understanding of the key drivers of workplace productivity, and the improved application of information technology.
- *Education and Training* – Improved access to dedicated FM education and training opportunities and creation clear career pathways into the profession.
- *Regulation Reform* – Explore opportunities to harmonise cross jurisdictional regulatory compliance requirements that have an efficiency impact on FM.
- *Sustainability* – Improved utilization of existing knowledge and the development of tools and opportunities to improve the environmental performance of facilities.

As of January 2006, the DITR Parliamentary Secretary, Bob Baldwin, MP, has assumed the oversight responsibility for the FM Action Agenda. The Implementation Board of 12 with John McCarthy as Chairman is making good progress on the four (4) Recognition Working Groups, Communications Strategy and FM Exemplar Project. The first FM Action Agenda annual report is due in August 2006.

7 DEMONSTRATING BEST PRACTICE

The *FM Exemplar Project: Sydney Opera House* was launched on 28th April 2005 as a CRC-Construction Innovation project with a team including the CSIRO, the University of Sydney, Sydney Opera House, Transfield Services and Rider Hunt Terotech. The project is due for completion by the end of 2006.

Sydney Opera House has a design life of 250 years primarily as a 'performing arts centre', "providing first class venues, facilities and services that support our artistic and business aspirations." according to Sydney Opera House Trust Annual Report (2004). However, at the same time is acknowledged as an 'architectural masterpiece' and an 'asset of heritage significance', being regarded as having 'iconic' status and value for 20th century architecture and contributes to the tourism value of Sydney. The facility comprises 7 theatres, 37 plant rooms, 12 lifts and over 1000 rooms. Sydney Opera House employs 300 full-time staff and a further 300 part-time staff, delivering over 2500 performances per annum. Sydney Opera House provides some unique FM challenges.

Sydney Opera House currently has an annual FM expenditure budget of approximately A$19 million pa – across a wide range of activities from minor maintenance through to significant refurbishments and upgrades. Sydney Opera House's FM Department has recently initiated a series of FM enhancements to the way they procure and implement FM services.

Additionally there is a planned future upgrade of the Opera Hall (estimated cost of A$400 million over the 2006-2008), ongoing acoustic enhancements, fire and hydraulic upgrades and maintenance, and architectural refurbishment works.

The FM Exemplar Project combines three (3) research streams dealing with *Digital Modelling*, *Services Procurement* and *Benchmarking* as a whole and then develop collaboration between them. It aims to achieve innovative FM strategies and models that will showcase improved FM performance and promote best practice.

Sydney Opera House has acknowledged the challenges they face with their existing documentation management. A digital backbone of Building Information Model (BIM); or accurate three dimensional (3D) geometry with attributes that define the detail of building elements, and relationships to other objects; will be critical for future FM activities. The *Digital Modelling* theme will develop an appropriate BIM strategy and investigate the potential of state-of-the-art information systems to enable a future integrated platform to support FM activities and processes.

The *Services Procurement* theme focuses on the maintenance and cleaning services procurement, especially with reference to in-house versus outsourcing methodologies, in the context of the user requirements, prevailing market and the service provision reliability and risk. Various procurement methods and a multi-criteria assessment approach for supporting decision making are to be investigated.

The *Benchmarking* theme focuses on the strategic asset management of iconic facilities with similar functionalities, with a bias for the performing art centres. Critical success factors in the functional areas of FM are to be identified against organisational objectives and key performance indicators in order to better monitor, control and improve FM with respect to performance targets seeking participation from international comparators. Collaboration between Services Procurement and Benchmarking includes sharing of the benchmarking data and utility of key performance indicators to support innovative procurement strategies.

Further it is envisaged that a significant component of the project budget will be expended on Australia-wide workshops, industry brochures including '*How To'* guides, conference and journal publications, and course development through higher education and TAFE institutions. In addition, Sydney Opera House will be able develop best practice benchmarks not only to justify the iconic facility status but to demonstrate industry leadership in FM.

8 CONCLUSIONS

The Facilities Management Action Agenda via its strategic plan released in April 2005, entitled '*Managing the Built Environment'* represents a collaboration between the Australian Government, public and private sector stakeholders, FMA Australia and other allied bodies. There is now a real commitment to achieve the FM Action Agenda's vision of a more "…*productive and sustainable built environment*…" through improved innovation, education and standards.

Arguably, the most significant challenge the FM industry faces is lack of recognition, not only of its distinct and relatively recent character, but of FM as a significant economic contributor and multiplier. Without identity and recognition any group of partitioners will struggle to attract quality candidates, access resources, achieve professionalism, develop standardisation and ultimately sustainability. The FM Action Agenda is a real opportunity to address such issues.

The 36 month implementation phase is now underway and will take a multi-pronged approach to enhancing the recognition of the FM industry and removing impediments to its growth with a 20 point action plan across the following platforms:

- *Innovation* – Improved appreciation of facility life cycles, and greater understanding of the key drivers of workplace productivity, and the improved application of information technology.
- *Education and Training* – Improved access to dedicated FM education and training opportunities and creation clear career pathways into the profession.
- *Regulatory Reform* – Explore opportunities to harmonise cross jurisdictional regulatory compliance requirements that have an efficiency impact on FM.
- *Sustainability* – Improved utilization of existing knowledge and the development of tools and opportunities to improve the environmental performance of facilities.

In addition, the FM Exemplar Project represents an excellent opportunity to identify best practice leverage off the iconic nature of Sydney Opera House's international and national profile to identify and develop best practice within the FM industry. The innovations and methodologies delivered by this Project should be implemental across the FM industry at the strategic, management and operational levels, with clear training and educational benefits leading to improved service procurement and delivery.

The FM Action Agenda makes a clear case for Facilities Management as an enabler of business change and community benefit.

AN INTEGRATED COLLABORATIVE APPROACH FOR FM– SYDNEY OPERA HOUSE FM EXEMPLAR

Stephen Ballesty [a b]

[a] *Rider Hunt Terotech*

Level 5, 41 McLaren Street, North Sydney, New South Wales 2060, Australia

[b] *Cooperative Research Centre for Construction Innovation*

Level 9, L Block, QUT Gardens Point, 2 George Street, Brisbane, Queensland 4000, Australia

Abstract: This paper presents an integrated collaborative approach for facilities management (FM), which utilises Sydney Opera House as an exemplar case study. The project has three (3) research streams, *Digital Modelling, Services Procurement* and *Benchmarking*, which are considered individually and as an integrated whole. The project aims to achieve innovative FM strategies and models that will potentially be of benefit to the Australian facilities management industry.

The *Digital Modelling* theme aims to develop building information modelling for facilities management and investigates the potential of state-of-the-art information systems to enable a future integrated platform to support facility management collaborative activities and processes. The *Procurement* theme focuses on FM service procurement, especially for outsourcing. Procurement methods and a multi-criteria assessment approach for supporting decision making have been examined. The *Benchmarking* theme focuses on the maintenance of iconic assets, specifically performing art centres and facilities with similar functionalities. Critical success factors in the functional areas of asset maintenance are identified against organisational objectives of Sydney Opera House and key performance indicators developed.

Separately, the suggested collaboration between *Procurement* and *Benchmarking* includes potential for the linking of key performance indicators to support Sydney Opera House's Total Asset Management (TAM) strategies and corporate objectives.

Keywords: facilities management, digital modelling, procurement, benchmarking, total asset management

1 INTRODUCTION

A unique opportunity has arisen whereby Sydney Opera House, the Australian Government, the CRC-CI, FMA Australia and industry participants are in a position to jointly support Sydney Opera House as the FM Exemplar Project of the Facilities Management Action Agenda (2005). This project allows the facilities management (FM) industry to develop and showcase innovative methods to improve FM performance and promote best practice.

The FM Exemplar Project consists of three (3) key FM research themes: digital modelling, procurement and benchmarking. Whilst each of these themes represents a key focus area, the ultimate goal which distinguishes the project from previous research is the aim to link each of these themes together to produce an integrated Facilities Management framework utilising one of Australia's most recognisable icons.

This paper presents the background to the FM Action Agenda and FM Exemplar Project in Section 2 and provides the research status to date on Sydney Opera House. Specifically Section 3 deals with the development of Digital Modelling, Section 4 discusses the Services Procurement strategies based on the Sydney Opera House case study and Section 5 presents a benchmarking framework to establish benchmarks and identify the best practice for Sydney Opera House and the FM industry, which includes the development of key performance indicators and data collection. Section 6 provides insights into the collaboration between procurement and benchmarking through data sharing and references of key performance indicators and recommendations for an integrated FM solution.

2 DIGITAL FACILITY MODELLING

Sydney Opera House has a design life of 250 years and a very high quality of construction and finish appropriate for NSW's most prestigious entertainment facility. The building comprises 7 theatres, 37 plant rooms, 12 lifts, over 1000 rooms. Sydney Opera House employs 300 full-time staff and a further 300 part-time staff, delivering over 2500 performances per annum. Obviously to track and plan all the activities including facility management operations, such as regular and incidental maintenance, cleaning, building updates, etc., an information system is necessary. The digital modelling part of this project investigates the potential of building information modelling and state-of-the-art information systems to innovate and support facility management processes.

2.1 Sydney Opera House's Existing FM Systems

Commencing in 1958, building documentation was based on hardcopy paper and pencil/ink drawings, pre-dating even the introduction of two dimensional computer aided design (2D – CAD) technology. While excellent catalogues of this information are available, accurate data is extremely limited, in hardcopy, microfilm or digital format. At the end of Stage I of the construction in 1966, accurate surveys (in imperial units) of the current infrastructure of the ground works and podium was carried out and to date these are the definitive data of those parts of the building. The lack of consistent, reliable data has become a major problem after 30 years of occupancy, particularly many services system modifications, numerous small works projects and now, the need for significant refurbishment. Working without accurate drawings, Sydney Opera House has developed a pragmatic information management system, where the facility's characteristics are used as a tool. For example, many external pipes and ducts have been colour coded, objects such as equipments and installations have been labelled and almost all objects (doors, rooms, etc) have a unique ID. Several information systems for tracking maintenance operations and keeping track of assets have been installed and make use of the unique IDs.

The building has reached a milestone age in terms of the condition and maintainability of key public areas and service systems, functionality of spaces and longer term strategic management. The current "documentation" of the facility is comprised of several independent systems, some overlapping and is inadequate to service current and future services required. A number of key concerns are evident for this situation:

- The existing information systems are still "paper-based" which can result in outdated documents and data re-entering in different (independent) systems;
- the current information systems cannot be readily adapted to support benchmarking processes;
- the current information systems only handle limited procurement information;
- The information system comprises several distributed information sources containing a mix of current and redundant information;
- The information systems are not linked together. Linking or integrating the information systems will support the alignment of facility management operations with business processes. For example maintenance planning can be optimised by taking business activities into account.

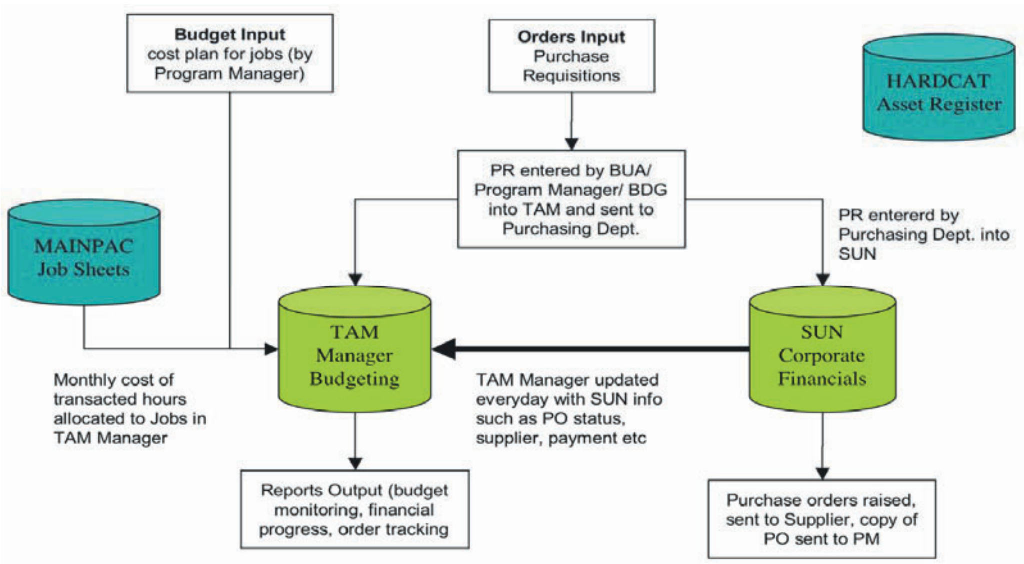

Figure 1

The key facility management systems currently used by Sydney Opera House.

2.2 Building Information Modelling (BIM)

An important consideration in this context is the use of an integrated model of the building, ie. a Building Information Model (BIM) to support in a comprehensive manner FM operations required by Sydney Opera House.

BIM is an integrated digital description of a building and its site comprising objects, described by use of an accurate three dimensional (3D) geometry, with attributes that define the detail description of the building elements, and relationships to other objects, e.g. a Duct *is-located-in* Storey Three of building Block B. The key generic features of BIM are presented as follows:

- *Robust geometry* - objects are described by faithful and accurate geometry, that is measurable;
- *Comprehensive and extensible object properties* - any object in the model has some pre-defined properties or extended properties to be customised by users. Objects thus can be richly described, eg. a manufacturers' product code, cost, or the date of last service;
- *Semantic richness* - the model provides various types of object relationships that can be accessed for analysis and simulation, e.g. is-contained-in, is-related-to, is-part-of, etc;
- *Integrated information* - the model holds all information in a single repository ensuring consistency, accuracy and accessibility of data;
- *Life cycle support* - the model supports the FM data over the complete facility life cycle from conception to demolition, extending current over-emphasis on design and construction phase.

The guidelines of BIM for Sydney Opera House have been developed stating how Contractors and other parties should supply their design information to Sydney Opera House. Adopting these guidelines enables Sydney Opera House to build up a digital repository of their facility which can be merged and re-used for different purposes.

3 SERVICES PROCUREMENT

The procurement research aims to review the current practices and make recommendations on an optimum procurement strategy for asset maintenance services and works. In particular, it will be developed from case studies of Sydney Opera House as an exemplar.

3.1 Procurement Strategies

Procurement strategies consider the achievement of strategic objectives, and operational requirements and constrains when deciding which procurement model is appropriate for providing a service. Figure 5 illustrates that the current Asset Maintenance Strategic Plan (AMSP) and the Operational Asset Maintenance Plan (OAMP) of Sydney Opera House generate 'demand statements' as evaluation criteria and strategic and operational requirements as performance criteria in the procurement process.

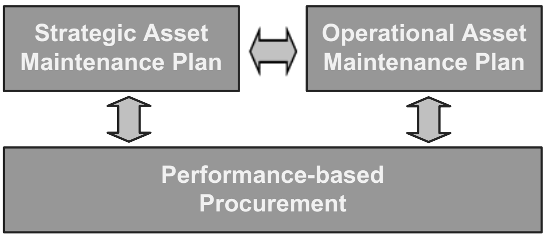

Figure 2

Illustration of the development of procurement strategies to meet the strategic and operational objectives of Sydney Opera House.

In the procurement process provision, options for required maintenance services and works are assessed and appropriate procurement routes are identified. The criteria of the multi-dimensional evaluation process consider the requirements formulated in the AMSP and the OAMP in the context of the prevailing market and the service provision reliability and risk, see Figure 6. The criteria are considered in the steps of the tender process by the various stakeholders of the process.

An important notion of this framework is the integration of a common evaluation system, founded on the strategic high-level objectives and the identified operational requirements, into the design phase and the sourcing, bidding and contracting phases.

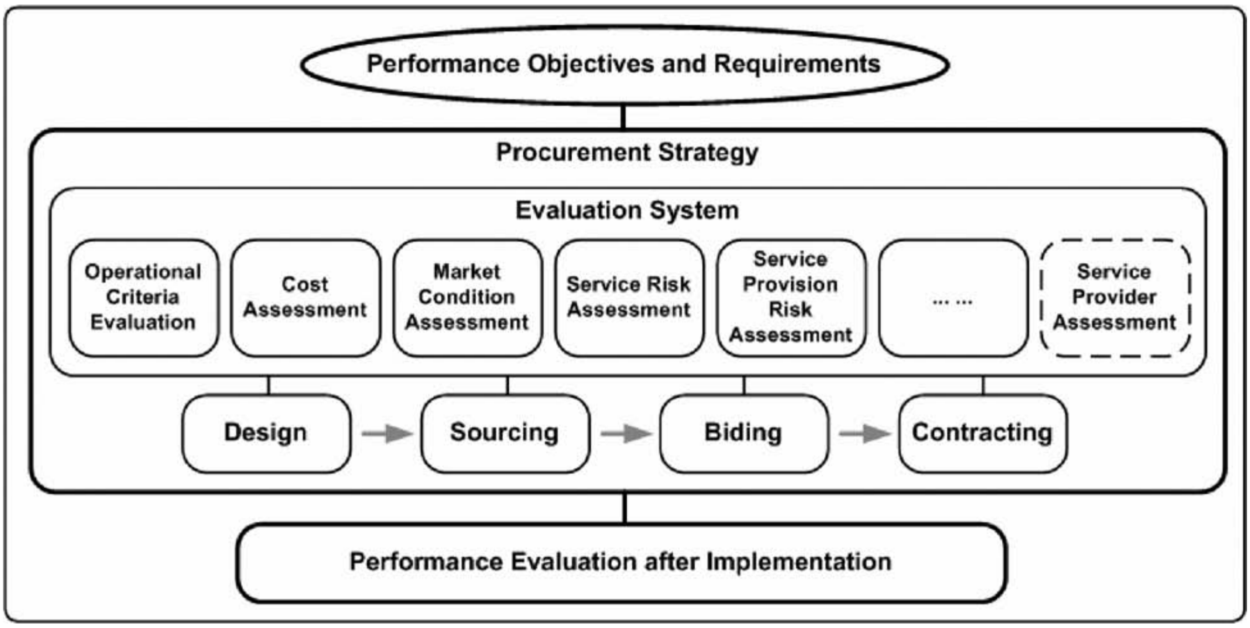

Figure 3

Development of a multi-dimensional assessment evaluation system for the procurement.

3.2 Procurement Vision

In order to ensure that the organisation's procurement approach is developed properly, it is necessary to outline how it will procure, i.e. to 'envision' targets against which performance could be judged. The following presents some examples of procurement visions:

- Maximise efficiencies and effectiveness in how Sydney Opera House makes purchases;
- Ensuring that procurement decisions are made on the basis of whole-life costs, cultural fit and not solely short term financial criteria;
- Ensuring that purchasing will be coordinated between departments where possible; in order to improve efficiency, appropriately planned and timed so as to increase overall value without increasing cost;
- Being fair and just in how and what it purchases and how the organisations 'treats' their Service Providers and Contractors;
- Providing leadership and building capability;
- Improving partnering and collaboration with our peers, and Service Providers and Contractors.

These visions can in turn be met by applying principles that provide strategic direction in how and what it procures, eg. minimising risks, being open and accountable, and being informed by customers' needs.

3.3 Procurement Principles

The following procurement principles may be developed to support the organisation's procurement strategies:

- Justification of business case;
- Developing clear and concise specifications, and good contract administration principles/guidelines;
- Appropriate balance between quality and price;
- Flexibility in developing alternative procurement and partnering arrangements, eg. fostering a culture of partnership, collaboration, and cooperation;
- Transparency and accountability;
- Compliance with legislation;
- Value for money;
- Equality of opportunity;
- Sustainability of procurement ('whole-life' consideration);
- Inculcate a culture of continuos improvement (ie. to provide for evaluation, improvement and change of circumstances during contract duration);

- Provision of professional work, moral and ethical attitudes.

3.4 Sydney Opera House Case Study

The current Sydney Opera House asset maintenance framework enables the following to occur:

- In-house (Facilities and Precinct Development Portfolio team): to focus on strategic issues, such as performance analysis, energy, environmental management and other strategies with the aim of resulting in better longer-term operational performance and reduced costs.
- Outsource (External Service Providers and Contractors): for issues other than strategic issues, with the aim of achieving long term efficiencies and cost benefits, e.g. maximised or increased life expectancy of plants, structures and major systems.

The procurement routes in Sydney Opera House for the following operational aspects are outsourced:

- Mechanical;
- Electrical;
- Building Maintenance;
- Fire Services;
- Security and Surveillance Systems;
- Transportation Systems;
- Stage Machinery Systems;
- Sanitary Plumbing and Plant;
- Consultant Services

A robust tender evaluation system supports an organisation making the appropriate assessment and selection of service providers and suppliers. Sydney Opera House has the following tender evaluation criteria for their cleaning services and select the appropriate criteria for each cleaning contract.

- Price;
- Compliance with specifications;
- Understanding requirement of work;
- General cleaning and management expertise (such as knowledge, communication skills, OHS, customer relations, standard of cleanliness, experiences, quality of references, capacity);
- Expertise in providing similar services;
- Quality of references;
- Capability to provide required services.

It is necessary for facility owners and managers to be able to continually monitor their progress and subsequently understand whether their Service Providers meet the user's requirements in terms of performance criteria and quality expectations. There should also exist the opportunity for continuous performance improvement and / or criteria modification over time to enhance satisfaction levels. Such information could be used by organisations to learn from their experiences and use them to facilitate their decision making process for future projects. Sydney Opera House sets out key performance indicators (KPIs) to regularly measure the performances of its service providers. Some examples from the contracts for the Maintenance of Mechanical Building Services are:

- No unauthorised disruption of operations;
- Work completed within time;
- Work completed to or better standards;
- Agreed budgets.

3.5 Findings

The trends in procurement appear to be pointing towards less adversarial procurement methods such as performance-based contracting, alliancing and relationship contracting which are believed to assist in the reduction of overall project costs and timeframes, to promote innovation and best practice, to enhance client / customer relations, user experiences and provide more satisfactory outcomes. However, all existing procurement methods may not be ineffective or under-performing. Services and works 'projects' are likely to possess a mix of characteristics from a range of contractual solutions. This affects the mode in which organisations may choose to select and manage their service provider and supplier relationships. There may be a need to examine multi-criteria decision-making tools/methods which enable organisations managing facilities to assess and select the appropriate providers in a more holistic manner.

Holistic assessment may be made with the aid of checklists where weighted scores are given to the criteria in relationship to their importance. The development of a multi-criteria analysis tool linked to data analysis referencing the KPIs could aid in the decision making process.

The diagram in Figure 4 addresses a relationship between an organisation's assessment of services procurement and benchmarking data collected, which could use KPIs as a link. The strategic decision determining the KPIs and the services and works procurement could be supported by the benchmarking data collected.

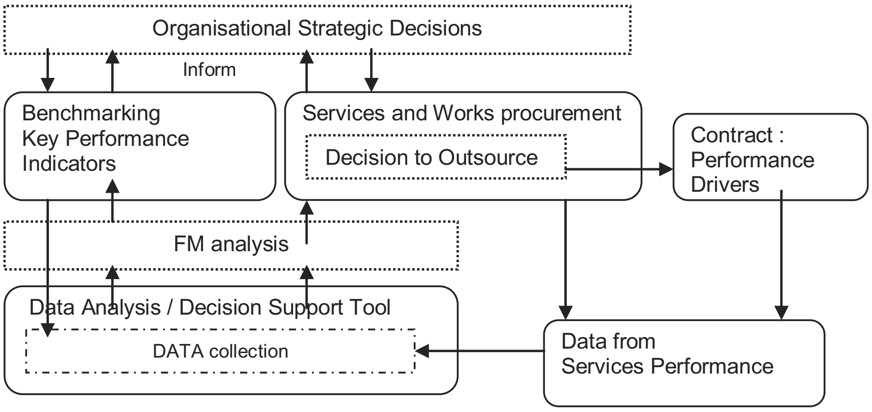

Figure 4

Illustration of the collaborative relationship between the procurement and the benchmarking data collected.

4 PERFORMANCE BENCHMARKING

4.1 Facilities Management Benchmarking

Clearly, the role of FM is to support the fundamental activities of an organisation or a specific facility(ies). Hence, the objective(s) of the FM functions should be compatible with and reflect those of the organisation.

Benchmarking systems in facility management can be employed to monitor, control and improve or to simply to rank the organisation and its assets according to its performance targets. Benchmarking can be performed by an organisation internally; or as an external exercise between comparable partners; or to assess and evaluate the development of a performance indicator over time. Figure 5 illustrates a proposed benchmarking system to assist Sydney Opera House in achieving their strategic objectives with respect to asset maintenance.

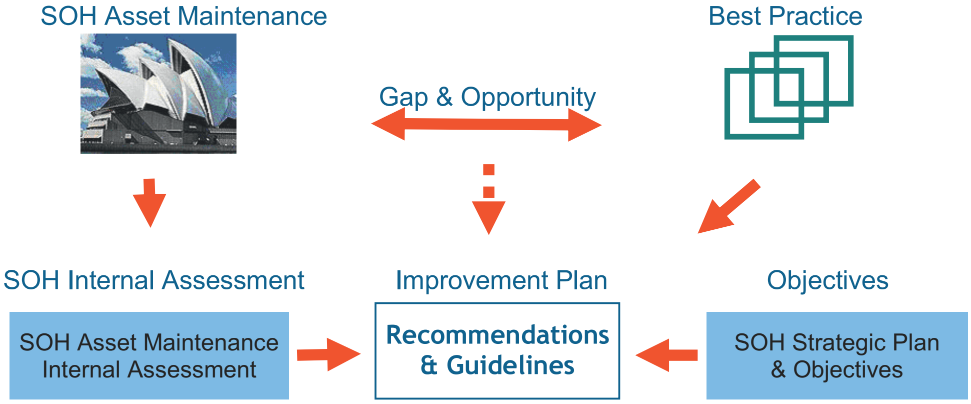

Figure 5

A proposed benchmarking system to assist Sydney Opera House in achieving their strategic objectives.

A classification scheme for applications of benchmarking in facility management was developed in this project, in order to be able to identify typical and especially successful benchmark types for specific objectives. The scheme is shown in Figure 6 for the example of the Building Fabric Index (BFI), as used in Sydney Opera House. The BFI is used with the objective of "monitoring and controlling": it is a quality benchmark, it looks at the trend of performance over time ("historic"), it is related to a specific function ("functional") and it has no driver ("none").

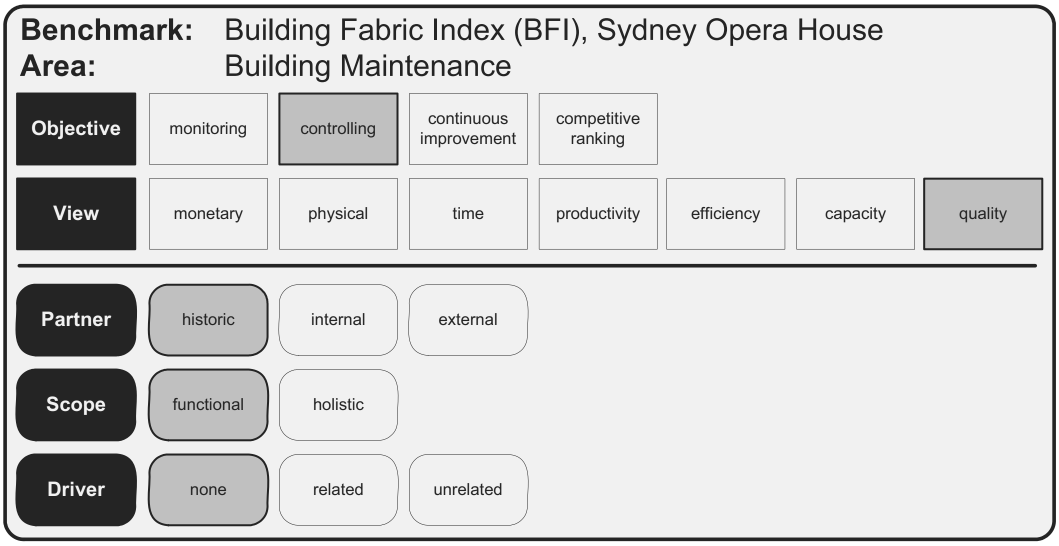

Figure 6

A classification scheme for benchmarks using the Building Fabric Index (BFI) of Sydney Opera House as an example.

4.2 Sydney Opera House Benchmarking Process

Based on the standard benchmarking process structure (Camp, 1989), a benchmarking process for Sydney Opera House cases has been developed, see Figure 7.

Figure 7

A benchmarking process structured for Sydney Opera House cases.

- *Identifying types of facilities and functionalities* refers to finding a group of facilities with similar characteristics, core business or comparable functionalities for benchmarking.
- *Choosing areas for benchmarking* selects features which are most valuable and relevant to Sydney Opera House for benchmarking.
- *Defining key performance indicators & measurements* describes performance objectives in terms of key performance indicators and establishes measurement methods and metrics.
- *Data collection and establishing common standards for comparison* refers to collecting data from a group of benchmarking partners and establishing common standards such as data structure and format for comparison.
- *Benchmarks and guidelines* identify benchmarks in the areas of interest and delivers recommendations and guidelines for Sydney Opera House and the FM industry in general.
- *Improvement plan* assists Sydney Opera House or the FM industry in improving performance in the asset maintenance area in terms of the benchmarking outcomes.

4.3 Development of Key Performance Indicators

Sydney Opera House has the primary function of a “Performing Arts Centre”. It is at the same time an “Architectural Masterpiece” and a “Heritage Building” and further is of “iconic” value for 20th century architecture and contributes to the tourism value of Sydney. These values bring objectives and requirements with them, which have to be integrated with or aligned to the objectives of the facilities management functions.

The development of key performance indicators (KPIs) is presented following a systematic structured approach as it is illustrated in Figure 8.

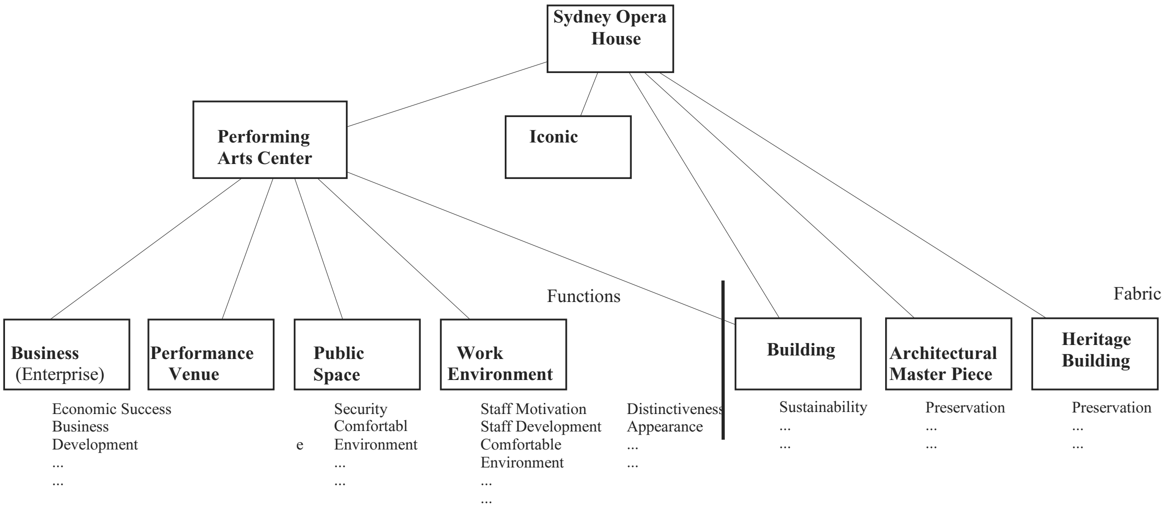

Figure 8.

Illustration of the KPI development.

Firstly the key organisational functions, and their corresponding function areas, their critical success factors and key performance indicators have been identified from available business documents such as reports and strategy plans. For instance, as a performing arts centre Sydney Opera House functions as a business with the objective of attracting and holding sponsors and partners. Its critical success factors include being attractive to sponsors and the branding of Sydney Opera House name while some key performance indicators may include the number and value of supporting sponsors. This is followed by the identification of the high-level objectives of facility management functions. According to the Sydney Opera House Trust Annual Report (2004), the key objective of facility management function is: “Providing first class venues, facilities and services that support our artistic and business aspirations.”

Secondly functions of facility management and its specific objectives are identified; for instance these include the building and custodial maintenance functions of facilities, are identified and their KPIs are derived.

Thirdly, these indicators are allocated to each of the perspectives. As an exemplar they have been categorist into four perspectives: financial; internal business processes; visitor and staff satisfaction; and innovation, growth and leaning.

The systematic objective development from high-level objectives to facilities management KPIs indicates which objective areas are relevant for the organisation and shall be employed to structure the benchmark system. Further it provides a hierarchical structured framework to identify the KPIs themselves.

4.4 Data Collection

The project made an initial contact with national and international organisations responsible for other “iconic” facilities seeking their participation with Sydney Opera House project as international comparators. Involvement will include an audit of the data that they are currently collecting, and it’s availability for benchmarking. The development of better data collection, quality assurance of data, standardised vocabulary, and comparable collection methods will be recommended to the participants.

5 TOWARDS FUTURE INTEGRATED FM SYSTEMS

The integration of different sources of information such as building information, maintenance information, service history and performance information, benchmark information, and business information can improve facility management operations in general. For example, queries retrieving bad performing objects can be cross checked with maintenance schedules. A scenario of a future integrated FM system based on the integration of information resources is illustrated in Figure 9.

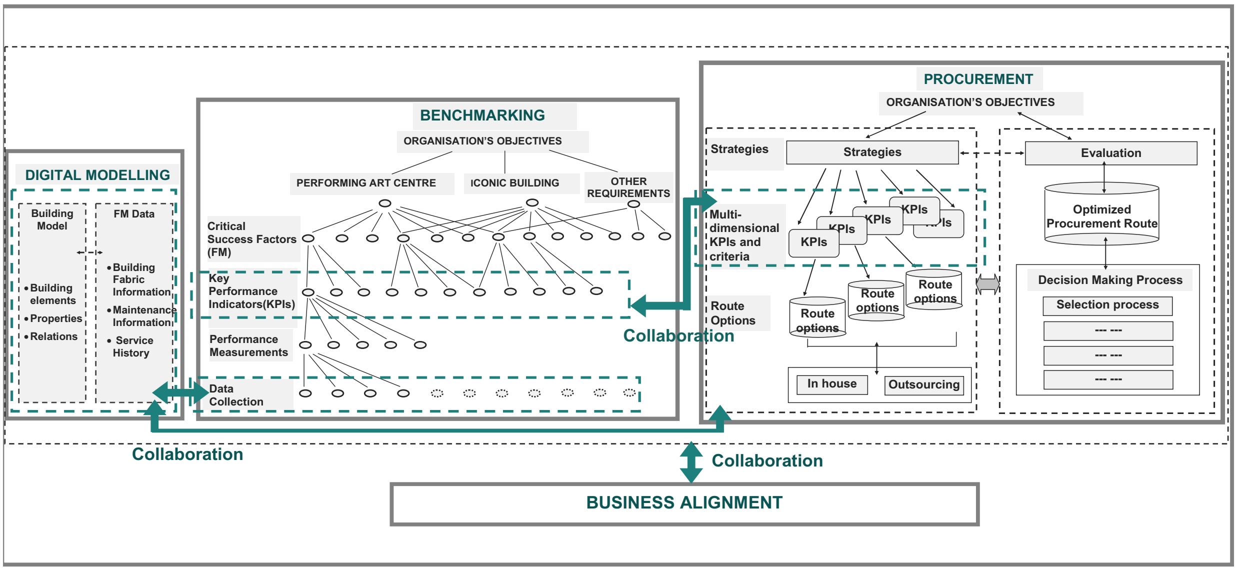

Figure 9

Illustration of a scenario of a future integrated FM system based on the integration of information resources.

It is suggested that the benchmark data collected be kept in a digital format for comparison and be able to integrate with the digital building models. Maintenance information, service history and performance, and business information are able to be easily retrieved from a data repository to enable an optimised maintenance schedule and procurement route. KPIs linked to the benchmark data repository can be utilised by Facility Managers to enable procurement strategies to be aligned with FM performance targets.

The future integrated FM solution should be supported by collaborative FM activities and processes. It should provide integrated information resources for sharing and use by Facility Managers, Contractors and General Management personnel. This enables improvement of collaborations on the operational level and faster and more effective FM processes, and executive reporting.

The future integrated FM system can be implemented using a centralised approach, or a decentralised approach. The centralised approach develops a central database that provides a common model for data sharing. The common model is complicate since it contains all relevant FM information to enable collaborative FM activities. The decentralised approach develops interoperability between different applications. Information sources can be communicated from one application to another for access and queries from different departments.

6 CONCLUSIONS

The Sydney Opera House FM Exemplar Project represents an excellent opportunity to leverage off the iconic nature of Sydney Opera House's international and national profile to identify and develop best practice within the FM industry. This project provides a broad range of practical input from client, consultants and service providers. The project's outcomes will in turn support the Australian Government's Facilities Management Action Agenda. The innovative methods delivered by this project should be implemented across the Facilities Management industry at the strategic, management and operational levels, with clear training and educational benefits leading to improved service delivery for the benefit of the community.

PROFIT CONTRIBUTION MAPPING

Mike Sondalini

Lifetime Reliability Solutions, 2 Denise Close, Shelley, Western Australia, 6148, Australia

Abstract: *Profit Contribution Mapping.* This paper introduces an enhanced financial technique to proactively identify and display operating costs and profits so operations and senior management can make decisions that deliver the best use of plant and equipment assets. Maximising profit from a business requires both efficiency and effectiveness from the production operation. An effective production process makes and delivers what the customer wants. An efficient production process delivers the profit the business shareholders want. Profit Contribution Mapping extends the value stream mapping concept and introduces financial measures to identify where profits are made during production and where they are lost. It combines accountancy, economics, engineering, maintenance, operations management and asset management to create a powerful management tool for effective control at the 'global' production process level and also efficient control at the 'local' process step level.

Keywords: value stream mapping, profit contribution mapping,

1 INTRODUCTION

A common difficulty encountered by engineering asset managers, maintenance managers and reliability managers is to convince 'bottom-line' focused Chief Executive Officers, senior managers and operations manager of the great value in adopting proactive reliability-based equipment care, use and purchasing practices. Because such practices can take years to show a financial return they are not easy to introduce into organisations with close horizon financial focus. Often financial management people simply claim that there is no clear economic sense in introducing such practices because the net present value of an initiative does not justify the capital expenditure required. Production managers can quickly claim that their current practices are suitable and it only needs people to 'sharpen their act' and all will be fine. Little do they realise the tremendous financial waste that such thinking causes their organisation now and in the future.

Because there are no suitable predictive financial or accounting tools available to readily explain to the non-asset management-aware person of the tremendous cost and waste resulting from poor plant and equipment operating and management practices, it was necessary to develop such a fnancial tool. The financial tool explained in this paper, Profit Contribution Mapping, shows an organisation the detailed consequential financial costs of using and persisting with current organisational and production thinking, practices and habits. It allows managers to perform 'what-if' scenarios by modelling the effects of different operating and asset management decisions to let them optimise results for the operation.

The value stream mapping method has proven to be an accepted method to influence production and senior managers on the worth of eliminating waste from their production processes. Because of the solid acceptance this technique has in industry it was selected as the base on which to develop a predictive financial model for justifying the adoption of sound facility management and world-class production practices.

2 PRODUCTION PROCESSES

A production or manufacturing process should be viewed as a system for supplying the customer's requirements. A system implies many interrelated parts working seamlessly together in a coordinated effort to provide an important and necessary function.

A production system involves the seamlessly operation of people, equipment and practices working in an ordered way to produce what the customer wants at a sustainable profit for the producer. An important job of managers, economists, accountants and engineers is to develop business systems that reliably and ethically achieve this seamless operation to the benefit of the organisation, its customers and the community. It is desirable to continually improve and tune the organisation to make it more efficient and do its functions faster, better and cheaper.

Production, processing and manufacturing systems turn raw materials into finished products through a series of steps that progressively convert them into saleable products. The conversion process typically requires added inputs such as labour, utilities like power and water, specialist services like maintenance, added materials like boxes for packaging, along with other numerous requirements to make products customers buy.

Production process and indeed service operations can be symbolized by a block diagram containing a series of boxes for each conversion step in the process, with materials, utilities, services and labour shown by arrows to represent their flow. Such a symbolic production, manufacturing or service process used to convert raw materials to customer-desired products is shown in the process flow diagram of Figure 1.

In Figure 1 raw materials are the direct materials used in the production process. The added inputs include the utilities (power and water) and services (such as boxes for the product, labour man-hours, lubricants for machines, etc) needed to complete the process step. The process steps use these to add value and make the products produced by the organisation. During production the product increases in value equal to the value added in each conversion step. Each value-adding step contributes part of the profit made when the product is sold to the customer. A process step does not produce perfect conversion and some losses occur.

From Figure 1 a few simple properties of a production process can be observed:

i. The process design establishes the process' capability to make the product.
ii. Product quality is determined by the process design.
iii. The bottleneck limits the maximum throughput rate for the process.
iv. The efficiency of operating each process step determines it profit contribution.
v. The customer demand rate dictates the product manufacturing rate.

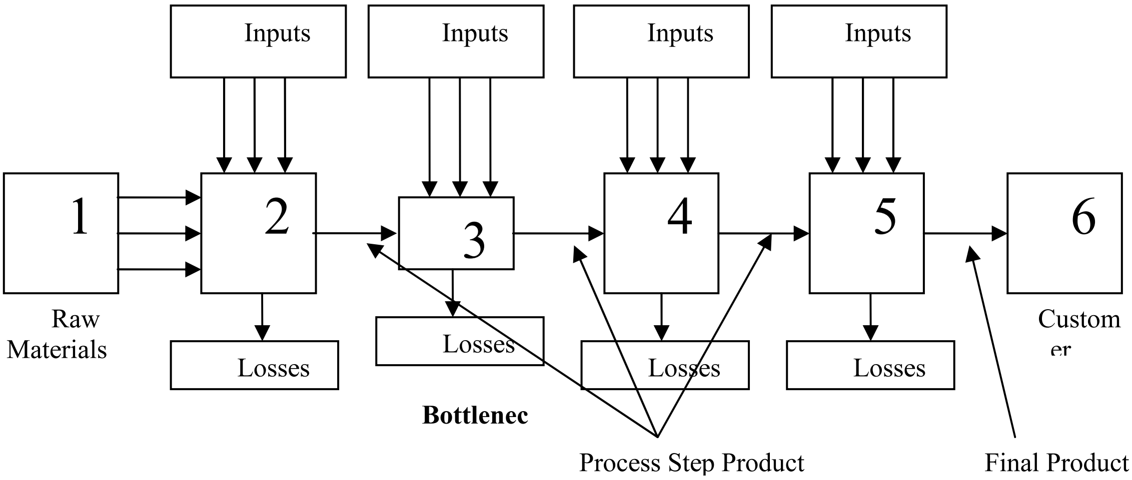

Figure 1. A Production Conversion Process

3 PROPERTIES OF PRODUCTION PROCESS

A production process should only make what the market will purchase. A production system has inbuilt natural checks and balances that keep a production process in-step with the market for its products. The rate of sale of the product to the customer is naturally controlled by what the customer wants and when they buy. It is important that production does not to make more product than can be sold; otherwise money is tied-up in product and inventory that no one wants.

The amounts of raw materials put into a process are governed by the market demand, the production usage rate and the ability of the business to pay for them. Similarly the added inputs throughout the process are governed by the individual process step needs and the cash flows available to pay for them. Where the customer demand rate is above the process' capacity to make the product, they are brought at the rate that the process can use them and can afford to pay. Market economics and business economics act to regulate and control the production rate.

This is the essence of a market-based, capitalist economy – the manufacture of products that people want in production systems that are balanced to the demand.

There is one more issue to consider in a production process - the losses. The process losses behave differently, very differently, to anything else in the production process! They are not naturally limited by demand. They are only limited by how much money is available to the production system. Because there are no systematic internal constraints on waste they are actively managed by minimising them at the design phase of the process and by managing them to minimal levels during the long operating phase of the business.

4 BOTTOMLESS PIT OF LOSSES AND WASTE

Usually not considered seriously important in business process design are the amounts of losses produced – the waste! The wastes include the obvious waste product and scrap materials commonly associated with production waste. But there are many other types of waste produced. All wastes take money from the profits that could have been made.

The other wastes, which are numerous and common but not often noticed, include such things as excess movement, lost heat, lost water, lost energy, excess storage space, excess in-process inventory, excess time, lost time, quality defects, excess forklift pallet hire, excess equipment hire, safety incidents, environmental incidents, excess paperwork, excess manning, and many, many more. (See Appendix 1 for a list of common costs in a production process.) Figure 2 shows the same process as before and includes all the wastes from the business and production process.

Some of these wastes are identifiable by using value stream mapping analysis. Profit Contribution Stream Mapping spots all wastes and gives them the financial value lost to the business to justify and encourage their rapid elimination.

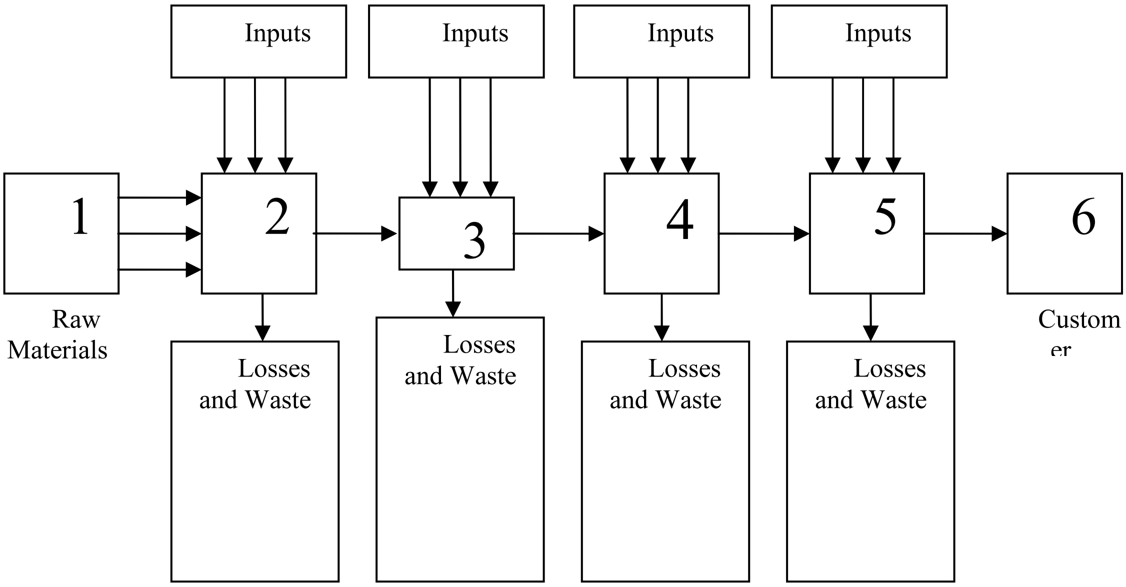

Figure 2. Losses and Wastes in a Production Process

The only natural means of waste control for a production system is how much money can be spent on raw materials and added inputs. Since creating waste has no natural means of self-control beyond bankrupting the business, it becomes necessary to develop business control systems that monitor the waste and force its minimisation and eventual total elimination.

There are now two other properties of a process that was not clearly evident before:

vi. Wastes extract effort and profits from a process.
vii. The process can turn raw materials and inputs into waste so that the process makes waste instead of profit, to the point where waste consumes all the profits.

Based on these seven properties, a business' production process can be interrogated to understand how money behaves within it and to identify the wastes that reduce its performance and profit. This analysis process is called Profit Contribution Steam Mapping (PCSM).

Once a process is operating, people's concerns naturally turn to making the product on time. What most people forget to do is to also make it efficiently, while their meeting customer's requirements. The demand to make product on-time often overrides the need to make it cost effectively. This leads to the situation in business where everyone is busy making product, but no one is busy making profit! If this situation occurs in an organisation, the creation of waste instead of profit dramatically rises. PCSM is a new way to help manager and engineers collect the cost information needed to operate a production system efficiently and effectively.

5 IDENTIFYING THE PROFIT CONTRIBUTION STREAMS

Figure 1 indicated that there are discrete steps in make a product and delivering a service. Each step has its own raw materials, which is the feed from the prior process step. It has its own added inputs needed to make the conversion. From each step come a ‘product’ and the wastes. Each process step is clearly identifiable from its predecessor and its successor and is self-contained in performing its conversion.

Since each process step is independent of the others it can be taken in isolation and viewed as a whole system in itself. This allows analysis of the process step separately. To make it clear which process step is being reviewed you draw a boundary around it on the process flow diagram. An example of segregating a process step for analysis is shown in Figure 3.

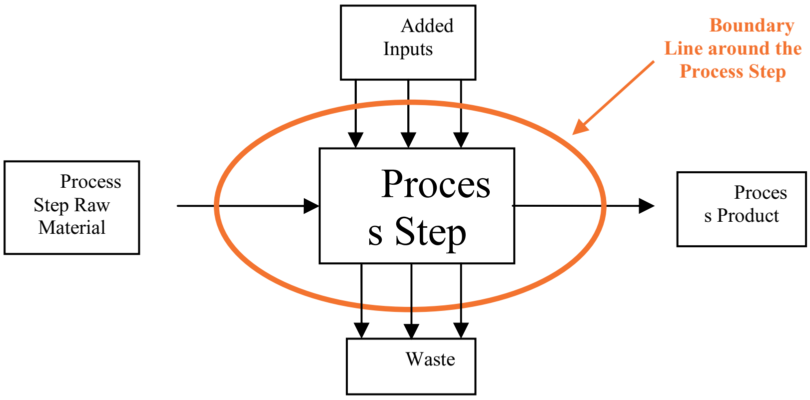

Figure 3. Local Process Step Profit Contribution Map

To determine process effectiveness and efficiency we need a measure. A good measure to use is money. Money is the universal language of business and most people understand the concept of using money to value an item or service. By using money to measure process product cost, added input cost, cost of wastes and the profit contribution from a process step, we can trend the process profit contribution step by step as the product is made. Figure 4 indicates the various money flows, both in and out of a production process.

Though only the money flows for Process Step 2 are shown, they equally apply for each step. By analysing each process step, the true costs of the raw materials, the additional inputs, the wastes from it and the total process step profit contribution can be determined.

Monitoring the costs and profit contributions of each process step provides a means to measure the efficiency of the conversion processes. The more profit contribution generated from a conversion step the more financially efficient is the step. By knowing the cost of all inputs and all wastes, the profit contribution made to the total profit by each process step can be identified. With profit contribution information managers, accountants and engineers can focus on new cost reduction, productivity and process improvements that return the best value for the operation.

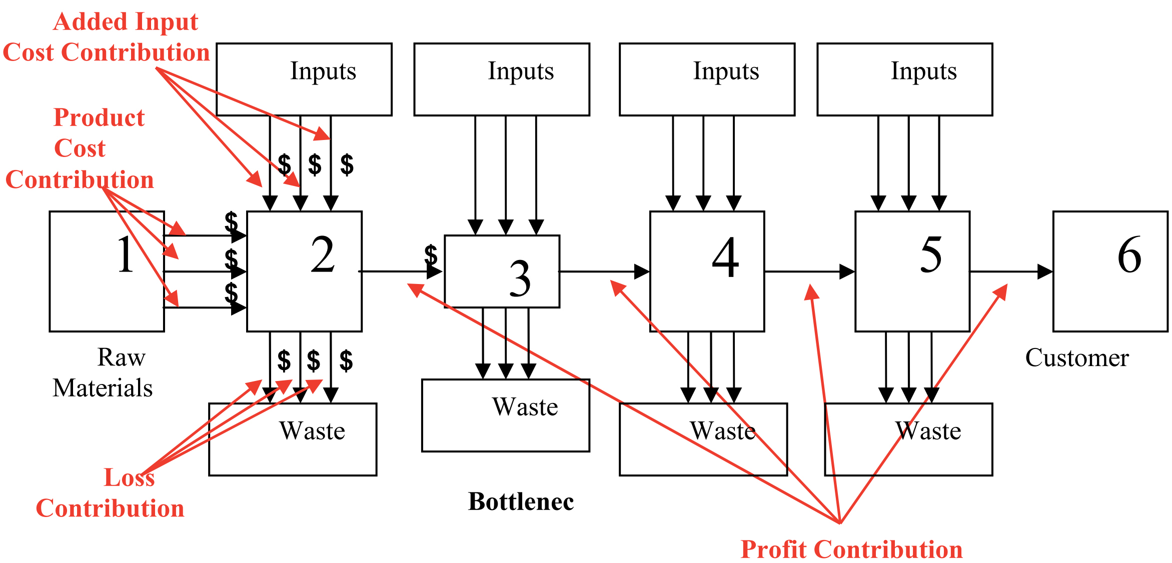

Figure 4. Process Profit Contribution Mapping

Figure 5 indicates how to identify each money flow associated with a process step. The boundary line makes it clear there is money coming into it from ‘raw materials’ and the added inputs required to make the process conversion. Each process step delivers its own process ‘product’ with its profit contribution from the value-adding performed in the step. In addition there are lost moneys that reflect process and operating inefficiencies, wastes and losses.

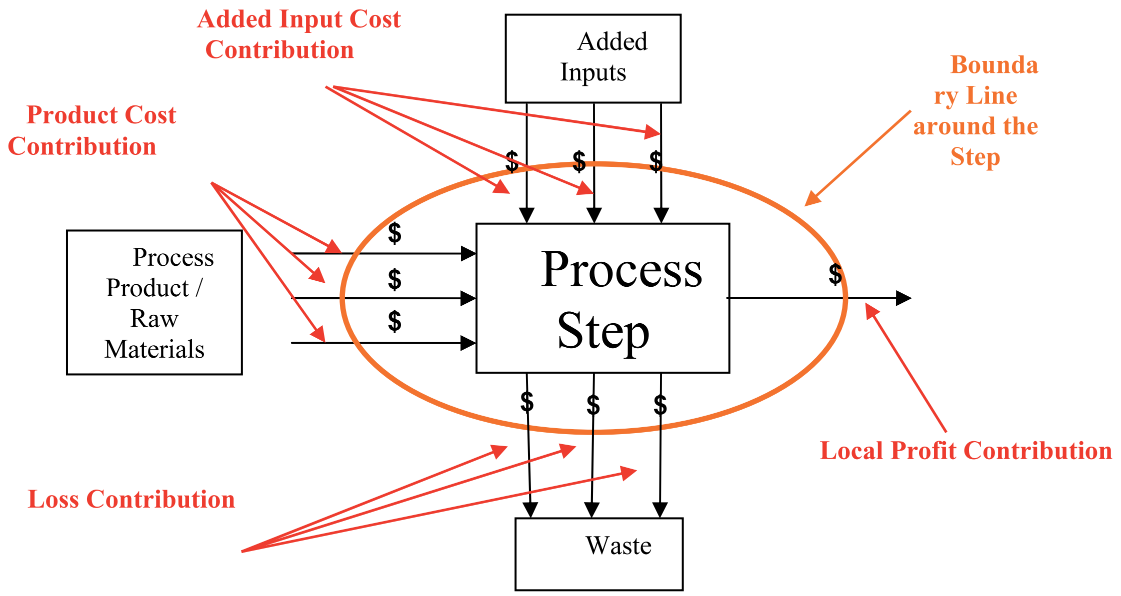

Figure 5. Local Process Step Profit Contribution Map

Figure 5 makes clear the importance of cost control in each process conversion step. If so much money is wasted in each step that the customers will not pay what it costs to make the product, there will be no sales and the organisation goes out of business. For products of equal quality it is very likely that the customer will find and use the cheaper producer.

With all the in and out money 'flows' in a process step identified they are used to analyse the profitability of the process step by calculating the costs and losses to determine its profit contribution. This can be represented by a simple equation.

Cost of Process + Cost of Added Inputs = Local Profit Contribution + Cost of Waste *(1)*

Product Input

Alternately the equation can be written as:

Cost of Process + Cost of Added Inputs - Cost of Waste = Local Profit Contribution *(2)*

Product Input

Strangely, from equations 1 and 2, it could be said we pay for waste twice, once when we buy it as an input and second when we throw it away as lost profit.

5.1 COST ANALYSIS

The power of Profit Contribution Stream Mapping is the clear understanding of production money flows it delivers through the use of visual management. A display of the business process is developed to indicate where the money goes into, around and out of the business. What happens with costs and profits is clear and issues highlighted by the mapping can be addressed.

5.2 ACTIVITY BASED COSTING

Activity Based Costing (ABC) is the most appropriate accounting technique to apply when determining process step costs. Standard costing is not suitable since overheads are allocated to direct costs. Rather it is necessary to capture every cost, from the smallest cost to the largest, as it is really spent. A total and true reflection of what happens in each process step during a set period of time is necessary.

Because the profit stream costing process identifies every cost individually, overheads allocation is not permitted. All overheads are identified separately and costed in exact proportion to their usage in each process step. If overhead costs were allocated to direct labour an incomplete mapping of the true costs would result.

The accuracy and completeness with which the process step costs are collected will directly determine the effectiveness of the profit contribution map as a management control tool. If data is complete and true then good, reliable business-improving decisions will be made to make the operation more efficient and profitable.

The appropriate time period to be used to collect the mapped costs may be an hour, day, week, month and even a year. The time period is dependant on the cycle time for the process step and the size of the time window necessary to identify all money flows for the process step.

Applying ABC permits identification of every cost with its component costs, and even sub-component costs. It is important that every dollar spent in the production of goods is accounted for and shown on the profit stream contribution map.

5.3 COLLECTING COST DATA

The cost data needed to analyse and manage a process is typically generated by the process as it produces its product. The cost of materials, labour, utilities, overheads and services are found on invoices or payslips. What is not normally available are the process costs accurately allocated to the process steps that incurred them. To manage a process step's efficiency it is necessary to cost every one of its inputs, products and wastes accurately.

An approach used to identify the money flows in a process step is to take the process step procedure and work through it. As it is read the process step raw materials, the added inputs, the wastes and the produced product are identified.

As shown in Figure 3, a boundary is drawn around the process step to clarify its associated 'flows'. Many of the inputs, wastes and products are shown on the process design drawings, or found in engineering documents, equipment manuals and in standard operating procedures. The data is confirmed by also personally observing the process step for a full cycle of production.

When onsite identify all electrical power supplies to the equipment, all pipes suppling services, all process products into the step, all added inputs into the step, all outputs and wastes from the step. This includes measuring the manpower, management, supervisory and maintenance efforts, times and costs incurred by the process step. It includes measuring forklift movements, vehicle movements, personnel movements, etc. that occur in the time period observed. It includes counting the number of lights and time they are on, how often equipment is hosed down and the amount of water used. All activities are collated and costed in a spreadsheet.

It will be necessary to go as far as identifying minor costs, like rags used for cleaning equipment and the cleaning detergents used. Another example would be to identify the use of personal safety equipment and company brought clothing each operator requires during the time period. Over a year these minor expenses can grow into serious costs that are easily wasted.

Find every dollar that goes into a process step and that comes out of it. Put on the mantle of the television movie crime investigator and look for all the clues to the puzzle. Unearth the truth, the whole and total truth of where money goes in each process step.

When studying a process step that involves movement of product and/or people, for example storing materials in a warehouse, time the length of the move, measure the distance moved and identify the equipment used in the work. Put a cost to the movement of product and materials so that it can be tested to see if it delivers real value for the expenditure.

All the process costs can be found in the business systems such as payroll, inventory and accounting. Unfortunately they most likely will be totalised costs. The labour will be for a person's total time at work and what is needed is what they spent in the process step. The power bill will likely be for the whole of a building, whereas the cost of lights and power for a machine in that building is required. The purchase of safety gloves will be in batches of dozens at a time but it is necessary to know how many are used by the people working in the process step.

The most accurate approach is to get the real usage of inputs and wastes. For example, the power used by the lights and machinery in the process steps need to be collected for the time period concerned. If that is not possible it becomes necessary to proportion the machine's share of the building's power based on the electric wattage stated by the manufacturers of the equipment used in the process step. By proportioning inaccuracies will be introduced that may eventually cause people to question the final conclusions.

If necessary introduce special means to capture cost information. Time sheets and record-of-use sheets can be developed, chart recorders can be connected to electrical equipment and meters can be installed to measure flows in pipes. When accurate cost control is important to the success of a business spare no effort to discover the total true costs of production.

5.4 LABOUR

- ***Direct Labour*** comes from the time sheets of the people employed directly in the process step being analysed. If the people are used in another process step then only cost time expended in the process step being investigated. The direct labour cost is the pay rate paid to the people working in the process step, multiplied by the time they spend in the process step during the selected time period costs are being collected for. Include all their on-costs such as allowances, superannuation, benefits, etc, proportioned to the period. Do not include allowance for overheads, as they will be separately identified.

- ***Indirect labour*** costs are the time spent by persons, other than the directly involved people, whose services are needed to ensure the process step is completed. It is necessary to measure and allocate times for indirect labour. This includes such costs as maintenance, supervision, middle and senior management time, inventory and storage personnel, purchasing department personnel, quality control personnel, etc. Identify these costs by interviewing relevant people to determine the time they spend in the process step. During a site inspection watch the process for a full production cycle and observe who interacts with the process step.

The indirect labour cost is the pay rate paid to the indirect people, multiplied by the time they spend in the process step during the selected time period. Include all their on-costs such as allowances, superannuation, benefits, etc, proportioned to the period.

If a short time period is analysed, say a week, and not all indirect labour is captured, it is still necessary to allocate a proportion of all the indirect labour costs to the time period. In this case take a longer time period, say a month or quarter year, and collect all the costs for the longer period then proportion and allocate them in weekly quantities.

- ***Indirect expenses*** are those costs incurred due to the presence of the people in the operation. An example is a manager's car and fuel which is paid out of operating revenue. Allocate them in proportion to the hours spent in the process step by the expense owner.

5.5 SUBCONTRACTORS

Subcontract labour costs and materials used in the process step need to be recognised and allocated in the same way as employed direct labour. There will be an invoice for the subcontractor's time and materials and the allocation of times and materials for the work done in the process step can be extracted from it.

5.6 UTILITY SERVICES

Electricity, water and such services will need to be measured and allocated to the process step usage during the time period.

5.7 MANAGEMENT, ENGINEERING, ADMINISTRATION AND SUPERVISORY COSTS

These costs cover the time managers, engineers, supervisors and administrative support staff spend doing work related to requirements of the process step. For example daily meetings, site inspections, human resources requirements, problem solving process issues, invoicing matching purchases, maintenance planning, etc. All support persons who interact with the process step need their times and costs recorded against the step.

Initially interviews can be held with people to ask them to estimate the time they spend on the process step. If necessary have them keep time sheets to record the actual times spent involved with the process during the time period.

5.8 ADDED INPUT MATERIALS

Direct material costs are for added input materials actually used in the process step. They are the obvious additions of substances into the process step. This includes such things as electricity for motors, boxes for packaging, lubricant for equipment gearboxes, air for pneumatic rams, etc. Typically these materials can be identified as entering the process step in a physical form. The parts of them wasted can be measured and given a value.

These costs depend on the quantity and value of each input material used during the time period. It requires counting the amount of the material used and multiplying by the cost of the added material. Material costs can usually be identified from invoices for the material. Sometimes the added material has been made by the organisation and no invoices are available. In such cases it will be necessary to get an accurate cost for it from the organisation. If none is available it will need to be calculated from the cost of the labour, ingredients, handling and manufacturing charges used to make it.

Indirect material costs are the costs associated with the indirect functions required to perform the process step. Such as paper for recordkeeping, electricity for lighting, a maintenance planner's computer, the cost of forklift hire to move pallets, the building storage space for spare equipment parts, etc. All these costs are real costs incurred to conduct business that supports the production processes and need to be identified.

It is necessary to measure them and quantify them so that they can be given a value. Measurement can be by stopwatch, distance, counters, etc. Their use in a process step needs to be identified and quantified to reflect how much is used in the process step conversion and how much is wasted.

5.9 PRODUCT COSTS

The cost of a product entering a process step is needed. An accurate value may be available from the accounting, or production department. If it is not available accurately it will need to be calculated for each prior process step commencing with the start of production.

5.10 IDENTIFYING AND COSTING WASTES

Direct waste is any unused direct labour or direct materials added into the process which are not fully used in making a product. Even if the added input is gradually converted through a number of process steps, as long as it is fully used it is not waste. Unconverted added input is waste.

For example, in some chemical processes the chemical reaction absorbs only a portion of the mixed ingredients. Those ingredients that are not converted by the reaction are wasted. A laboratory can analyse for the unconverted ingredients and tell how much was unused.

Another example is water used to clean equipment. If the water is not fully used in the process to make product but disappears out of the process, then it is wasted. Leakage out of the process is waste. Spillage from a process is waste. Another example of waste is side-steam materials collected in bags or bins to be disposed of outside of the process.

Indirect wastes are those wastes that relate to the unnecessary use of indirect labour and indirect materials. They are more difficult to identify because they are not easily observable. Examples include wastes related to lost time in meetings, to lost energy, to lost compressed air, to safety equipment thrown away before being fully used, to storing unneeded materials in a storeroom. There are numerous instances of such wastes.

The detection of indirect wastes is through observation. That is why it is necessary to be present during a full cycle of a production process and observe all process steps and their inputs to identify wasted costs, materials and product. Look in the rubbish bins used in the process step area of the business and see what is thrown away. Are lights and air conditioning left on overnight unnecessarily? If required develop and instigate systematic means to spot and record the waste and its value during the period investigated.

5.11 COMPARISON WITH STANDARD COSTS

Every organisation should have a standard costing system for its products. If there are standard costs available compare them with the costs from the profit contribution mapping analysis. Using existing standard costs double-checks the analysis and concerns can be raised when costs are far from the standard costs previously allocated.

5.12 USE OF COMPUTERISATION AND TECHNOLOGY TO CAPTURE COSTS

The work involved in identifying and costing component inputs, products and wastes for each process step can be large. If a company choses, it can use modern technology and computerisation to capture many of the costs automatically. Labour can be identified electronically by using electronic cards and time clocks. Materials can be identified electronically via electronic tagging or bar coding.

Wastes are difficult to identify electronically. It may be necessary to change work procedures and include the recording of waste. Introducing counting and measuring of wastes will allow people to identify the causes and address them before they get even worse.

Through the use of Global Positioning Systems equipment, materials and people movements can be tracked and any time losses identified and addressed.

5.13 MANAGING WITH PROFIT CONTRIBUTION MAPPING

Once all the flows into and out of a process and its steps are identified and costed the profit contribution map can be created.

6 THE PROFIT CONTRIBUTION STREAM MAP

A simplified partial sample of a Profit Contribution Stream Map is shown in Figure 6 for a section of canning line. All the costs are shown cascading to and from the process steps. The time between updating the map depends on the urgency of the situation. If it is necessary to make changes quickly, then more updates are needed than if the situation is stable.

At least every month the profit contribution map ought to be updated. If the mapping process can be done electronically it would be useful to do an update weekly, as this frequency allows better control of the operation. In some cases it might be necessary to map a particular process step more often than the entire process because of the importance that step has in the operation.

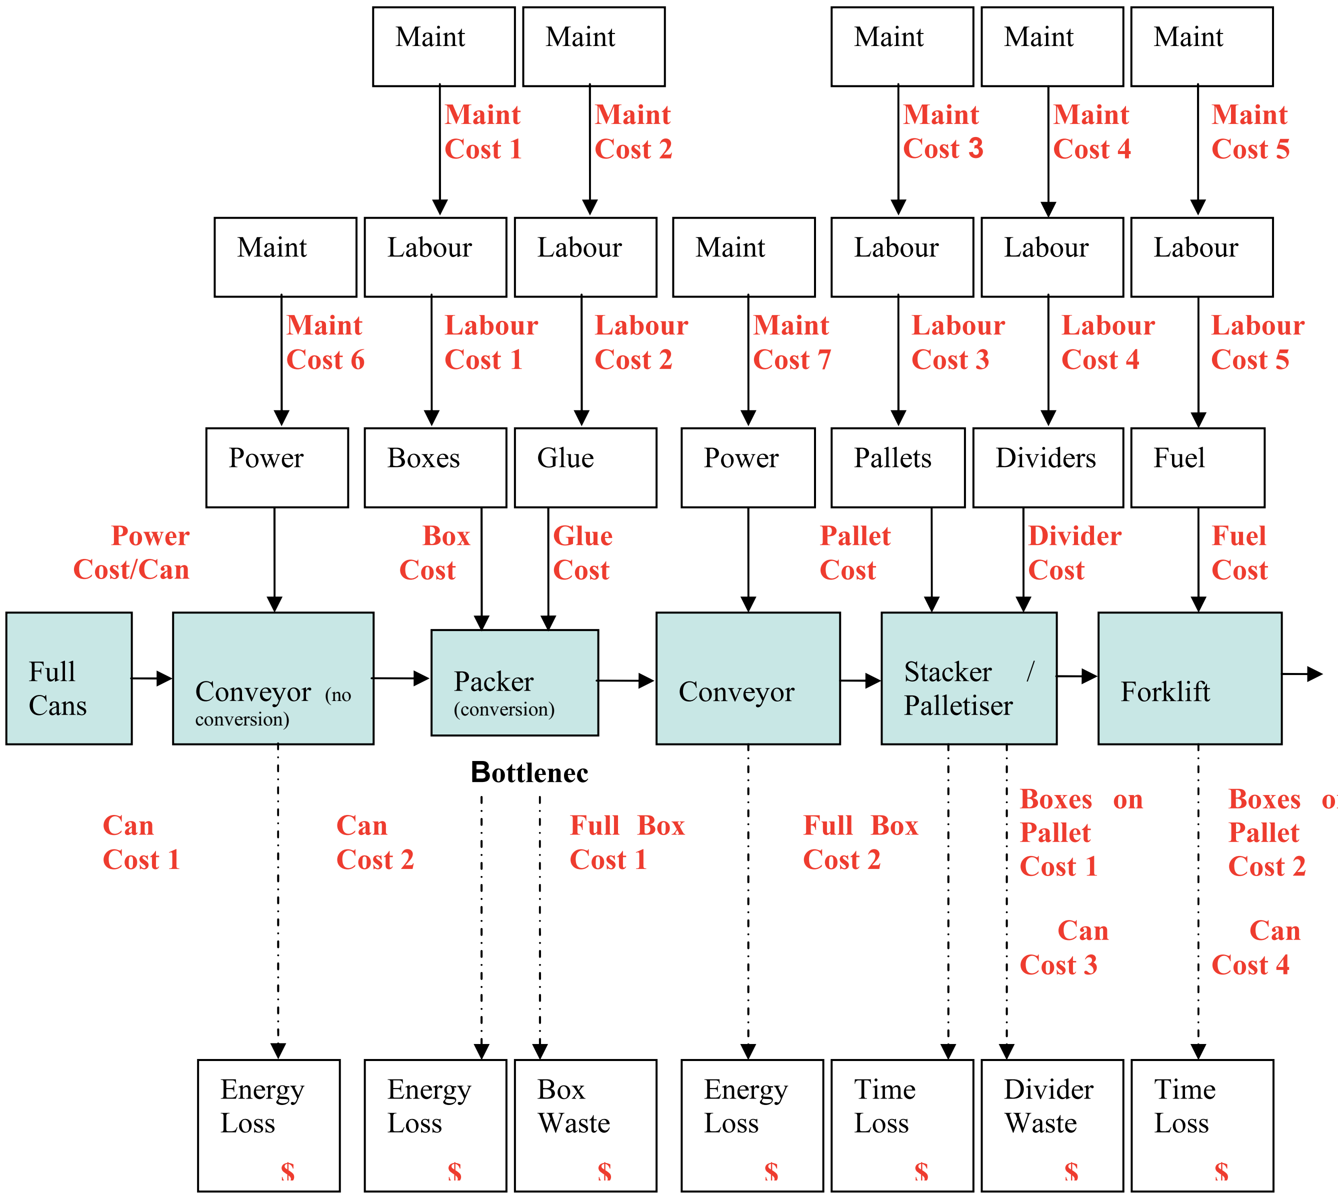

Figure 6. Profit Contribution Map for a Canning Line

6.1 PERFORMANCE MEASURES AND REPORTING

The problems that are highlighted by the profit contribution analysis can be addressed by the business management and personnel with new strategies applied to maximise the profit contribution. After a process step is analysed in detail it is easy to understand and appreciate how its many factors interact and impact each other. The accurate costing of inputs, wastes and conversions will identify problems. Through detailed questioning the reasons can be uncovered and the required changes made.

If change is required it is necessary determine what that change will be. The issues will need to be discussed with everyone concerned to fully appreciate and understand the situation’s history and reasons for occurring. The new changes will also need discussion, review and analysis for possible unwanted consequences. Finally a decision will be taken and changes will be made. When the changes are introduced they too will need to be measured, monitored and reported.

6.2 PERFORMANCE MEASURES

Selecting the right measures to monitor and report will be critical to the success of the change process and to the speed of its implementation. The measures need to be meaningful to the users, truly reflect the situation, are within their control to improve and inspire continued improvement.

One of the change strategies will be to introduce performance measures that identify poor efficiencies and the practices that cause them. Performance measures based on the issues identified by the analysis will drive the right behaviours and actions from people. The measures can be graphed and trended to show performance improvement.

Some typical measures to use are listed below. Measures can be developed that are suited to specific circumstances. The purpose of measuring is to know exactly what is happening. Once the current situation is clearly understood an assessment can be made as to whether it is satisfactory or it needs to be changed. If a change is made the effects will be seen in the performance measures. It may take several months for the effect of a change to be observed. Where the measures indicate an unsatisfactory result, a correction is necessary to get on-track.

- ***Usage Efficiency:*** This is the classic output divided by input. Select the process flows that are important and develop an appropriate efficiency measure for each and trend them over time.
- ***Productivity:*** These are measures of process performance. They are time based ratios of output during the time period. From the profit contribution map select the productivities which are important to measure. Productivity can be measured at the process step level and at the global process level.
- ***Throughput:*** This measure is a count of what passes a selected point in the production process during a period of time.
- ***Waste Cost:*** This measure counts the cost of waste in dollars per dollar spent to purchase the original material.
- ***Quality:*** This is the proportion of production that meets customer specification. It is another measure of a wasteful process.

To get a complete understanding of what happens in a process requires more than one measure. Business processes involve many interactions that affect each other and it requires a number of ratios to identify what is occurring in a process. Do not use any more measures than necessary. Maintaining measures requires time and money, which are then not available for use elsewhere. Experiment with the right measures to apply before deciding which ones to keep and use.

6.3 PROFIT PERFORMANCE REPORTS

Keep reports simple by using headings to categorise the report and visual means for displaying information. Show trends graphically in a suitable form to make their message clear to users. Use balloon notations in the graphs to highlight issues that need attention. Apply colour and font variations to enliven the report.

When a table is required to list details show summary entries and totals for each category. Keep the details for when people ask. Draw people's attention to the conclusions and their implications by providing an executive summary at the top of the report.

7 CONCLUSION

Engineering asset management is as much about the wise use of money as it is about the wise use of operational management, engineering and maintenance to deliver top performance from production equipment and processes. By fully understanding the costs and money flows in a production operation, its managers and employees can make good decisions that are effective and efficient for the well-being of the business, the shareholders, themselves and their community.

8 APPENDIX

8.1 THE MANY COMPONENTS OF PRODUCTION COSTS

- Labour : both direct and indirect
  - operators
  - repairers
  - supervisory
  - management
  - engineering
  - Overtime / penalty rates
- Product waste
  - scrap
  - replacement production
  - clean-up
  - reprocessing
  - lost production
  - lost spot sales
  - off-site storage
- Services
  - emergency hire
  - sub-contractors
  - travelling
  - consultants
  - utility repairs
  - temporary accommodation
- Materials
  - replacement parts
  - fabricated parts
    - materials
    - welding consumables
    - workshop hire
  - shipping, loading, transport
  - storage
    - space
    - handling
  - disposal
  - design changes
  - inventory replenishment
  - quality control
- Equipment
  - energy waste
  - start-up
  - shutdown
  - handover/hand back
  - decommissioning/commissioning
  - inefficiencies
  - emergency hire
  - damaged items
  - moving in, out, about
- Additional capital
  - replacement equipment
  - new insurance spares
  - buildings and storage
- Consequential
  - penalty payments
  - lost future sales
  - legal fees
  - loss of future contracts
  - environmental clean-up
  - death and injury
- Administration
  - documents
  - purchase orders
  - meetings
  - planning and schedule changes
  - investigations and audits
  - invoicing and matching
  - utilities

ASSURING QUALITY IN MAINTENANCE

Alexander (Sandy) Dunn

Director, Assetivity Pty Ltd, PO Box 219, Como Western Australia 6952, Australia.

Abstract: For the purposes of this paper, we will define Maintenance "quality" as the extent to which maintenance actions lead to intended (desirable) outcomes. It is a central proposition of this paper, that maintenance quality is not currently being effectively or proactively managed. The latest research indicates that maintenance actions may be leading to desirable outcomes as little as 50% of the time. Yet most organisations have done little to actively measure, manage, or improve the quality of their maintenance activities. This paper will outline some practical actions that organisations can take to improve the quality of their maintenance activities. These include suggestions in the areas of:

- **Dealing with Human Error in Maintenance,**
- **Maintenance Task Design, and**
- **Maintenance Work Instructions and Documentation**

Key Words: Maintenance, Quality, Human Error, Task Design, Work Instructions, Quality Assurance

1 INTRODUCTION

Maintenance Quality Assurance can be considered in two ways. The first is at a higher, management level, which focuses on establishing the management processes, systems and performance measures that ensure that the maintenance function best meets the needs of the organisation. The second deals with Maintenance Quality at a task level – what actions must be taken to ensure that specific maintenance, repair and overhaul activities are performed to the required quality standard? This paper focuses on this second aspect of Maintenance Quality.

The assurance of Maintenance Quality is not a topic that, for the most part, has attracted much attention. Traditional approaches to Quality Assurance have revolved around either document control – particularly of maintenance procedures, and the timing and nature of predictive and preventive maintenance programs. These approaches have typically focused on ensuring that rules and procedures are followed – but, for the most part, with some notable exceptions, little effort has been put into ensuring that the maintenance procedures themselves support the delivery of high quality, consistent outcomes. In particular, maintenance task design, and the documentation of those tasks, rarely take into account the likelihood of human error, and even more rarely, design and document these tasks in such a way that human error is minimised.

2 WHY SHOULD WE BE CONCERNED ABOUT MAINTENANCE QUALITY ASSURANCE

There is an increasing body of evidence that suggests that poor quality maintenance should be a significant concern of all Maintenance Managers.

As far back as 1968, Nowlan and Heap [1], in their ground-breaking work that led to the establishment of the technique that we now know as Reliability Centred Maintenance, identified, when analysing the failures of hundreds of mechanical, structural and electrical aircraft components, that these failures occurred with 6 distinct patterns, as illustrated below.

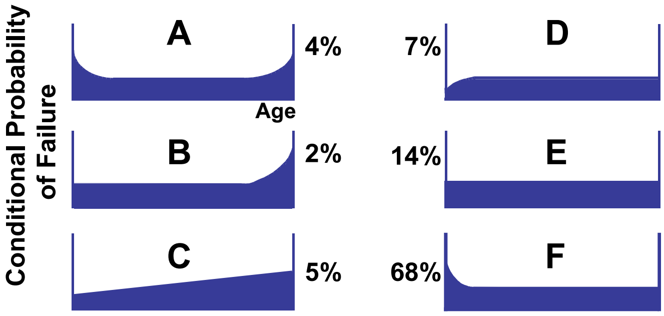

Figure 1 : Nowlan and Heap's Six Failure Patterns

The interesting finding, in the context of this paper, is that more than two-thirds of all components demonstrated early-life failure. It has been estimated that maintenance errors ranked second to only controlled flight into terrain accidents in causing onboard aircraft fatalities between 1982 and 1991 (despite the application of RCM techniques in the airline industry during this period) [2].

Subsequent studies have largely validated Nowlan and Heap's statistics. This includes work performed by Broberg in 1973, MSP in 1982 and SUBMEPP in 2001 as shown in Table 1 below

Table 1

Reliability Characteristic Studies

	Nowlan & Heap (1968)	Broberg (1973)	MSP (1982)	SUBMEPP (2001)
A 	4%	3%	3%	2%
B 	2%	1%	17%	10%
C 	5%	4%	3%	17%
D 	7%	11%	6%	9%
E 	14%	15%	42%	56%
F 	68%	66%	29%	6%

Reprinted from: Allen Timothy M., U.S. Navy Analysis of Submarine Maintenance Data and the Development of Age and Reliability Profiles, Department of the Navy - SUBMEPP, 2001, p.10

The Nowlan and Heap and Broberg studies were both conducted on aircraft, while the MSP and SUBMEPP studies were conducted on US Navy vessels. It should be noted in this table above that the low level of Failure Pattern F failures in the MSP and SUBMEPP data is explained by the fact that navy vessels go through extensive testing before they are returned to service following significant routine maintenance – any failures that are experienced during this testing period were not captured in the failure database used by the MSP and SUBMEPP projects [3].

A study of coal-fired power stations indicated that 56% of forced outages occur less than a week after a planned or maintenance shutdown [4].

Professor James Reason [5] has compiled a table summarising the results of three surveys – two performed by the Institute of Nuclear Power Operations (INPO) in the USA, and one by the Central Research Institute for the Electrical Power Industry (CRIEPI) in Japan. In all three of these studies, more than half of all identified performance problems were associated with maintenance, calibration and testing activities. In comparison, on average only 16% of problems occurred while these power stations were operating under normal conditions.

Reason also quoted the results of a Boeing Study [6] which indicated that the top seven causes of in-flight engine shutdowns (IFSDs) in Boeing aircraft were as follows:

- Incomplete installation (33%)
- Damaged on installation (14.5%)
- Improper installation (11%)
- Equipment not installed or missing (11%)
- Foreign Object Damage (6.5%)
- Improper fault isolation, inspection, test (6%)
- Equipment not activated or deactivated (4%)

We can see from this, that only one of these causes was unrelated to maintenance activities, and that maintenance activities contributed to at least 80% of all IFSDs.

A study conducted by Boeing and US ATA [7] found that maintenance error was a crucial factor in aircraft accidents from 1982 to 1991, contributing to 15 % of the commercial hull loss accidents where five or more people were killed. Rankin and Allen [8] established the economic costs of these maintenance errors, estimating that 20 to 30 % of in-flight shutdowns are due to maintenance error, 50 % of flight delays are due to engine problems caused by maintenance errors, and 50 % of flight cancellations are due to engine problems caused by maintenance errors.

If poor quality maintenance causes so many incidents in highly regulated and hazardous industries such as Nuclear Power Generation and Civil Aviation, what proportion of failures may be being caused by Maintenance within organisations that operate in less regulated environments?

What are the outcomes of maintenance-induced failures? Clearly, depending on the industry in which you operate, there are potentially significant safety and environmental risks. There is a long list of catastrophic failures in which, the inadequate performance of a maintenance task played a significant role. Some of these include:

- Flixborough
- Three Mile Island
- Piper Alpha
- American Airlines Flight 191
- Bhopal
- Japan Airlines Flight 123
- Clapham Junction
- Etc. etc.

But besides the obvious safety risks, perhaps the bigger consequences are economic. General Electric has estimated that each in-flight engine shutdown costs airlines in the region of US$500,000. Replicate that figure across other industries, and the cost of poor maintenance quality could be staggering?

Clearly, we need to do something to reduce the number of equipment failures that are being caused, not prevented, by maintenance. Yet this area has received very little serious attention by most organisations.

3 DEALING WITH HUMAN ERROR IN MAINTENANCE

Reason [9] argues strongly that human error is inevitable. It is an unavoidable consequence of our psychological and physiological make-up. He argues further, and convincingly, that error is not limited to a few "high risk" individuals, but is universally spread throughout the population – that sometimes the worst mistakes can be made by senior people carrying the greatest responsibility. If we accept this proposition, then since it is difficult to eliminate errors completely, continuing emphasis must be placed on developing interventions to either reduce the likelihood of human error in maintenance, or to make maintenance procedures more error-tolerant.

Reason and Hobbs [10] identified several risk areas where maintenance error is most likely to occur. We can summarise these risk areas by categorising them according to whether they relate to individuals, tasks, workplace supervision and organisation, or the enterprise.

- INDIVIDUALS
  - Reliance on Memory – the greater that an individual tends to rely on memory – particularly for more complex tasks – the greater the risk that the task will not be performed correctly
  - Pressures – for more complex tasks, the greater the time pressures placed on the individual (either direct or implied) the greater the risk of an error being made
  - Tiredness – the more fatigued the individual, the greater the risk of an error being made. This fatigue is often a direct result of shift rosters and patterns, as well as circadian cycles when working shift work.
  - Competence at Performing Tasks – the less competent, or familiar, an individual is with a particular task, then the greater the risk of error
  - Deliberate Violations Based on Individual's Risk Assessment – some individuals are more likely to demonstrate high-risk behaviours by not conforming with specified rules and procedures

- TASKS
    - Ambiguity of Task – if the task to be performed is not clearly specified, and the procedure to be followed in performing the task is not clearly understood, then there is a higher risk of error
    - Frequent, Repetitive, Routine Tasks – tasks that are performed frequently by the same individual, and which require low levels of attention in order to perform those tasks represent a higher risk of error
    - Design Issues Affecting Maintainability – if equipment is not designed ergonomically to permit adequate access and lighting to perform maintenance tasks, or increases the level of fatigue when performing maintenance tasks, then there is greater risk of an error being made.
    - Fatigue – if the task to be performed is strenuous, or requires considerable physical or mental effort, then there is a higher risk of individual fatigue, and resulting error.
    - Past Errors – if a particular task or task step has been performed incorrectly in the past, this is an indication that this particular task is likely to be more prone to future error.
    - Installation Tasks – the risks associated with error are greater for installation or assembly tasks than they are for removal or disassembly tasks.
    - Complexity of installation/assembly – if the task is more complex
    - Functionally Isolated Tasks – steps in a procedure which are not obviously cued by preceding actions are more likely to be subject to error.
    - Recent Changes – tasks or procedures which have recently been changed – particularly those which have been performed many times previously using an old procedure or method, are more likely to be subject to error.
    - Differences with Similar Tasks – tasks which are very similar to other tasks, but have few, but important differences, are more likely to be subject to error
    - Hidden Errors – if a task or step in a procedure was omitted, or performed incorrectly, and this error is subsequently hidden from view, then this represents a greater risk
    - Visibility/availability of cues – if the task required cues, parts or tools that are not readily at hand and visible, then there is a greater risk of error
    - Close to Completion – if the task is performed close to the end of a larger activity, then there is a greater level of risk. This is particularly the case if the task is to occur after completion of the main objective, but before the entire activity is complete.
    - Multiple Personnel Involved in Completing the Task – if the task is to be performed by more than one person – and particularly if task completion requires handover to another person – then the risk of error is greatest.
    - Require Removal of Tools or Other Items – if, on completion of the task, tools, parts, or other items are required to be removed from the equipment or the immediate location of the task in order to permit safe and reliable operation of the equipment, then the risk of error is greater
    - Optional Steps – if the task includes optional steps that are sometimes required, and at other times not required, then the risk of error is greater.
- WORKPLACE, SUPERVISION AND ORGANISATION
    - Availability of Supervision – if supervisors and team leaders are not available to perform regular, on-the-job assessments of work quality, and compliance with procedures, there is a greater risk of an error
    - Quality of Monitoring and Supervision – if supervisors do not adequately accept responsibility for work quality, do not perform regular, on-the-job assessments of work quality, and do not monitor compliance with procedures, there is a greater risk of an error
    - Reliance on Remembering Complex Instructions – if, when individuals are allocated work, they are expected to remember complex instructions, then the risk of error is greater.
    - Interruptions – the more interruptions that an individual is subjected to when performing a task, the more likely that an error will occur – usually an error of omission.
    - Breakdowns in Coordination – tasks that require coordination between individuals and groups – particularly those tasks which are started by one individual, and continued by another, as is frequently the case with tasks that take more than one shift to complete – represent a higher risk of error
    - Excessive Authoritarian Leadership Style – leadership styles which do not recognise the inevitability of human error, and which respond to such errors with punishment, rather than seeking understanding, and

searching for practical solutions to avoid recurrence are more likely to lead to errors being hidden – the net results being failure to reduce the number of errors occurring

  - Non-compliances based on Group Norms - some work teams and groups are more likely to demonstrate high-risk behaviours by not conforming with specified procedures, as a result of peer group norms that have been established
  - Fatigue – the more fatigued the individual, the greater the risk of an error being made. This fatigue can be related to the nature of the work that has been assigned to individuals, and the length of the shift worked – particularly if overtime is involved.
  - Poor Housekeeping – untidy and cluttered workspaces in the area where tasks are being performed are more likely to lead to parts or tools being misplaced, or the incorrect part or tool being used.
  - Inadequate Spares – if spare parts are not readily available for important maintenance tasks, then there is a risk that alternative, less reliable parts will be used, or that parts that should be repaired or replaced will be reused. This represents an increased risk of failure.
  - Inadequate Tools and Equipment – if the correct tools and equipment required in order to perform a task properly are not available, then there is an increased risk that alternative tools or methods will be used, with consequent increase in the risk of an error.
  - Shift handovers – inadequate communication at shift handover, where a task is to be continued on a following shift, represent significant risk. If the status of the current task is not adequately communicated, then there is a risk of a critical step or action being omitted.

- ENTERPRISE-WIDE
  - Non-compliances based on Perceived Cultural Norms – some organisations and departments are more likely to deviate from approved procedures, as a result of explicit or implicit sanctioning of such behaviours.
  - Failures to Detect or Respond to Non-Compliances – if there are inadequate formal, independent quality assurance processes in place, there is greater risk of an error
  - Shift Rosters – the more fatigued the individual, the greater the risk of an error being made. This fatigue is often a direct result of shift rosters and patterns, as well as circadian cycles when working shift work.
  - Organisational Structure Fails to Support Elimination of Errors – if accountability for monitoring, and improving, work quality is not clear, or is not adequately resourced, then there is increased risk of errors
  - Ineffective People Management – if individuals are not explicitly made aware of their role in ensuring adequate work quality, then the risk of error is increased
  - Ineffective Training and Selection Process – if competencies are not adequately assessed, and improved, the risk of errors is increased
  - Commercial Pressures – organisations where commercial pressures for short term financial performance are extreme are more likely to be subject to errors
  - Operational Pressures – organisations where pressures to achieve short term operational output targets are extreme are more likely to be subject to errors
  - Inadequate Planning and Scheduling Processes – organisations where operational and maintenance planning and scheduling processes are not sufficiently well established, or do not plan or schedule work with adequate detail, are more likely to be subject to errors
  - Inadequate Maintenance and Warehouse Infrastructure – organisations where maintenance workshop facilities and warehouse facilities are inadequate, or inadequately maintained, are more likely to be subject to errors.
  - Inadequate Error-Detection and Error-Containment Programs – organisations which do not have independent quality assurance processes in place to detect, and correct or contain the effects of errors are at higher risk.

So how can we deal with this multitude of risks that can contribute to maintenance error, and a loss of task quality? Reason and Hobbs suggest several different types of interventions.

For dealing with the individual risks, Reason and Hobbs suggest that two key activities take place. The first of these is training individuals in error awareness. This is intended to make participants aware of the factors that are most likely to lead to them making errors, to recognise when these factors exist, and provide them with strategies and methods of dealing with these factors. The second activity is aimed at reducing the number of deliberate violations performed by individuals. This means dealing with the three factors that impact on the likelihood of individuals to deliberately break the rules – their individual attitudes to risk-taking behaviour, social controls that individuals take into account when deciding whether to break the rules, and the extent to which individuals feel that they can control and modify their own behaviour.

For task-related risks, there are several alternative proactive measures that can be taken. These include:

- Effective equipment design for maintainability
- Designing the task to minimise the situations in which errors are most likely
- Using effective Maintenance Work Instructions and documentation

We will discuss the last two of these in more detail in following sections of this paper.

For dealing with workplace, supervision and organisation risks, there are also several actions that can be taken, including:

- Minimising individual fatigue through effective work allocation
- Effective allocation of work to individuals to minimise repetition and boredom, as well as ensuring that competent people are allocated to work
- Structuring workplaces to minimise the likelihood of interruptions
- Developing strong processes for coordination within and between work teams – particularly shift handover processes
- Ensuring that work is well planned and scheduled, that adequate time has been allocated for completion of the activity, and that all required parts, tools and other equipment are readily available
- Ensuring a tidy workplace, and encouraging tradespeople to maintain organised and tidy work environments while they are performing tasks, as well as after they have completed the task.

At an organisational level, Reason and Hobbs recommend the implementation of both reactive and proactive measures for dealing with errors.

Reactive measures could include formal Root Cause Analysis of appropriate incidents after they have occurred. This Root Cause Analysis process, to be effective should fully investigate all of the contributing causes to the failure, whether these be physical causes, human causes, or organisational causes. The most effective solutions to preventing these failures from happening again, will be those that deal effectively with the organisational causes of failures.

Proactive measures could include formal risk assessments, investigations of "near misses", and the proactive identifications of gaps in the organisational defences that reduce the risks associated with maintenance errors. Possible areas that could be assessed in this risk assessment would include:

- The knowledge, skills and experience of maintenance personnel at all levels
- Employee morale
- The availability of tools, equipment and parts to perform maintenance tasks
- Workforce fatigue, stress and time pressures
- Shift rosters
- The adequacy of maintenance procedures and work instructions

Reason and Hobbs consider that effective organisational measures to minimise the risk of maintenance errors require the establishment of a "Just Culture", "Reporting Culture" and "Learning Culture" within the organisation. A "Just Culture" is one where there is a strong level of trust between all individuals and groups within the organisation. They see this as being the prerequisite to the establishment of a strong "Reporting Culture". A "Reporting Culture" is one where all errors and failures, no matter how seemingly insignificant, are reported. A "Learning Culture" is one where the lessons of the past are remembered, and solutions are effectively implemented in order to minimise the risk of future errors. Those who have researched so-called "High Reliability Organisations" (HROs) have noted that high levels of failure reporting are a significant feature of those organisations [11].

4 MAINTENANCE TASK DESIGN

In the area of task design, there are many things that can be done to ensure that the risks of unintended consequences are minimised. These could include:

- Ensuring that adequate "hold" points are put in place at critical points in maintenance tasks, beyond which point tradespeople should not proceed without having their work checked by an independent person, and the quality of the work performed to that point verified. This could particularly be the case where the work performed may not be visible if the tradesperson was to continue. Examples of this could include inspection of internal vessel, turbine or heat exchanger repairs after the work has been completed, but before the equipment is closed up and returned to service.

- Incorporating adequate reminders within job procedures which are more likely to make omissions more obvious. For example, if there are items which must be removed in order to conduct maintenance repairs, and which must be replaced before the equipment is returned to service, and replacement of these items has a high risk of being overlooked, then these items may be tagged with some form of highly visible flag in order to make their non-replacement more obvious.
- Ensuring that parts which are removed and which are to be replaced and not refitted are placed immediately in a different location to the new parts which are to replace them. Parts may even be marked or tagged to indicate that they are to be scrapped or refurbished.
- Encouraging tradespeople to place parts that have been removed, and which are to be refitted, in an ordered or structured arrangement – so that all parts to be refitted can easily be identified, and failure to refit a required part is more easily identified. For regularly performed jobs, a kit or shadow board may be used to temporarily store these parts while repairs are being performed.
- Another alternative, to ensure that parts that have been temporarily removed are refitted is to secure these items to the equipment by means of a tether. This prevents these parts from being moved to a location where they may be overlooked.
- Ensuring that items of machinery are adequately protected from contamination by the ingress of dust or other foreign objects into sensitive internal parts while these machines are being maintained. This could take the form of fitted covers over inlet points.
- Ensuring that work is performed in logical sequences of grouped actions. The risk of error is higher if the activities performed are not logically related.
- Attempting to minimise the number of tasks to be performed after completion of the main objective of the maintenance activity. Where possible, these tasks should be sequenced to occur prior to the main objective being achieved.
- Include, where practical, full functional testing of equipment prior to it being returned to service.

5 MAINTENANCE WORK INSTRUCTIONS AND DOCUMENTATION

The quality and content of Maintenance Work Instructions and Documentation is vital, as evidenced by the following findings from the civil aviation industry [12]:

- A 2004 UK Flight Safety Committee determined that the top three causes of maintenance mishaps were:
  - Failure to follow published technical documentation
  - Using an unauthorized procedure not referenced in the technical documentation
  - Supervisory personnel accepting non-use of technical documentation or failure to follow maintenance instructions.
- A 2001 FAA study found that documentation is the leading contributing factor to maintenance events. In most cases organizational issues resulted in failure to use documentation that was available.
- A 2002 study of procedural issues from NASA Aviation Safety Reporting System incident reports showed that the following factors contributed to documentation-related errors: procedural design flaws, user errors, currency and accessibility of documents, and organizational practices.
- Aviation maintenance personnel spend from 25-40% of their time searching for, using and completing maintenance documentation.

The Federal Aviation Administration includes the following advice regarding actions that should be taken to ensure that Maintenance Work Instructions and Documentation are of adequate quality to minimise the risk of poor documentation leading to maintenance error [12]:

- Develop guidelines and standards for documentation development. The guidelines/standards should include the following:
  - Use a standard format and page layout.
  - Use one action per statement.

- Write DANGER, WARNING and CAUTION statements using current international (American National Standards Institute/International Standards Organization) standards.
    - Avoid using acronyms and abbreviations.
    - Ensure that where an arrow is pointing to a figure or graphic it is immediately obvious.
    - Use (…) Simplified English.
    - Verify the documentation by having a second person check for technical accuracy.
    - Validate the documentation by having a sample of users check for usability.
- Provide a process for immediate and longer-term improvements to technical documents based on user feedback.
- Ensure prompt acknowledgement to submissions for document change.
- Respond to the document improvement suggestion in a timely manner.
- Develop measures to track specific documentation problems and corrective actions.
- Be sure the document delivery system is functional and well maintained.
- Use advice from documentation research and industry best practices.

Additional steps that should be taken to ensure that maintenance work instructions and documentation minimise the risk of error (based on information contained in [13] and [14]) include:

- Ensuring that illustrations are used where appropriate, as these can often convey instructions far more quickly than written text.
- Ensuring that any illustrations used are clear, and correct
- Ensuring that all steps required in order to perform the task have been included within the procedure
- Ensuring that work instructions and documentation are readily available to the person performing the task.
- Ensuring that all instructions required in order to perform the task are contained within the one document –references to other essential documents should be avoided wherever possible
- Ensuring that the work instruction is accurate for the specific make/model/serial number of the equipment being worked on. Frequently "generic" work instructions do not apply to specific equipment items – particularly if these have been modified.
- Ensuring that all the steps are in the correct sequence
- Ensuring that similar procedures in different references agree (for example, that the work instruction given on a job card agrees with that contained in the Manufacturer's Manual, or vice versa).
- Ensuring that the procedure can be followed, in practice
- Ensuring that there is proper version control over work instructions and job procedures
- Group complex work instructions into phases, with each phase consisting of many, related tasks
- Focus on the key risks that may prevent the job from being performed safely and to the required quality standard.
- Use call-out boxes and other methods to highlight key actions that must be taken, tolerances that must be met and other items that represent the highest risk of the task not being performed correctly
- Ensure that instructions are written in the first person, not the third, and use the active voice, not the passive.

6 CONCLUSION

This paper has attempted to illustrate that the issue of Maintenance Quality is one that is not currently receiving adequate attention within most organisations. It has also attempted to illustrate that improving Maintenance Quality has the potential to generate significant improvements in organisations' financial, safety and environmental performance. It went on to discuss some specific risk areas relating to maintenance error, and make suggestions of actions that could be taken in designing maintenance tasks, and documenting work instructions, in order to minimise the risk of maintenance error, and enhance Maintenance Quality.

ALIGNING OPERATIONS, MAINTENANCE AND ENGINEERING TO PROVIDE THE SEEDS OF SUSTAINABLE ASSET MANAGEMENT – A CASE STUDY

G Williamson

Assetivity Pty Ltd., Suite 12, Como Corporate Centre, 11 Preston Street, Como, Western Australia, 6152, Australia..

Abstract: Successfully delivering large capital projects imposes many challenges on both Project Management and the Operation and Maintenance teams. This paper discusses some of the key issues relating to the Projects/Operation's and Maintenance interface, as experienced by the author while leading a large, asset-intensive organisation during a period of enormous growth. The paper will share the learning experiences gained not only through the development of this organisation but also some of the technical issues which impact on plant and asset management performance during the early life of a major new asset. The paper provides an insight, from an Asset based Operation's Department perspective, of how to improve Engineering, Operation's, Maintenance and Project Management processes to realise not only cost and schedule advantages but also to improve post start up performance of the new equipment.

Key Words: Project management, operatons, maintenance

1 INTRODUCTION

Sustainable Asset Management is not just related to the physical asset and how we engineer, operate and maintain those assets. To be successful we must take a holistic approach by taking into account all the aspects which impact asset management including the 5 broad areas of (1) Operation's and Maintenance Strategy, (2) People, Skills and Culture, (3) Organisation Structure, (4) Management Processes and Practices, (5) Use of Technology. This paper will explore how all these factors were attempted to be addressed and the learning achieved for both the Operating and Project organisations. The case study is derived from the authors own experiences and reflects the Capital and Operating intensive environment of the period 1997 through to the end of 2005, within the LNG area of the Oil and Gas industry.

Throughout the paper the term Operation's or Operation's department's refers to the structure of the company in which the author worked, and is the collective term for the Production, Maintenance and Engineering Departments which formed the Operation's Group.

The Management of Assets are also not immune from the particular business environment any Asset Holder may find themselves in. What may be considered Good, Excellent or Acceptable Asset Management in one business area, may be totally different to the business requirements of another area. Also Life Cycle planning for given assets may differ across industries, with expected life spans being anything from a small number of years to much longer periods.

With many variables placed before those charged with the task of Asset Management, it is clear that we must start by defining as many of them as possible. Therefore this paper and its supporting presentation starts by explaining the Business environment of the case study, this is done to provide a basis for the reader to understand the subsequent sections, and also to assist in comparing their own circumstances, and perhaps provide some ideas, in pursuit of Sustainable Asset Management in their own unique business areas. In Life Cycle Terms the paper focuses on the development, start up, and initial operation phases and provides the reader with an insight of the Learning Experiences gained by Operations and Projects within this part of the Asset Life Cycle

2 CAPITAL PROJECT AND OPERATION'S EXCELLENCE ~ A CHALLENGE TO ALL

Within a short period of time, namely three years, the company had experienced the establishment of its production assets and people assets in a Greenfield environment and had witnessed the transition into a full production company. A further two years were to pass during which time the benefits of a company and its resources growing together, were already providing rewards in terms of better than expected availability figures. Nevertheless the competitive environment the company found itself in was requiring management to improve business performance. This resulted in the need to compare performance through industry benchmarking and to provide strategic targets to the organisation to enable new sales and development to take place. LNG markets through out the world during the period 2000 – 2005 were characterised by demand outstripping supply and therefore new production facilities were required. This challenged the technical design teams to provide even larger plant capacities at a stable or reducing Capital investment cost. To fund these projects and also to demonstrate sound production management, the Operating and Maintaining organisations were required to meet high levels of availability, to demonstrate reliability of supply to customers at the same time doing so at a reduced cost of operations. The author found himself in this environment initially as Maintenance Manager then transitioning through the role of Manufacturing Manager to a totally new function as Operations Expansion Manager. These positions developing as a result of the pursuit of lower or best in class operating costs, in an environment of enormous expansion and capital investment to satisfy the LNG industry and its customer's demands for secure and reliable supplies of environmentally friendly energy sources.

The challenge facing the author and the company only two years after initial operation was to achieve class leading production capability at lowest cost, while working in an expansion environment of some of the largest ever capital developments, in the Oil and Gas sector.

The establishment of the first two trains in the period 1996 ~ 2001 was fully supported by the Operation's department resources, during this time the site work progressed as the company established its Operating Organization and recruited and developed its staff and their competencies. In terms of Operations involvement the entire department was able to focus and support the Project as well as growing in learning as the work progressed towards commissioning and start up. It should be noted that following successful start ups, the first two Trains have achieved world class reliability.

During the 2001 to 2003 period as the Operation settled into the routine production plan, it became opportune to look externally at similar Operations and see what lessons could be learned and put in place to improve work processes with a target of minimizing Operating costs. At the same time however, new larger production facilities were being planned and contracts established for Engineering and Construction of these facilities, with the Project organisations being tasked with finding improvements in Capital costs and project schedules. A clear concern quickly developed in this scenario regarding the ability to provide the people and processes from the Operation's departments to support involvement in the new projects, and of course to ensure that sustainable Asset Management principles were upheld.

As a result of potentially conflicting business directions it was recognized that learning, and team work, would play a vital role in the successful start up of new facilities. By early 2004 with the announcements of even more increases in production capacities, Operation's involvement in projects became critical to ensure the company could meet the expectations of its customers. From an original capacity of 1.2 Billion SCFD the company would see growth to 3.6 Billion SCFD by 2005, with a current capital investment portfolio taking the company to over 10 Billion SCFD over the following five years.

We will now take the reader through some of the innovations the Operation's departments have made to the way they work and learn from experience in a dynamic capital intensive environment.

3 A STORY OF LEARNING IN THE OPERATION'S DEPARTMENTS

In reviewing the direction taken along the path of improvement in the initials years, it is important to refer to some first principles. The first stage therefore on this journey is to address the term "Learning".

In a busy environment of Engineering, Constructing and Commissioning a project, the demands faced by the project departments and the Operations departments can sometimes be seen as non related. This is of course not the case as the operability and maintainability input which the Operations Department can offer to the various stages of the project life cycle can indeed have benefits to both organisations. The first lesson we would offer, however, is that Learning will not just happen and be of future benefit, unless there is a structure put in place by which lessons can be captured, recorded, analyzed, and eventually used to improve current and future projects.

Several techniques can be used to ensure that good asset management lessons can be captured, and the traditional technique of post project workshops was the tool selected at the end of the 1990's by the Operations and Project departments to capture those lessons. These were held post start up and resulted in the creation of an extensive, and most importantly, agreed list of lessons to be applied in future projects. This practice continued through the period when the third train became a firm project. There were, as would be expected in any company wishing to promote continuous improvement, some enhancements to the learning process. First it must be noted that the list of lessons derived from the experience of the initial two trains, was reviewed, and where appropriate, applied to the new project. The structure of how the company approached the learning processes however changed significantly. Obviously lessons still had to be captured, therefore use was still made of the workshop structure, but now the workshops were tailored to specific areas, such as Construction Activities, Start Up activities, engineering activities etc. The most important change however was the establishment of an on line Continuous Improvement Data base.

The data base was structured as a repository for several key content areas. The first of these areas was Technical Queries where items can be captured at any phase of the project and by anyone involved in the project. The database provided an audit trail to ensure that resolutions were worked to eliminate any problems. The second area was warranty items which also appear pre and post start up, and may lead to improvements being made to future projects. This would occur once the claim is analysed and rectified with the potential root cause of the problem which resulted in the claim, being identified and understood. Of course not all items will lead to a new lesson for Operation's, as they may result from manufacturing defects or installation defects, but even in these areas learning observations can still prove beneficial to future work. The third and obvious key area was the creation of a central register of all the lessons learned which could be accessed by all, and will grow as more lessons are developed, becoming an invaluable source of data.

In establishing and using the data base a realized hidden benefit appeared in terms of the ability of the data to be interrogated, similar to a Root Cause Analysis tool. As an example, by looking at the various areas such as Technical issues and Warrantee issues we were able to identify a trend of QA/QC issues in the manufacturing processes of various suppliers, which required enhancement of quality control support to hopefully benefit future projects. A key feature of using a data base which is accessible to all relevant parties and can be searched by multiple criteria, was it not only captured Learning, but we were able to put it to far greater use.

To make the Continuous Data Base a sustainable tool it was required that each function nominate a gatekeeper of data for their own areas of business. Therefore specific functions within both the Project Organisation and the Operations organisation nominated such gatekeepers. The role of the gatekeeper was first to be the custodian of improvement data input to the database and along with other gatekeepers, being responsible for database improvement. With the second key function of being an advisor to their respective managers, as to how the database was being utilised by their function or department

4 INFLUENCES WHICH SHAPED OPERATION'S WORK

With large complex projects, ensuring that everyone involved understands the roles and responsibilities each have, can lead to some surprises and gaps even in the most well thought out projects.

During the Commissioning and Handover of the third train project to Operations for start up, it was found that there were several areas where each party thought the other was clear on who did what and when. This was the case with the completion of Hydrostatic testing of pipe work, where the EPC contract clearly indicated that Operations were responsible for re-instatement of pipe work. However, because of the lack of attention to detail and also the assumption that specifications would be the same as the previous plant, the issue was missed. Although at the time the resolution was worked and mutual support provided for the benefit of the project, it was clear that a gap had appeared. One of the learning points here was the need to treat every situation as unique and to ideally ensure that changes to practices and specifications within a contract document also go through the same Management of Change process that changes to the actual facilities do.

This resulted in the need for some analysis and focus on the complete picture related to Handover and Commissioning, and resulted in the introduction of clearer process flow charts of this stage of the project, and amended contracts where appropriate. This provided clarity in contractual boundaries as well as roles and responsibilities concerning Witnessing and Verification activities.

With the significant interaction between several projects at differing development stages and the use of synergies between them and the running revenue generating plant, to limit costs of the development. There emerged a significant requirement for Tie Ins of new equipment to existing running plant. These tie ins were not just restricted to mechanical equipment such as pipe work, but also involved Electrical and Control Systems tie ins including software programme changes. With the list of projects facing the company, and also the time span between the purchasing of the original plant and the new project, it was clear that this area was going to command a lot of attention. This manifested itself for example, where the latest version or model of equipment was to be used in a new project, but relied on some functionality of plant purchased up to 10 years previously, and then inevitably the older plant systems would have to be upgraded. The upgrading however had to be accommodated within the commercial business boundaries of the running equipment. To approach this work it was decided to establish a full time role for the coordination of all the activities associated with Tie Ins and the impact on the execution of the company's Management of Change processes. Resources were dedicated to this task and the work load continuously monitored to ensure that correct procedures were applied in this critical area. This was aimed at ensuring that construction schedules were met, and also most importantly, that there was no impact on the running of existing equipment, through the potential for tripping running plant.

Allied with the technical queries mentioned in the previous paragraph, during the final stages of train three works a Doubts and Concerns Forum was established. The purpose of this forum was to answer questions raised by Operations staff as they became involved in the start up phase. Simple examples involved the placing of valves into the pipe work the correct way round, and more complex problems such as the running performance of pumps and compressors after initial introduction of product.

Another area was evidenced from Trains 3 and 4 work, namely the correlation between schedules. Given the size of these projects and the various geographical locations of design offices and manufacturers, it became clear that schedule dates could vary significantly in these different locations. To improve the schedule data a single scheduling tool was introduced which provided the capability for each individual schedule owner to manage their own data, but when rolled up into higher level company schedule, any conflicts would be immediately flagged and resolution sought. This of course could only be achieved by all parties using the same IT platform, which was a significant task in accommodating all locations including several major and minor contractors and suppliers of equipment.

As with all projects it was anticipated that equipment may fail during start-up and initial running due to design or manufacturing defects. The project staff in such situations is an invaluable support resource to Operations during this time.

From experience the signing of the handover mechanical acceptance paperwork did not necessarily mean the end of projects involvement. Therefore the need for an element of continuing project engineering support was identified and put in place as a permanent feature for future start ups.

One of the most critical changes Operations made post Train 3 experience was that an Operations organization which is geared to best in class operating structures would not be able to adequately contribute to the various project phases. To counter this, an entirely new function was formed, namely the Operations Expansion Department. The purpose of this new department was to provide the Operation's support by coordinating engineering resources to the early stages of the project, and also provision of a start up team. The Start Up team had the role of handling the handover processes and initial operation, eventually in turn passing care and custody to the running Asset Teams.

5 ASSET BASED ORGANISATIONS AND SUPPORT TO ASSET DEVELOPMENT

As previously mentioned the most significant change to the way Operations approached project work was the creation of a dedicated department to handle the project interfaces and the sound application of Operability and Maintainability requirements into future projects

One of the most aggressive and challenging learning's initiated in 2004, was to:

- Set up an Operations Expansion Team to address, support, coordination and resolution of all pre-commissioning, commission and start up issues
- Also the Operations Expansion Team was tasked to effectively interface with Operating and Engineering Experts to ensure that the best solutions to problems were identified and assessed, with the solutions satisfying the Asset Management principles of sound engineering practices, construction, and integrity specifications.

In the first year, the Operations Expansion Team, at a very minimum, relieved the existing Operations Asset Teams from the combination of handling daily problems as well as all the expansion/growth issues. This had an immediate positive impact allowing the Operation Asset Team to focus primarily on "running" the existing facilities. Whereas previously, the Expansion work load had been managed within the existing Asset Teams, which obviously proved to be an added extra stress to managing and coordinating an already full operations work plan.

As all operations teams find out, simplifying the daily job tasks and focusing on the key operation jobs allows the Operations Manager to reduce manpower to what is absolutely required for economic unit cost management.

Through the use of clearly mapped Project and Handover processes, the Operations Expansion Department were able to focus on meeting the challenges in its involvement with Projects. Further as the department carried the responsibility to handover eventually to the Asset Teams, a clear focus could be given to such areas as adequate documentation in particular in the area of spare parts management and input to the company IT systems.

6 TEAMWORK – THE REALITIES

Large scale projects will only succeed as a result of good team work between the various parties, and some of the links which have been put into place as a result of experience to date are discussed below.

The Operations Expansion Department plays a key role in ensuring a successful and most importantly a seamless transition through the various project phases. This is not just restricted to the start-up phase but also to the transfer of information during the design and detailed engineering phases. Relationships with the main Operations group were achieved through the adoption of clearly linked Business Objectives, which were continuously stewarded. Attendance at the regular departmental meetings ensured that all were kept up to date on developments, ensuring that mutual support between the two Operation's functions could be negotiated. This also ensured that the correct level of technical expertise could be made available in support of activities such as Drawing reviews, Model reviews Reliability and Maintainability Studies, and Hazops.

In terms of the relationship with the project teams, the Expansion Department had its own staff placed in the various Engineering offices around the world, able to respond to project questions during design stages or to seek further Operations Support as appropriate. These roles were seen as highly beneficial to all. Again as with the parent Operations organization the attendance at project meetings laid the foundation for good communication links. A clear learning which was put into practice was the use of an "Offsite" meeting, held between the project and the Operations Expansion Department on a Bi-Monthly basis. This meeting addressed strategic issues and identified opportunities for improvements which were prioritized and given to owners to pursue and put in place.

The projects covered both the upstream as well as the downstream facilities in an environment of multiple projects all at different stages of the project life cycle. In this business environment schedules play a vital role, a common platform for schedule management and clear ownership of the various parts was needed.

Within the multiple projects and suppliers environment, it is not unreasonable to expect that some may not perform, and therefore that failures may happen. Through use of the continuous improvement database it became possible to identify trends and potential weak areas, this is turn allowed the formation of contingency plans to assist in pre-empting potential trouble areas. Typical proactive measures were enhanced testing, provision of spares or extra support manpower. The lesson was to be prepared and examine “what if” scenarios, perhaps based upon analysis of each projects learning points and technical queries, to establish contingency plans.

A frequent characteristic during the exciting phase of start up is that when equipment does mal function Operation’s staff jump in to fix the problem. A clear lesson here was to create discipline within the organisation to follow a logical process chain of, when something goes wrong Operations Identify then Engineering along with Operations analyse and rectify. Valuable time and more importantly failure history can be lost in the enthusiasm and excitement of start up. Problems do appear, so ask the process questions first rather than the technical questions.

Re-iterating the Learning Story, learning opportunities will be lost if they are not documented. With the Continuous Improvement Data base it was hoped to institutionalize the capture of learning opportunities.

7 CLOSING REMARKS

The life cycle of Asset Management starts in the design phases of a project and grows through the equipment selection, construction and commissioning of a new facility. Frequently these phases are characterised by the lack of involvement of those who will be charged with the health of the asset for many years to come, and this may be as a result of complacency or even a deliberate policy. In this paper we have attempted, through the telling of a story of learning, to show how one company approached the issue. Therefore by focusing on processes, systems and organisational issues, the chances of a successful Life Cycle of Asset Management were improved.

IMPROVING THE FINANCIAL BOTTOM LINE IN HEALTHCARE WITH CMMS

Duncan Newsome [a] and Kevin Farrington [b]

[a] *Principle Consultant Possumworks, Varna St Waverley NSW 2024 Australia, and Director Corporate Services, Calvary Health Care Sydney Rocky Point Rd Kogarah NSW 2217, Australia.*

[b] *Director, 3pi International, Capalabar, QLD 4157, Australia.*

Abstract: Private Healthcare has always had an eye on the financial bottom line, generally through close management of staff hours per patient day. These days with decreasing budgets and increased service demand, CEO's in the Public Healthcare System are faced with similar requirements of meeting budget targets. In the Aged Care sector with tight margins and aggressive competition meeting budget is critical to survival. This paper addresses an overlooked area by most healthcare providers, which assists in reducing both the current year outgoings and the long-term return. While you would be hard pressed to consider the maintenance department as a revenue centre, when viewed from another perspective with appropriate use of an efficient CMMS properly structured and supported the maintenance department can be considered to be an additional source of revenue by:

- **Early appropriate intervention (preventative maintenance) reducing the risk of early retirement of expensive and often complex machinery**
- **Detailed tracking of expenses related to locations, equipment and cost centres**
- **The ability to triage (sort) appropriate requests from inappropriate requests**
- **Accurate reporting on cost per sq meter**
- **Improved productivity from internal and contract maintenance staff**
- **The ability to monitor contractor KPI's and enforce contract compliance**
- **In this paper, we will address how healthcare market sectors can benefit from the maintenance professional by reducing the bottom line and increasing revenue benefit.**

Key Words: CMMS, Productivity, Savings, Healthcare

1 CURRENT ENVIRONMENT – HEALTHCARE MAINTENANCE

Private Healthcare has always had an eye on the financial bottom line, generally through close management of staff hours per patient day. These days with decreasing budgets and increased service demand, CEO's in the Public Healthcare System are faced with similar requirements of meeting budget targets. In the Aged Care sector with tight margins and aggressive competition meeting budget is critical to industry survival.

The current reality for maintenance within the Healthcare environment is a reduction in on site trade and supervisory staff to a level where only the most rudimentary repairs and maintenance is undertaken by employed trades staff, and the majority of Preventative Maintenance (PM) and repairs are outsourced. This is exemplified by the reduction over the past twenty years in employed maintenance trade qualified staff in most facilities. An average maintenance department for a medium sized facility of 100 bed capacity would a one time have had a maintenance department consisting of a maintenance supervisor and 3 – 5 trade qualified staff (plumbers, electricians, painters and chippies). Today these facilities usually have one trade qualified staff members who is responsible for the coordination of the PM and repairs program for the facility under the direction of the Director of Finance or another executive of the facility.

The maintenance budget is usually the last to be increased (if at all) to cover the normal increased cost provision of services to increasing complex buildings and assets. When a facility anticipates financial pressures to reduce cost, maintenance tends to be seen as an area in which cash flow can be instantly reduced to minimise anticipated budget deficits. This short term approach has little or no regard for the long term consequences resulting from the delayed or cancelled facility and asset maintenance which may occur if the budget situation continues for a number of years. This is of course at odds with the expectation that maintenance departments will maximise asset life, and the facilities will always look presentable to the customer (patients, relatives, etc). Typically failing infrastructure is always more expensive to fix at a latter point in the life cycle and if the delay is long enough the cost of repair or replacement will have increased exponentially.

As Dave Berger (2003) noted in his article on Asset Management – controlling the life cycle it is a "pay me now, or pay me more later situation". Effective use of a capital asset plan coupled with a good CMMS will ensure that money is saved and not wasted. It is within this environment that staff responsible for facility maintenance must deliver on the expectations of the owners or the executive. The key to harnessing the complete benefit to the organisation is by taking full advantage of the functionality available within the CMMS. The first step is to discuss facility maintenance with the facility directors in financial terms. It is imperative that, maintenance management is able to clearly articulate the benefits to the organisation, which will be derived from maintenance supported by an effective Computerised Maintenance Management System (CMMS). By addressing the following questions with management, the maintenance manger will have the framework to produce an effective and efficient delivery of PM and repair maintenance to the facility:

1. What is the goal of our CMMS implementation?
2. How will our CMMS assist us? And
3. What are our real expectations following implementation of the CMMS?

The revenue saved by maintenance by following a proactive maintenance framework, will improve the financial bottom line for that facility. Although, it needs to be noted that in change management terms, when implementing any program or project, there is a cost involved in terms of gaining commitment from the staff and the organisation or there is a cost from resistance to implement. Either way there is cost and effort involved if your project is to succeed.

2 PREVENTITIVE MAINTENANCE

While PM is a concept generally well understood in management and maintenance groups, the appropriate application and implementation of PM is not as well understood. Following installation of many key assets, such as lifts, HVAC and hydraulics, the new owners are presented with either: a comprehensive and expensive list of PM instructions from the installer who is also contracted to provide the PM & repair servicing to that asset item or an extremely sketchy list with some vague references to manufactures documentation. Unless the owners (either in management or maintenance) have the appropriate technical discipline to assess the presented PM schedule it is usually accepted as is. Significant external factors such as seasonal load variation are not often considered, and periodic PM occurs regardless of the asset workload. The cost implication in either case can be a significant impact on a facilities budget through either funding "overkill" PM program or early capex asset replacement due to failure of the item through under-maintaining. A classic example of this is High Volume Air Conditioning (HVAC) PM. Some of the external factors impacting on the asset which should be considered include: climatic conditions, particle contamination levels of intake air, building occupation rates; all of which vary throughout the year, thus rendering the standard PM routine of 3 monthly, 6 monthly and annual inspections / services as inappropriate to load. The important factor here is that generally the manufacture's recommended PM routine is based on the asset working at maximum capacity in the most testing conditions all year round.

It is crucial to know if the PM schedule is delivering the appropriate service for the asset to reach it's maximum life and producing any mandatory certifications required for the asset. Without an appropriately configured CMMS, it is a difficult task to achieve. If a facility is currently using a spreadsheet or hardcopy, which can be entered into a spreadsheet, all the facility data could be transferred into the CMMS with the set-up defining frequencies and standards for each frequency. At a predefined interval the CMMS will print out a work order with the predefined tasks, job steps and any Safe Working Practices (SWP) associated with the service. The CMMS should adjust the next date for service dependant on the date the last service was completed. The savings from having PM's automated using a CMMS result from a lesser clerical load on the maintenance staff, and by not having earlier than necessary servicing undertaken, and when the maintenance inventory is connected to the PM's, inventory costs are also lowered by sourcing any parts required on a Just In Time (JIT) basis. Following completion of the service and updating the records on the CMMS a service history is created enabling management reports to be run evaluating issues such as time to next failure, and whether to repair or replace based on facts.

3 EXPENSE TRACKING

In a typical facility when an expense-tracking audit is undertaken it becomes clear very quickly that not all cost centres are equal when it comes to spending the maintenance dollar. In this exercise, it is appropriate to separate high cost asset repairs from general facility repairs. When comparing two cost centres engaged in similar work with similar activity levels it could be expected that repair expenditure rates should be similar. This is usually not the case. Some cost centres appear to have a disregard for costs generated relating to facility "repair" within their location. For example, the cost associated with an office reshuffle (moving furniture, repainting, rehanging notices boards, reorganising data and phone cables) each time there is a personnel change. Similarly, by identifying repair types, it becomes easier to identify staff behaviour pattens resulting in repair requests. Consider wall repairs, these can generally be related to two conditions: careless porters and / or insufficient wall buffering. Broken toilet seats in patient areas may be a result of clinical staff incorrectly transferring patients or a poor quality inventory item.

The ability to manage and track costs related to maintenance projects, particularly in times of maintenance restrictions due to budgets is crucial to performance management of cost centre managers. Disregard for the general repairs budget will have some cost centre managers resorting to understating the work required and job splitting (authorisation from different independent sources within the facility) to achieve small (and some times medium sized) projects. An example of an office space refurbishment to accommodate two clerks follows:

Authorised Works – 2 trades coordinated through maintenance approx $500 of work requested		**Works undertaken – 5 trades from various sources approx $1700 spent**	
Repaint	$350	Repaint	$350
Data point installation (1 computer port)	$150	Data Point installation	$150
Office desk (Relocate from existing stock)	$10	Refurbish existing desk	$125
Filing cabinet (Relocate from existing stock)	$10	Purpose built additional desk	$250
		Additional phone point installation	$150
		Additional phone	$35
		Refurbish and paint filling cabinets	$100
		Replace two office chairs	$250
		Purchase and install two notice boards	$75
		Installation of new ceiling lights	$125

It is crucial to track maintenance expenses generated by medical staff. Assets purchased by Doctors are generally not assessed under new product acquisition guidelines, which normally include an engineering assessment. This assessment includes: availability of local support and parts, reliability, PM costs. Consideration should also be given to loss of organisational revenue in down time waiting for parts. Thus creating a situation of potential under utilisation, (determinable through mechanisms such as Overall Equipment Effectiveness), and the loss of revenue blamed on the maintenance department because sourcing parts may require a 6-9 week lead-time. The requesting doctor changing hospitals or dropping the associated service before the life expiry of the asset of course compounds this situation. By combining mechanisms such as OEE, with a properly configured CMMS, an overall increase in asset availability of approx 5% is achievable.

On a broader scale in a maintenance department that is reactionary to breakdowns using non-controlled stores (or inventory), if KPI's such as Mean Time Between Failures and Mean Time To Repair are not regularly monitored and reported, a false indication of the state of the asset would be given by the fact of a high availability of the asset. The correct use of these indicators would tell us that we in fact might have a highly unreliable asset, which is costing an excessive amount of funds to keep the asset in service. Thus enabling the facility management team to make the repair or replace decision based on fact. A common mistake is not predetermining the level at which an asset goes beyond economic repair. A classic example is a syringe driver costing $1500, a typical breakdown will require a part worth $650 and $100 labour, therefore one repair will cost almost 50% of the initial purchase price generally at a point of 75% or greater of the life cycle of the asset. The asset in this case should be deemed as beyond economical repair.

Lack of inventory tracking is another significant cause of expense. Healthcare is not the only industry to suffer from untracked and unaccounted for inventory. The issues here are firstly the initial cost of the items (usually allocated to maintenance), which are then located about the facility, unaccounted for, and when consumed the cost is rarely applied to the cost centre consuming the item. The challenge here is to reduce the inventory to JIT items and clearly identified critical parts.. If for example you replace 10 fluorescent lights a week, it wouldn't make a great deal of sense to stock 200. The other issue here is standardisation wherever possible will also reduce the inventory. The next challenge is associating the cost of these items with a work order and allocating the total cost to the appropriate cost centre Clearly by controlling the inventory and attaching inventory to asset repairs a facility will not only gain a true cost but will not have thousands of dollars of inventory stock sitting on shelves. In most facilities, a saving of between 8-12% should be achievable.

The human resource element (the maintenance staff) is another area, which is not often under scrutiny to achieve set productivity levels within the normal working day. The questions to be asked cover two competing elements: first how many tasks are completed by each tradesperson on average each day. If this is evaluated with time taken for each, estimation can be made as to individual productivity; second, are tasks being undertaken just because staff are available. An analysis of job types and their priority in terms of mission criticality will indicated if over servicing is occurring or not. By moving to a planned or scheduled task approach there are further efficiencies to be gained over an unplanned or reactionary approach, it has been estimated by Daryl Mather (2006) that these efficiencies may be as much as 50% or greater.

In the instance where most elements of maintenance are outsourced, planning can deliver additional effectiveness for the maintenance department. For example the call out fee for outsourced trade could be at $75 per hour, if the task at hand is n urgent and only takes 15 – 30 minutes there is a productivity loss corresponding to the amount of time paid for (1 hour) but not consumed (30 – 45 minutes). By planning ahead and grouping non-urgent tasks into appropriate trade batches, and matching tasks to time units where able, the facility is able to reduce non-productive time across most repair orders raised.

However, the amount of savings actually realised will of course depend on the ability of the organisation to truly embrace the changes that can be achieved and to drive them through all levels of the company. It is not uncommon to see the full possible gains not realised in the first years of the implementation as the maintenance resources may, wisely, be deployed on reliability projects in order to usher in the next phase of maintenance development in a more controlled and permanent manner. Using this methodology, of reducing lost productivity hours from trades, we have achieved an overall reduction in maintenance expenditure of 5%.

4 TRIAGING REPAIR REQUESTS

The ability to cash flow a facilities standard maintenance repair costs is crucial to achieving budget while maintaining a functioning facility. Without a budgeted monthly cash flow for repair maintenance, it becomes exceedingly difficult for the maintenance manager to evaluate and correctly prioritise repair maintenance beyond all items presenting a safety issue. These must be removed from service and repaired as soon as practical, particularly if it is an asset critical for clinical service function. By moving work requisitions into a planned rather than reactive framework could provide savings against the maintenance budget.

To effectively triage the work requests the following management decisions need to be made:

- On a scale of 1(low) – 10 (critical) where does an asset sit
- On a scale of 1 – 10 the importance of the cost centre requesting work (e.g. Operating Theatre may rank 9 or 10)
- Grouped work categories – that is minor work of a similar nature

By evaluating a work request against these factors, it becomes easy to prioritise the list of competing demands into a planned work schedule. Correctly triaging, or prioritising work requests, the maintenance manager has the ability to group work types enabling a cost effective approach, minimising the number of call outs with associated non productive time. This is further developed by massaging grouped work requests into achievable (in terms of time/cost allocation) work units, defined as a block of work which fills a contracted unit of time, i.e. 3 tasks which amount to 1 hour of work, where the contracted unit of work is 1 hour). In this way, for example several requests for patch painting over a number of cost centres could be consolidated into one work order for an external contractor. This technique will also allow some work requests to be moved to another financial reporting period (week / month / year) as appropriate to satisfy cash flow or financial delegation requirements

5 MONITORING CONTRACT COMPLIANCE

The opportunity to capitalise over the life cycle of an asset does not rest solely with good management through the CMMS. While managing an asset through the CMMS will provide capital savings, if a facility is to maximise the potential for further saving it is essential that appropriately documented service contracts are established, detailing not only the asset service specifications but service contract KPI's. Another key issue is ensuring that asset maintenance has been undertaken in the manner prescribed to the specifications listed and in the periodic framework required. Mapping the actual services provided against the designated service specification, enables an analysis can be made as to the effect the servicing has had on the life and performance of the asset. This exercise will also illustrate service performance failures, deviations or non-compliances by the contractor. It will allow the astute maintenance manager to evaluate the quality of replacement parts used and their contribution to the asset life. An example of contractor failure in routine servicing of air handling units for a HVAC is the premature replacement of the drive belts twice in succession, the immediate questions are: has the contractor used the specified replacement part and did they check the pulley alignment at the first replacement? The answer was no in both instances when the correct part was installed and the alignment checked normal belt wear was experienced.

6 MAINTENANCE KEY PERFORMANCE INDICATORS (KPI'S)

To maximise the potential of an implemented CMMS it is essential that management defines the corporate direction and the business rules it applies to the facility corporate practices to enable the articulation of appropriate KPI's. It is also essential that KPI's be externally benchmarked where appropriate to like facilities and services to ensure that a best practice approach is adopted.

The approach I have used to determine KPI's was by categorisation of indication groups that would be required by management and then analysing what indicators would deliver a result. When comparing my list with that provided by Daryl Mather (2003) of Strategic-Advantages in his standardised approach to KPI's list, there was a high correlation between the two. The combined list of KPI's, from which you could expect to cover most the relevant issues pertaining to implementation of a CMMS, and produce data from which sound management decisions can be made, follows:

Definition of the high level KPI's used by the facility to monitor and control maintenance performance:

- **Unit costs for maintenance**
    - By Equipment
    - Per maintenance employee
    - As a measure against Estimated Replacement Value of assets
    - By cost centre
    - By Contractor
- **Overall Equipment Effectiveness**
    - Availability
    - Mean Time Between Failure (MTBF)
    - Mean Time To Restore (MTTR)
    - Utilisation
    - Quality
- **Defining what is capital works and what constitute operating costs.**
    - What criterion determines a plant improvement?
    - What constitutes like for like replacement?
    - Changes to Process and instrumentation drawings?
    - Changes to operating improvements?
- **Defining authorisation levels in dollar cost terms of each role within the maintenance organisation**. Thought needs to be given to bottlenecks that may be created from the facility delegations manual and the organisational structure.
- **Determining a prioritisation system that will allow the best use of resources across the facility**:
    - What resources to be used across various plants?
    - What resources to be used across various sites?
    - What are the structures of the work groups or teams to be included?
    - What work will be outsourced?
    - What are the time limitations to complete a task? e.g. max 30 minutes
- **Determining what are the definitions of various types of work orders.**
    - Safety
    - Capital
    - Preventive Maintenance – life cycle, and inspection / preventative
    - Repairs
- **Determination of the definitions of types of maintenance and setting levels to be used as benchmarks.**

  If there is a declaration by management on the internal benchmark level to be achieved, it needs to be clearly articulated that the benchmark levels <u>must</u> be derived from whatever maintenance strategy is adopted by the facility. External benchmarks in this instance do not necessarily apply to your facility unless there is a similar match up in the strategic approach and from a “like” industry or facility.

  - Preventative Maintenance – %
  - Predictive Maintenance – %
  - Corrective Actions – %
  - Breakdowns - < %

- **Standing work orders** – Their needs to be an initial focus on this area, determining which items need to be covered by standing work orders. Although there are many approaches, it is best to utilise these for overhead items such as training, holidays and breaks. Use of these as blanket work orders elsewhere will blur the results available from the CMMS system.
  - **Defining business processes and the KPI measurements required for controlling these.**
    - Backlog management
    - Age by Priority measurement
    - Number of safety work orders (trended)
    - Planned work orders per work group
    - Planning/ Scheduling systems
    - Planned/ Scheduled ratios, again these should be industry specific in terms of tolerances, and a risk analysis should be undertaken as part of the process of determination.
      - Planned / Scheduled – %
      - Planned / Unscheduled – %
      - Unplanned/Unscheduled - < %
      - Stores Service rates - %
      - Work completed on time by priority schedule
      - Execution and Data capture systems
      - Highlight the standard of coding required to provide a base for future analysis
      - Fault causes?
      - Duration between Work Order and Work Completion
      - Parts used?
      - Standardised text entries for free text?
- **Engineering works**
  - Criteria for review and execution stages
  - Monitoring / measurement of effectiveness
  - Integration for execution
  - Criterion for inclusion, including justifications process
- **Analysis and actioning loops**
  - Root Cause Analysis processes and reporting required for accurate targeting of the "critical few" items.
  - Measurement of effectiveness

7 IMPLEMENTATION, TRAINING AND EMBEDDING

To succeed, a maintenance program must be embedded into the culture of both the maintenance department and the facility and delivered with role specific training to staff throughout the facility and contractors.

Introducing the concepts raised in this paper to a facility must be undertaken within a change management framework. Initially, it is imperative to have a vision of what you are trying to achieve. The David Firth (1999) has identified the Seven Factors needed to implement Vision as:

- The vision is freely chosen
- Consideration of alternatives has been made
- Clear knowledge of consequences
- Prized and cherished by you
- Publicly proclaimed throughout the organisation
- It is acted upon (repeatedly), not just talked about.

"If your intentions are clear, you create an electric field of possibility that actually pulls creativity out of yourself and those around you. This is the real power of intention. It inspires you in ways you could not predict… Growth is an excitement to individuals and companies and comes from stretching to achieve things that may not have seemed possible even a week earlier" Gay Hendricks: The Corporate Mystic (cited in Firth, 1999)

When you have established your vision for the maintenance program, it is important to understand the dimensions of the Corporate Culture within the facility. This entails understanding the current cultural climate within which the facility operates, considering the organisations business focus and how the leadership and management functions. It is also important to understand the structure of the organisation and the resources it has available to undertake your project, which should include personnel development and customer focus. Principles, which should be applied for success in building consensus for change, are: Involvement, Education, Honesty, and Congruency. Further discussion on the change management required for implementation has not been included in this paper due to word limitations.

Training will need to be developed, or adapted, in using the system to accommodate the facility business rules and processes of the facility. The focus of the training is such that each of the employees knows what their responsibilities, accountabilities and what the role relationships with others in the organisational structure are. Elements that should be considered when estimating the training required not only include the maintenance staff and various department heads around the facility, it should also include the contractors. Here it is important to ensure that the relationship that is developed with contractors enables them to function effectively within your facilities environment. This process commences with a fully documented contractor induction, complete with a contractors handbook, will commence the integration into your facilities culture. It is important that contractors understand where your organisation is coming from and what the organisation needs from them, both in service delivery and how they conduct their business on site. To facilitate improved communication between contractors and your internal customers an important consideration is the introduction of contractors to key staff members. Remember that each department will have it's own operational issues in regards to how a contractor can perform a service within that area.

Abstract: Pumping sets are common but often critical operating assets in the industry. Such pumps often do not have adequate pressure and flow instrumentation that could detect abnormal hydraulic operating conditions. This paper presents field investigations of two submerged vertical pumps with suspected cavitation and flow induced vibrations in a power plant. These pumps had a history of catastrophic impeller failures. The vibration analysis allowed an assessment to be made on the pump of concern; upon which visual examination of the newly installed impeller was made that confirmed the occurrence of cavitation. High frequency random vibration was shown to be a good indicator for flow excitation and cavitation. Comparison of results under service conditions between a cavitating and non-cavitating pump are presented. Failure modes showed cavitation erosion and a sheared impeller blade. Evidence of excessive clearance and/or sleeve bearing wear was also noted in the pump of concern. The investigations confirmed concern relating to operations during low tide and combined pumps operated in parallel where inadequate submergence was identified as a likely cause to the impeller failures. The investigations implied a system design problem and pump operating conditions compounding the system design error that had resulted in frequent failures of the pumps.

Key Words: Cavitation, Flow excited vibrations, Pump, Detection, Diagnosis

1 INTRODUCTION

Pumping sets are common and often critical operating equipment in the industry and in particular in the power generation and petrochemical industry. This paper presents field investigations of cavitation and flow induced vibrations in two submerged vertical pumps (referred herein as SVP1 and SVP2) used for pumping of cooling water to the condenser of a steam turbine in a power station of an Independent Power Producer (IPP) in Malaysia. The Station has 2 unit gas turbines with an additional unit steam turbine, operating as a combined cycle plant with steam generation from a waste heat recovery boiler. The rated capacities of the gas turbines are 2 x 110 MW, and an additional 110 MW from the steam turbine; with a total plant power generation output of 330 MW. The IPP commercial obligations require total load dispatch from the Station being a base load plant to be operated in a combined cycle mode. In the event that the steam turbine is not operational, any electricity generation from the gas turbine is not accepted for dispatch to the national electricity grid. Failure of the submerged vertical pumps would potentially result in a total plant shutdown. Criticality of these submerged vertical pumps is obviously very high.

The pumps were identical (make, model and operating speeds) and installed in parallel connected to a common header after discharge routed to the condenser. The pumping medium is sea water. Seawater is drawn from a suction pit connected to the sea via a water intake tunnel. A photograph of the pumps is given in Figure 1(a) and a schematic drawing in Figure 1(b). While the pumps could be operated either independently or in combined pumping modes - operating continuously 24 hours per day, both pumps need to be operating when the turbines are operating close to base load (full load capacity) conditions. In the event that only one pump is operating, some load restriction would be required as there would be insufficient cooling water to the condenser. Each pump has 4 blades, and the pump vertical shaft supported on cutless rubber bearings (sleeve bearings) located in an inner tube in the riser tube. The motor had rolling element bearings. The drive shaft is approximately 10.5 meters from the sea level. The design specifications of the pump are total dynamic head (TDH) of 16.2m, flow capacity of 13,800 m^3/hour, and operational speed at 595 rpm. The pumps are axial flow with a specific speed (Ns) in the order of 8500. The manufacturer's recommendations for minor inspections (maintenance) are scheduled on an annual basis, and major overhaul scheduled once every 5 years.

2 NATURE OF PROBLEM AND MANAGEMENT ISSUES

Both pumps had a history of premature impeller failures, and had been an issue of concern to the plant with respect to unscheduled breakdowns and interruptions to electricity load dispatch (noting that there would be some reduction in plant capacity whenever a pump becomes unavailable, and a total plant shutdown when both pumps are not available). While it was originally thought that the problems associated with these pumps were a mere case of unreliable machinery and thereby having to fix the pump whenever a failure occurs; the work and sequence of trial and error remedies to have the pumps brought back to service points to a potential system design error and operational conditions compounding the error. There are currently no flow measurement devices on the pumps, and came fitted with an analogue pressure indicator on the common discharge pipe only. As such it was not possible to verify actual pump operating conditions on a single pump basis or on a combined system operating mode basis. The plant management obviously requires identification on the root cause(s) to the pump failures, and whether there is indeed a system design problem with the pumping system such that a long term solution for improved pump reliability could be identified. In the event of a system design error significant remedial works shall be necessary and in all likelihood can only be implemented during a long major outage, preferably to be scheduled with one already planned in two years time (2008). A brief history of the failures and attempted solutions of fixing the problem is described below. A table summarizing key observations and the corresponding site measurements for vibrations is given in Table 1.

Table 1: Summary of recent failures in the pumps, work done to the impeller (Pump SVP1) and vibration investigations

Date	2002 - 2005	1 October 2005 (1st Visit)	18 Jan 2006 (2nd Visit)	25 March 2006 (3rd Visit)	26 May 2006 (4th Visit)
Pump SVP1	Original impeller. Catastrophic failure of impeller in Dec 2003. Broken blade welded back in Dec 2003. Failures to impeller in Sept 2004 and Nov 2004	New impeller of different design (different shape compared to original impeller)	Refurbished (original) impeller	Refurbished (original) impeller	New impeller (original design)
Pump SVP2	New pump replacement in 2002 (with original impeller design)				
Vibration Site Measurements	No vibration history available.	Vibration measurements undertaken with SVP1 and SVP2 in combined operating mode	Vibration measurements undertaken with SVP1 and SVP2 in single operating mode	Vibration measurements undertaken with SVP1 and SVP2 in combined operating mode	Vibration measurements undertaken with SVP1 and SVP2 in combined operating mode
Condition of SVP1 impeller	Frequent failures of the impeller.	New impeller (different design) was removed at end Oct 2005 and replaced with refurbished impeller of original design		Refurbished impeller failed on 21 April 2006, and replaced with new impeller (original design).	

These pumps were installed in 1997 when the power plant was converted from an open cycle to a combined cycle plant. While there had been problems with the pumps, there was however no records for these pumps to assist plant personnel currently responsible for its maintenance to historically track the failures since installation. There was however a total pump replacement (herein referred as SVP2) in 2002 that was necessary as a result of a catastrophic failure of the original pump arising from a broken impeller. Ever since this pump replacement, minor pitting on the pump blades of SVP2 was noted during periodic maintenance and inspections. While minor cavitation was suspected in SVP2 based on the visual evidence from the pitting of the blades, the unit had however been operating relatively trouble free since 2002. The other pump SVP1 is however more problematic. There had been unscheduled breakdown failures (of more than 10 times over the past three years), with a major catastrophic failure due to a broken impeller during end December 2003, Figure 12. Instead of an entire pump replacement in this case (as compared to SVP2 in the previous year) the broken impeller of SVP1 was welded back on January 2004, and a dynamic balancing undertaken prior to its return to service. After 9 months of operation a similar failure occurred on the impeller. Another welding job was undertaken to return the impeller back into service in September 2004. After two months of operation, the impeller failed again for the third time in similar pattern.

This pump was then rendered unavailable for a relatively long period of time as attempts were made to seek a resolution to the problem. The pump vendor then recommended a new impeller with a revised design (with a reduced trailing edge profile perhaps in an apparent attempt to reduce forcing on the impeller blades). The pump with the revised impeller was then installed in September 2005. Almost immediately upon operations of the pump (SVP1) with the new revised design impeller, cavitation was suspected since vibration levels were excessively high with a corresponding rattling sound from the pump clearly audible. The absence of OEM fitted sensors for pressures and flow meant that pump operating conditions could not be monitored for any onset or occurrence of cavitation. There were OEM's fitted vibration sensors on each pump, but with readings limited to overall amplitudes only. SVP1 had vibration levels of 9 mm/s (as noted on 1st October 2005), whereas vibrations of the other relatively trouble free SVP2 were typically in the order of 3 mm/s. The new impeller of revised design as fitted to SVP1 was immediately removed, and a refurbished (original) impeller was fitted back in October 2005. The refurbished impeller failed (yet again) in April 2006. A totally new impeller replacement with the original design was fitted in May 2006.

The above behavior of SVP1, while in hind sight should have been expected, nevertheless posed a dilemma to the plant personnel and senior management. Frequent making "good" a broken impeller, failed attempt in a new impeller design (albeit on the recommendations of the pump vendor/OEM) and a new impeller replacement (of the original design), and not forgetting a new pump replacement for the other pump SVP2, suggested the inability to identify and remedy root cause(s) of the problems. Continuing operations in such a manner cannot warrant trouble free operations, improved pumps reliability and plant availability. Vibration measurements were used to help in the potential identification of the root causes correlated with other visual observations under a situation of inadequate instrumentations for actual pumps performance verification. The vibration based investigations presented herein strongly implied a system design problem and pump operating conditions compounding the system design error.

3 CAVITATION AND ITS DETECTION

Physical examination of the impellers when removed for inspection showed evidence of cavitation for all impellers. The preferred method to determine cavitation is by pressure measurements [6-9]. In the above pumps, there were no suction pressure indicators for such measurements in particular. As the pumping sets did not have any instrumentation for flow and pressure measurements to confirm occurrence of cavitation, vibration analysis was initiated in an attempt to confirm the onset and/or occurrence of a cavitation. This also presented an opportunity to examine the feasibility and the practicability of the detection of cavitation as a field validation of an experimental study of the authors [5].

Cavitation usually occurs in a flowing liquid where the local pressure drops below the saturation vapor pressure of the liquid at a given local temperature, causing liquid evaporation and generation of vapor bubbles in the low pressure region. Fluid machinery is a common application where low pressures are routinely generated by hydraulic action, for example on blade surfaces, with a consequent possibility of cavitation. The existence of cavitation is undesirable as it results in deterioration of the hydraulic performance, lead to physical damage affecting the equipment or component structural integrity and higher noise. Onset of cavitation is defined by ISO 3555 as a 3% drop in the pump pressure head without inlet or discharge throttling at a given flow rate. A characteristic audible sound (rumbling stones or 'marble' sounds) would be emitted from the pump when cavitation is occurring.

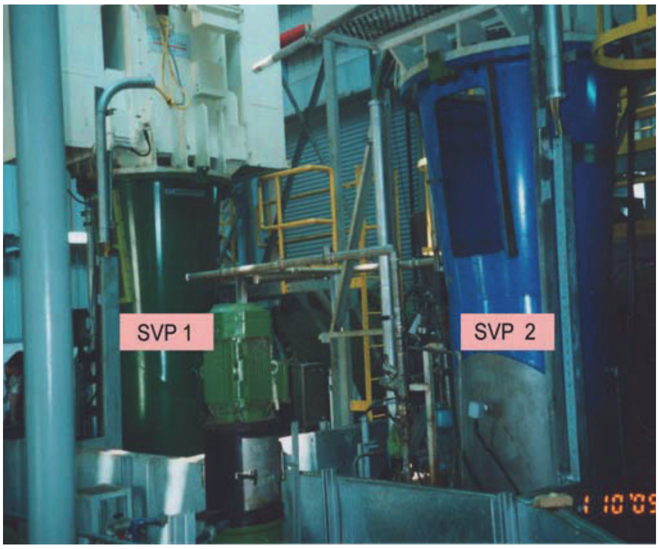
Detection of cavitation in pumps has been by subject of interest. Jeremy Jensen (2000) reported that the dynamic pressure was a direct indicator of cavitation, whereas Net Positive Suction Head Available (NPSHA) monitoring was an indirect indicator. Jorge L. Parrondo (1998) reported that pressure at outlet pump is sensitive to changes when cavitation occurs. The sensibility of pressure at the inlet of the pump was also regarded as a satisfactory indicator. Experiments have shown that there is a discrete frequency tone with the audible noise spectra, typically at half of blade passing frequency (BPF), which is strongly dependent on the cavitation process and its development (M.Cudina,2002). The discrete frequency tone at half of BPF could therefore be used to detect the incipient of cavitation and its development. T. Uchiyama (1998) investigated a fault diagnostic method for centrifugal pump using neutral network approach.

With the use of computational fluid dynamics (CFD) to analyze the viscous, turbulent flows, vortices in fluid machinery in presence of cavitation could be visualized in a computational model. These tools are however fairly complex and not readily available to the plant personnel in practice. A more conventional and robust method for the detection of cavitation and flow induced vibrations in general based on vibration measurements represent the most viable tool to the plant personnel.

4 FIELD MEASUREMENTS

Vibration measurements were undertaken on both pumps with different operating modes and impeller fitted for pump SVP1. Table 1 tabulates the respective vibration measurements undertaken for corresponding operating conditions. Vibration spectra and time waveforms of the respective pumps were measured and assessed. In the more recent site surveys bump tests were also undertaken on the pump casing and piping when the pumps were not operating to identify structural resonances For the purpose of this paper only selected results are shown and discussed for brevity. Since prior baseline measurements were not available, a comparison between the two pumps were undertaken with the intent of comparing vibration characteristics of the pump of concern (SVP1) with the pump that was regarded to be in fairly good conditions (pump SVP2 on the basis that this pump had been operating trouble free since its replacement in 2002). This was deemed a reasonable approach since both pumps were identical (same model and same operating condition) operating at a similar running speed (585 rpm). There may be some differences in the structural mobility due to its physical installation next to one another although measurements were undertaken at almost similar positions on the respective pump sets. Measurements and comparison of the measured data for SVP1 and SVP2 were undertaken in similar location and directions.

Measurement at the commonly preferred location at the bearing was not feasible as there was no convenient access to the bearing. Measurements were therefore restricted to secondary locations on the pump casing. Additional measurements were undertaken on the pump discharge base flange, Figure 2(a), at the mechanical seals, Figure 2(b), and at the motor.



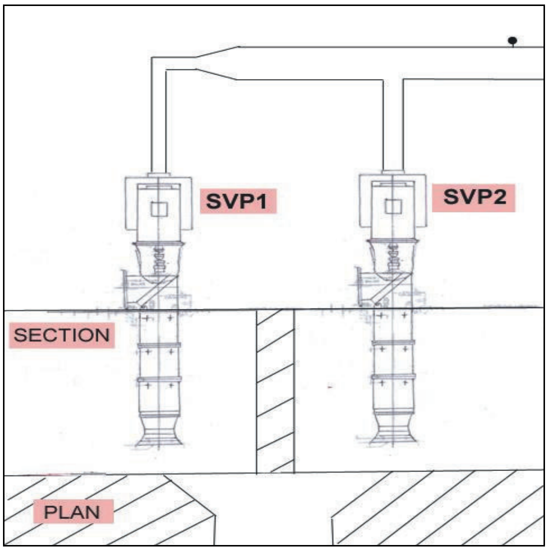


Figure 1(a): SVP1 (in green color) & SVP 2 (in blue color) located adjacent each other

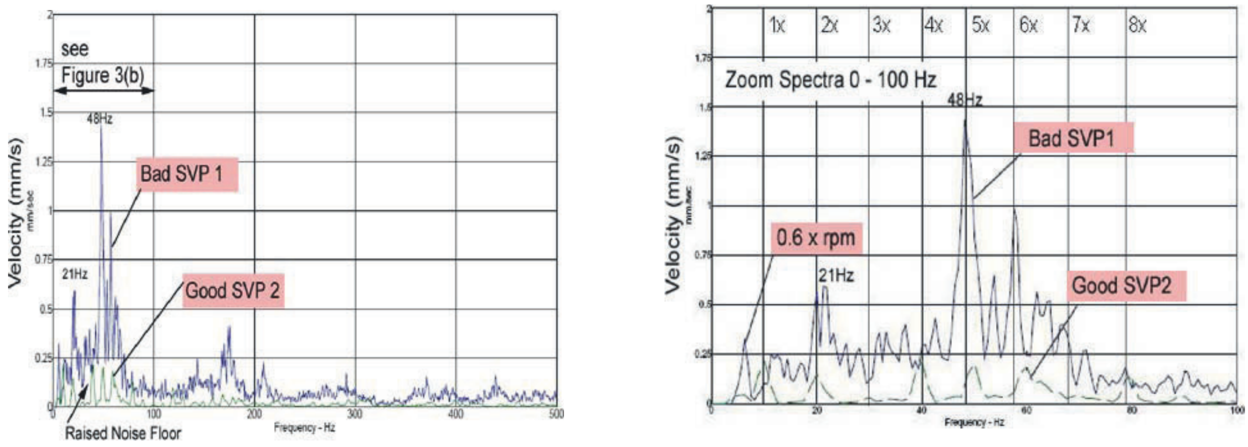
5 RESULTS

A series comparison between the vibration data was taken on various locations from SVP1 (fitted with the new revised impeller design) and SVP2 are shown in Figure 3 to Figure 8. The blue line (solid line) as shown in the following figure presents vibration data for SVP1, while the green line (dashed line) presents vibration data for SVP2. Results comparing the original impeller (blue line) and new revised impeller design (red line) for the same pump SVP1 are given in Figure 9 to Figure 11.



(b)

Figure 3: Comparison of casing vibration of SVP 1 (revised impeller) & SVP 2 (Casing pump discharge - Horizontal)

Vibration velocity spectra measured on pump discharge casing are given in Figure 3(a), and the zoom spectra in Figure 3(b). The spectra for the "bad" pump SVP1 showed pertinent vibration response peaks at 6.25 Hz (~0.6x rpm), 21 Hz (2x rpm), 31 Hz (~3x rpm) 48Hz (5x rpm), and 58 Hz (6x rpm); Figure 3(b). The blade passing frequency at 4x rpm and 2x BPF (8x rpm) was not so evident in this bad pump. Multiples of harmonics of up to 8x rpm and raised noise floor in the spectrum of the bad pump SVP1 were therefore clearly evident. This suggested that clearance related problems where sleeve bearings wear to be present. The "good" pump SVP2 did not demonstrate high vibration response peaks, nor was the harmonics multiples so clearly evident. The blade passing frequency at 4x rpm and 2x BPF (8x rpm), although of lower amplitudes as compared to the bad pump, was nevertheless present in the good pump SVP2.

The dominant vibration response peaks of 48 Hz while suspected as a possible resonant peak was however not confirmed from the measurements. A subsequent bump test undertaken on the pump discharge casing showed a resonant frequency at 21 Hz for the pump casing, and a resonant frequency of 31 Hz for the inner tube of the riser tube (holding the shaft).

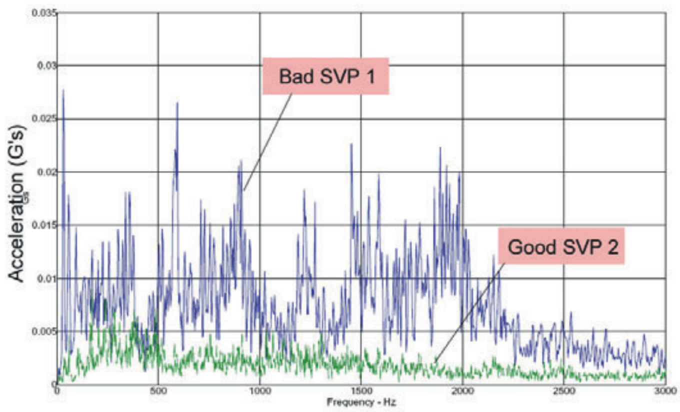


Figure 4: Comparison of casing vibration of SVP 1 (revised impeller) & SVP 2 (Pump discharge base - Axial)

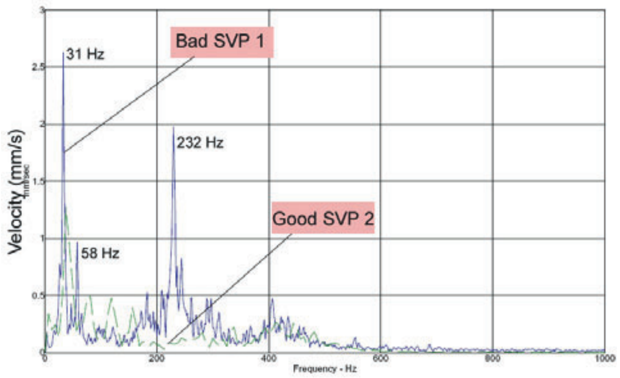
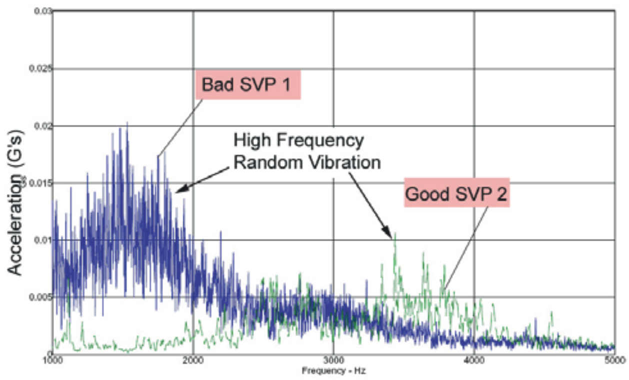
At the pump discharge base (measured in axial direction), vibration acceleration amplitudes of the bad pump SVP 1 were significantly higher than the good pump SVP2 (Figure 4); with overall vibration amplitude of 0.20 Gs for SVP1 and 0.07 G's for SVP2. Impulsive vibration peaks (spikes) and high frequency random vibrations were very evident in SVP1. Random vibrations at high frequency are often associated and recognized as characteristics for cavitation and flow turbulence (flow excited vibrations). The vibration spectra peaks of the good SVP2 as compared to SVP1 were significantly lower. The measurements therefore confirmed presence of cavitation and flow induced vibrations.

Measurements at the mechanical seals in the axial direction showed increased vibration velocity response peaks at 31Hz (~3x rpm), 58 Hz (6x rpm), 232 Hz (6x BPF), Figure 5(a). The resonant frequency of 31 Hz for the inner tube within the riser tube as excited by the flow was particularly evident. The 232 Hz peak (although at 6x BFP) currently remains unconfirmed as to whether this is a component resonant frequency. Random vibrations were evident in the frequency range from 150 Hz to 500 Hz in the acceleration FFT for both SVP; but were more pronounced and significantly higher in the bad pump SVP1, Figure

5(a). In the bad pump SVP1, Figure 5(b), the random vibration tended to be in the frequency range from 1000 Hz to 4000 ; and in the good pump the random vibrations, although less intense, were from 2000 Hz to 4000 Hz.



(a) Velocity spectrum (0 – 1000 Hz)



(b) Acceleration spectrum (1000 – 5000 Hz)

Figure 5: Comparison of vibration of SVP1 (revised impeller) and SVP2 (Mechanical seal – Axial direction)

Tri-axial vibration measurements were also undertaken on the motor. Comparisons of the vibration response are given in Figure 6. It was confirmed that vibrations of SVP1 were more severe than SVP2 in all measured directions (axial, horizontal and transverse). The axial vibration velocity dominating peak response of 23.1 mm/s was at 29.5 Hz (3x rpm), with other pertinent response at 6.25 Hz (0.6xrpm) 1.4mm/s and 10 Hz (1x rpm) 1.0 mm/s. Visual observations confirmed severe shaking of the SVP1 motor at the top. The 30 Hz response (as marked up in Figure 6) was identified to be a resonant frequency of the inner tube within the riser tube to hold the shaft; and in this instance was most likely to be excited by random vibrations associated with flow excitation present in the bad pump SVP1 (as evident from Figure 5 and Figure 6 above).

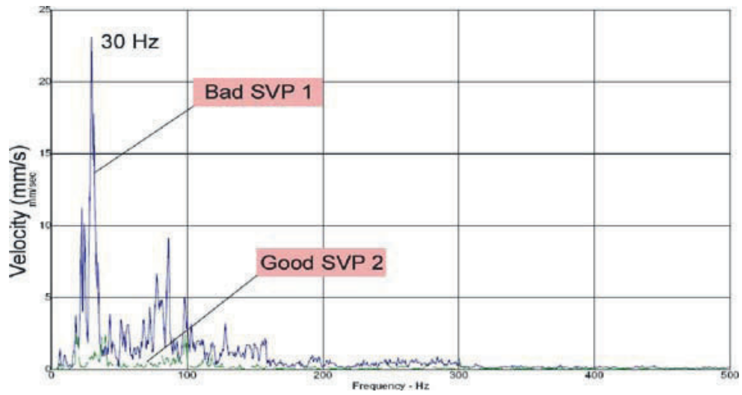


Figure 6: Comparison of vibration of SVP1 (revised impeller) and SVP2 (Motor casing - axial direction)

In the horizontal direction, vibration at SVP 1 was marginally higher than SVP2 at frequency of 50 Hz to 300 Hz, Figure 7. In the transverse direction vibration response peaks of 6mm/s vibration at 6.25 Hz, 5.7mm/s at 45 Hz, 4.3 mm/s at 57 Hz, and 5.9mm/s at 83 Hz were noted, Figure 8. The vibration amplitudes showed a more severe vibration in the transverse direction than the horizontal direction for the bad pump SVP1; in all likelihood due to the flow direction of the sea water towards the bell mouth of the submersible pumps in the transverse direction.

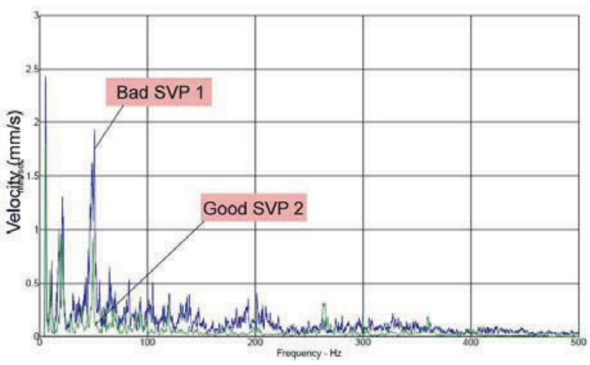

Figure 7: Comparison of vibration of SVP1 (revised Impeller) and SVP2 (Motor horizontal direction)

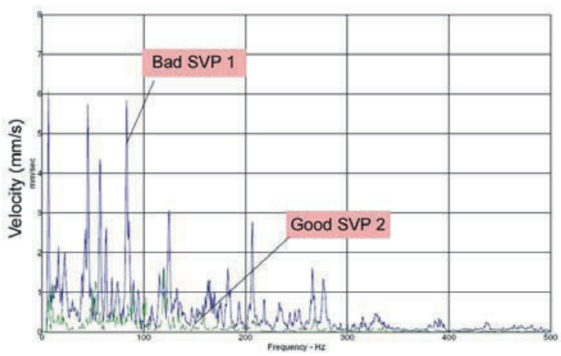

Figure 8: Comparison of vibration of SVP1 (revised impeller) and SVP2 (Motor transverse direction)

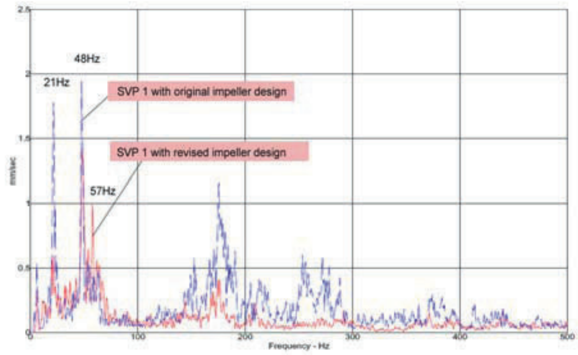

Figure 9: Comparison of casing vibration of SVP1 with original and revised impeller

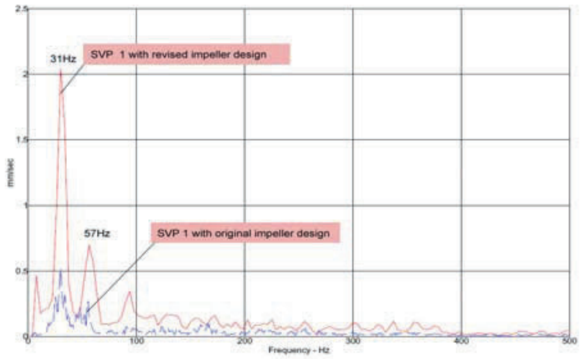

Figure 10: Comparison of pump discharge base vibration of SVP1 with original and revised impeller

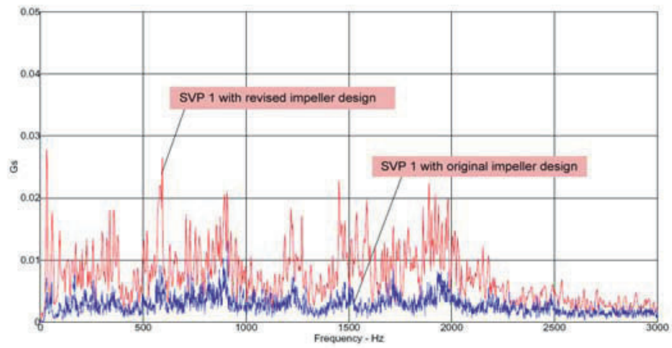

Figure 11: Comparison of high frequency vibration spectrum of SVP1 with original and revised impeller

The above figures (Figure 9 to Figure 11) present typical comparisons of measured vibration response comparing the original impeller and new revised impeller design in the same pump (bad pump SVP1). The measurements showed higher vibration response with the original impeller design, where the resonant peak of 21 Hz and 48 Hz associated with resonant frequency of the casing (21 Hz) were prominent, Figure 9. This suggested higher flow excitation to the casing with the original impeller design. Measurements at the pump discharge base, Figure 10, and at the mechanical seal however showed a lower vibration response with the original impeller design. The structural resonant frequency peak of 31 Hz of the inner tube within the riser tube was particularly evident. Random vibrations associated with flow excitation and turbulence was also higher in the pump with the revised design impeller, Figure 11. This was consistent with the relatively more severe cavitation in the pump with the revised design impeller.

6 DISCUSSIONS

High frequency random vibrations commonly associated with flow turbulence and cavitation were very much evident in the bad pump SVP1, particularly when viewed (i.e. measured) in the acceleration parameter. This was particularly evident for measurements undertaken at the pump discharge base and the mechanical seals. In the good pump SVP2, high frequency random vibration could also be observed on the mechanical seal although generally less pronounced (severe). Some nominal random vibration was also observed for the pump discharge base at this good pump SVP2. Structural resonances of the casing and components making up the riser tubes were excited by these random vibrations. The site measurements confirmed acceptable vibration signals for measurement undertaken at locations of the pump discharge base and mechanical seals, in the absence of permanent vibration sensors installed at the submerged bearing housings. Signal strengths and data that could be extracted from measurements at these secondary locations were consistent with observations in experimental studies and recommendations in the literature. Visual inspections of the impeller and blades confirmed occurrence of pitting associated with initial stages of cavitation and/or combination of erosion.

Vibration severity in the bad pump SVP1 was consistently higher than SVP2 at all measured locations. The vibration velocity spectra of the bad pump SVP1 also suggested excessive clearance and/or wear in the sleeve bearings which could be a consequence of the excessive vibrations in the bad pump SVP1 (and less so as a root cause of the severe vibrations).

The above measurements and aural evidence from the pumps confirmed the need for the pump of concern to be opened up for visual examination on several occasions. The rotor shaft and impeller assembly when removed from its casing and the riser tube in several instances confirmed a damaged impeller. A photograph of the damaged impeller in one of the several cases of impeller failure is shown in Figure 12. The failure mode appeared to be a blade shearing off at the root connection with the central hub (where stress concentration is likely to be highest). Such a failure is more consistent with excessive hydraulic forcing than erosion wear associated with cavitation. In the case with the revised impeller design, cavitation was evident from the pitting of the impeller blades which occurred on the newly installed impeller just after 3 weeks of operation, Figure 13 and Figure 14.

The measurements and failure history suggested that the second pump SVP2, while being identical to the bad pump SVP1, has a less severe vibration problem with less severe hydraulic excitation although showing evidence of some cavitation. It is therefore possible that there are differences in the hydraulic operating point of pump SVP2 which resulted in a less severe state of cavitation and flow induced vibrations. Differences in water entry conditions at the bell mouth and material differences in the impellers between the two pumps (implying that the impeller of SVP2 had a higher degree of resistance to the erosion and pitting from the cavitation) may also be possible. Not withstanding the above observations, it ought to be recalled that this pump SVP2 did suffer earlier failures that required a complete pump replacement. Audible 'rattling' noise of the bad pump SVP1 was particularly more pronounced, and less obvious in the good pump SVP2. This correlates well with the relative severity of the vibration amplitudes and vibration spectra patterns of the two pumps.

Figure 12: Damaged original impeller of the SVP1 (note displaced position of damaged blade)

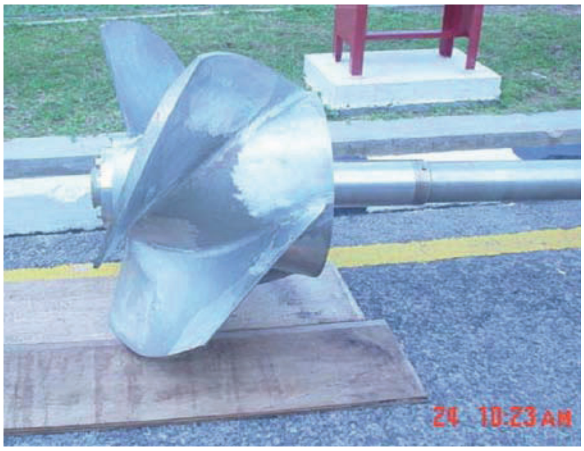

Figure 13: New impeller (revised design) of the SVP1 after 3 weeks operation

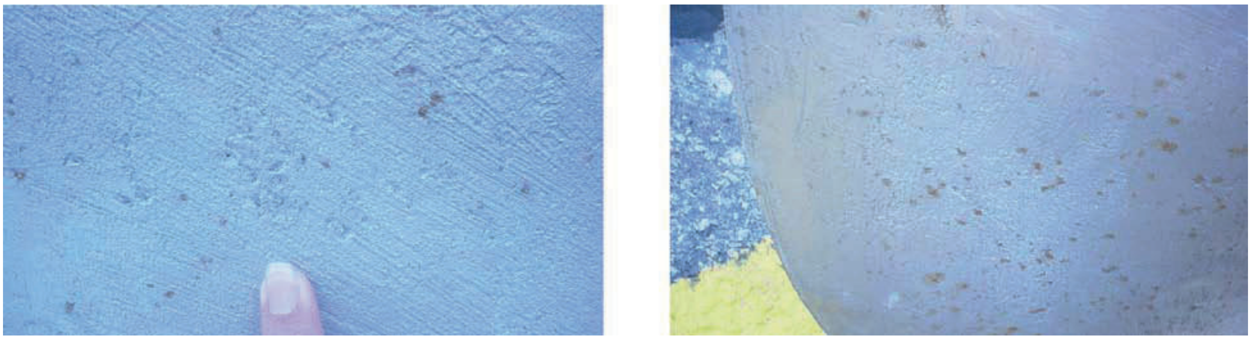

(a) **(b)**

Figure 14: Pitting found on the blades after 3 weeks operations for new (revised design) impeller.

While cavitation was more evident in the bad pump SVP1 than the good pump SVP2, it cannot totally explain the recurring failure mode of a sheared blade at the root of the impeller, Figure 12. This therefore suggested the presence of excessive hydraulic forces arising from flow turbulence in addition to cavitation in the pump. Resolution of the flow induced vibrations (flow turbulence) and cavitation problems would require a review of the pumps system design, and in particular the suction heads of these submersible pumps and the sump pit design. During high tide of the sea, the submergence of the pumps was approximately 5m from the bottom of the sump. At low tide, the water level would drop to between 3 to 4m from the bottom of the sump; Figure 15. When both pumps were operated simultaneously in a combined mode, the water level at the sump pit dropped further by almost 1m as compared to the case when only one pump was running. This inevitably resulted in a situation when the pumps are now at/or below a critical operating zone below the minimum submergence required by the pump. Inadequate submergence (i.e. a drop in the suction head) would potentially result in a cavitating state. This would be consistent with vibration measurements that showed acceptable vibration levels when only one of the two pumps is operating as compared to high vibrations when both pumps are operated in a combined mode. Visual examination of the water surface in the sump pit during pumping operations nevertheless showed steady (still) water surface without undue turbulences or vortices.

The fact that there is a drop in water level in the sump pit when the pumps were operated in a combined mode (full capacity) suggested that there may be a system design error with the sump pit where sea water entry at the water intake tunnel may be undersized (or obstructed). The water level also drops to a situation with little or no margin above the minimum submergence level during low tides. As such cavitation and turbulence within the impeller may be inevitable.

In axial flow pumps, cavitation and flow turbulence cannot be explained in the same way as radial-flow and mixed flow pumps. The water enters an axial-flow pump in a large bell-mouth inlet and is guided to the smallest section (called the throat) immediately ahead of the impeller. The capacity at this point should be sufficient to fill the ports between the impeller blades (assuming normal full submergence). When the head is increased beyond a safe limit, the capacity is reduced to a quantity insufficient to fill up the space between the impeller, creating cavities of almost a perfect vacuum. When these cavities collapse the water hits the impeller with a force sufficient to pit the surface of the vane. Conventional good practice to avoid cavitation in axial flow pumps suggests avoidance of the following:

- i) Heads much higher than the head at peak efficiency of pump;
- ii) Capacity much lower than the capacity at peak efficiency of pump;
- iii) Suction lift higher or submergence head lower than manufacturer's recommended levels;
- iv) Heads much lower than the head at peak efficiency of pump; and
- v) Capacity much higher than the capacity at peak efficiency of pump.

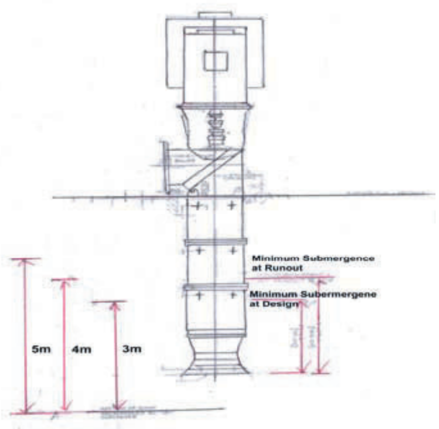

Figure 15: Minimum submergence required

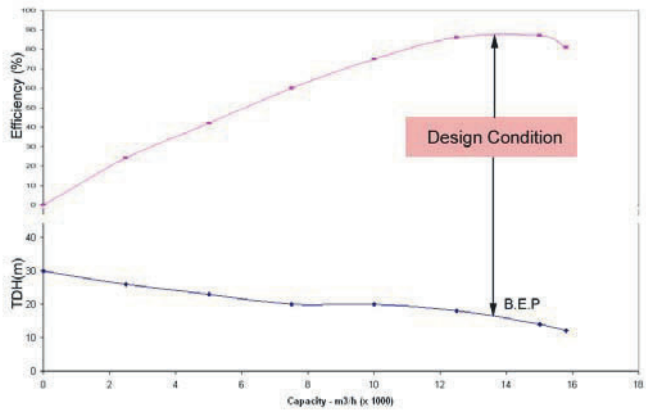

Figure 16: Design performance pump curves for SVP 1 & SVP 2.

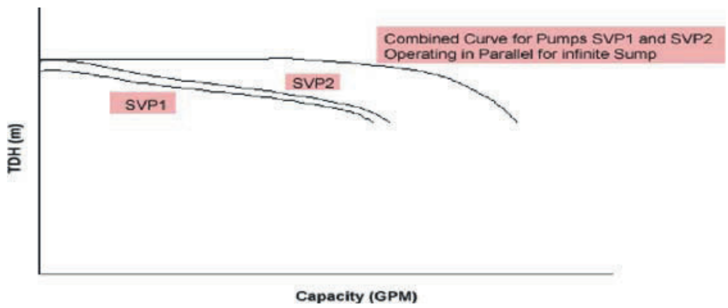

Figure 17: Typical performance curves for individual and pumps operating in parallel

As the pumps SVP1 and SVP2 do not have proper pressure and flow rate measurements devices or indicators, it was obvious that an immediate task is to install pressure measurements sensors on the suction and delivery sides. A flow measurement device (either by direct measurements or indirect measurement devices such as a Yates meter) should also be considered to confirm the pump operating points. Consistent with good practice, the operating point should be at its best efficiency point (B.E.P). Cavitation is generally not expected to occur if the pump is operated in close proximity to its B.E.P., Figure 16. In the absence of any pressure or flow measurement instrumentations (except for a simple analogue indicator on the common header of the discharge pipes) in the current situation, it was not possible to determine actual operating points of the pumps on an individual basis and when operating parallel in a combined mode. As it stands the system performance curve in a combined mode is not unknown (other than what is shown in Figure 17 as a hypothetical curve for an idealized infinite sump), nor are the actual operating points of the respective pumps in a combined mode (and individual mode) known. It is also uncertain if the pumps are operating at the same hydraulic state (balanced state) when operating in a combined mode.

7 CONCLUDING REMARKS

The investigations strongly implied a system design problem and pump operating conditions compounding the system design error that had resulted in frequent failures of the pumps. High frequency random vibration was shown to be a good indicator for flow induced vibrations and cavitation detection. Cavitation and flow excited vibration on the pump with frequent unscheduled failures (pump SVP1) was successfully detected with vibration-based diagnosis. The failure modes in the pump showed shearing of the impeller blade at its root and cavitation erosion. Excessive clearance and/or journal bearing wear in the bad pump SVP1 also suggested consequential damage in this pump arising from higher vibration severity of the pump. The measurements also confirmed a better condition of SVP2 as compared with the pump of concern SVP1 consistent with visual examination of the physical conditions of the respective impeller conditions. This work also confirms that an assessment of the pumps operating conditions and in particular onset and/or occurrence of flow turbulence and cavitation could be made using vibration analysis in situations with inadequate pressure and flow instrumentations installed in pumps often being the case in typical industrial installations.

This initiative allowed field measurements to be undertaken being the subject matter of this paper for validation of an experimental study in Universiti Teknologi Malaysia.

ASSET MANAGEMENT OF POWER APPARATUS

S. Birlasekaran and G. Ledwich

School of Engineering Systems, Queensland University of Technology, Brisbane 4001, Australia.

Abstract: This paper presents the details and difficulties on asset management process of power apparatus used in power network. The actual condition of power apparatus is far more important than its age. The regulatory and market forces in the current competitive energy market that are challenging the electric utility require more proactive methods of utility asset management. The utilities try to implement from the classical time based maintenance to a condition-based, predictive maintenance program using the concepts of reliability centered maintenance. Many diagnostic and condition monitoring techniques are developed for in-service power apparatus. Precise information about particular aspects of an assets performance is presented in a user-friendly way. Management group monitors the asset and network performance, investment and operating costs, and develop policy and standards, leading to an overall strategy for the network. On line static and dynamic data is the essential ingredient to effective asset management. The cost of condition monitoring can be recovered by reducing maintenance costs. Life cycle cost of an apparatus can be broken down into three distinct areas: purchase cost with installation, operations and maintenance, and decommissioning. The essence of asset management is to reduce the cost of keeping the asset in service and extending the period for which the asset provides satisfactory service. Assets age differ at different rates depending on the duty imposed on them. The current technology suggests that effective reliable age can be predicted more scientifically by blending financial aspects and condition indicators. The trend of condition indicators can predict potential failures and enabling corrective maintenance which is normally less expensive than repair following a catastrophic failure. More organized knowledge base needs to be developed to achieve this goal. This paper reviews the asset management process, the simple theory of power apparatus failure and the existing condition monitoring methods to predict that and the modern trend of intelligent asset decision process.

Keywords: Asset management, diagnostic and condition monitoring techniques, predictive and reliability centered maintenance,

1 INTRODUCTION

Management of aged and new optimally designed operating apparatus is the challenge to be faced by the utility managers to get reliable and economical electrical output in the competitive energy market. An asset manager has to make a variety of technical and managerial activities such as strategy and policy definition, fault management, asset value history and location, planning tools (system capacity, security, losses), risk management (system security, critical asset), system performance, health & safety policies, customer information and financial performance. Intelligent managers' move from routine time based maintenance to condition based maintenance to optimize the cost of operation. Condition indicators are being used to fix the remaining life of operating apparatus and to estimate the loading level.

The classical international standard [1] uses the thermal rule to identify the degradation level - like 10° rise in operating temperature may reduce life by half based on the laboratory measurements. The indicator of life may be tensile strength or breakdown strength which will reduce with increase in temperature of operation. In practical situation, apparatus may be subjected to linear and non-linear electrical, mechanical, chemical and thermal over loading at various levels. In addition, it operates in a power network of other aged apparatus in which the weak link has to be identified to cause the power outage [2]. To increase the reliability of power supply, operators move for on-line and off-line condition monitoring methods [3] [4]. Many of these methods are practiced depending on the expertise available in that organization. Mostly decisions are made from comparative measurements on similar type of aged apparatus. No precise universal rule can be formulated as a variety of conditions monitoring techniques are applied depending on the budget available for maintenance decision of 'go' or 'do not go'. If on-line monitoring is applied, the volume of collected data is more to store and process to come up with condensed useful information. Some techniques identify the degradation with the signal buried in the dominant background electrical and other noises, and ambient climatic disturbances [5] [6]. To get the dynamic condition indicators, signal processing and model studies are more effectively used with the improved low cost electronics and signal processing [7] [8]. This knowledge based data processing is the approach for modern asset management to identify the degradation rate, fault diagnosis and risk level [9] [10]. This paper presents some of our reported research work and some industrial practice for asset management of power apparatus.

2 ASSET MANAGEMENT

Asset management is a balancing act in which asset performance is balanced against shareholders expectations [11] [12]. Key stakeholders expect power companies to maximize earnings from existing assets while positioning themselves for future growth [10]. Reliability is defined as the probability that a system will perform a given function satisfactorily for a specified time under specified operating conditions. Reliability centered maintenance assures the delivery of safe, reliable electric power to customers. With that objective, asset management employs predictive modeling, risk management and optimized renewal decision making techniques to establish asset lifecycle options and related long-term cash-flow predictions. Tools exist to enable us to determine the condition of the plant. The asset management process adds value by converting this right information at the right time into decisions which reduce the overall lifecycle cost of the network. Fig.1 shows the flow of decision based on three requirements.

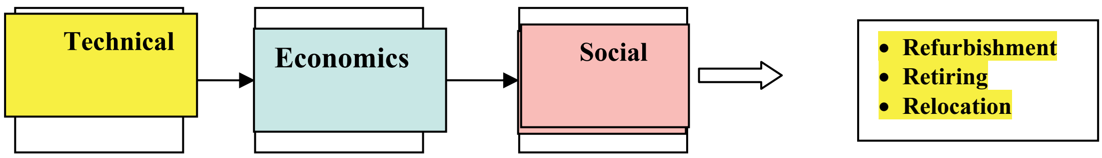

Figure 1 Management decision process

The technical aspect of the apparatus should be evaluated based on the various condition indicators, construction properties of that apparatus and the loading requirements.

The second factor is economic, based on assessing the total cost. It includes the present value of the apparatus (depreciated), the cost of replacement, cost of energy not supplied or cost of supplying the required energy using another source, corrective maintenance cost, preventive maintenance cost, operating costs of cost of energy losses, cost associated with technical condition.

The third factor is social and relies on risk management and optimal strategy with respect to essential requirement for human welfare. It evaluates the impact of any failure and acceptability of power interruptions in such locations. It depends on the critical locations like hospital and airport.

The last two factors can be evaluated by the application and financial managers. The technical factor is the important parameter in asset management to increase the asset value significantly. Many times, the asset can be refurbished by removing the causes of local initiating failure mechanism at a very earlier stage. To do that, the knowledge base is to be improved relating the trend of degradation level with the condition indicators. The condition indicators may be from mechanical, chemical, physical and electrical sensors and the range of fault frequency spectrum may vary. In this paper, some of the electrical condition monitoring methods are presented drawing upon case studies from the published literature.

3 THEORY OF FAILURE

In service, assessment of the age of an asset is not simple. Degradation of insulation is initiated in a localized area due to high stress. It spreads, leading to failure of the apparatus insulation and other supporting structures of windings.

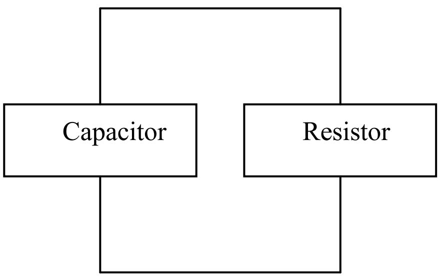

Figure 2 Model of power apparatus

This degradation is a slow process and the time from initiation of defects to failure may vary from one month to a few years depending on the stress. An ideal insulator is represented as a capacitor. Once the defects of different form built up, energy dissipation occurs and can be represented as a resistive element as shown in Figure 2. This is the electrical model of any power apparatus insulation in macroscopic view. The released active energy will be small and difficult to detect, a number of different condition monitoring diagnostic methods are available for use. Some managers use the absolute or relative value of condition indicator for taking some decision and many others rely on the rate of change of that condition indicator with time to make a decision. Normally, the confirmation of defect formation is done in a few stages. A good field engineer uses his common senses (like smell, visual inspection of change in color, sound and heat emitted by apparatus) related to load current with the installed preventive indicators like hot-spot indicator and Buchholtz relay operation [13]. The unusual operation will be taken as prelude for the initiation of defect in the system. Figure 3 shows the typical distribution of classified faults in transformers.

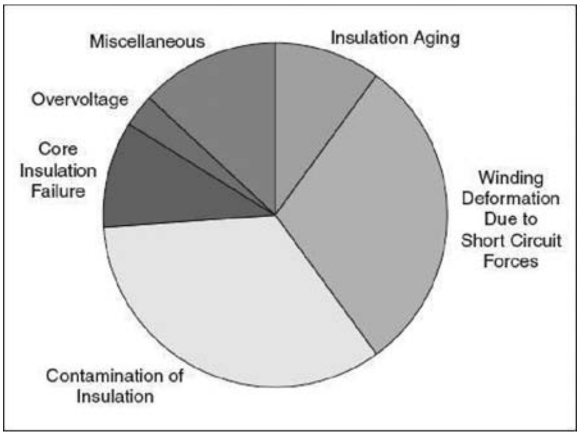

Figure 3 Distribution of faults in power transformers of 15 to 20 years old [14]

4 CONDITION MONITORING TECHNIQUES

Once the engineer identifies some unusual operation, one normally plans the preventive maintenance steps to avoid catastrophic failure. The corrective process once degradation is suspected is done in many ways depending on the expertise and tools available. It is traditionally done in off-line mode in which the power apparatus will be deenergised. Using external perturbation voltages, the developing defect severity and location can be identified. In modern days, on-line intrusive and non-intrusive techniques are effectively being used.

4.1 On-line diagnostic techniques

In this technique, the emitted signals due to normal 50 Hz high voltage (HV) operation are monitored to identify the faults.

4.1.1 Non-intrusive methods

4.1.1.1 **Thermography** – Heat generates infra red radiation. Using infrared camera at a suitable safe distance, the heated location of power apparatus can be identified [15] [16]. Figure 4 shows the change in color intensity at the heated location of joints in 3 Φ connection of a phase in transformer and circuit breaker. It is a non-invasive technique.

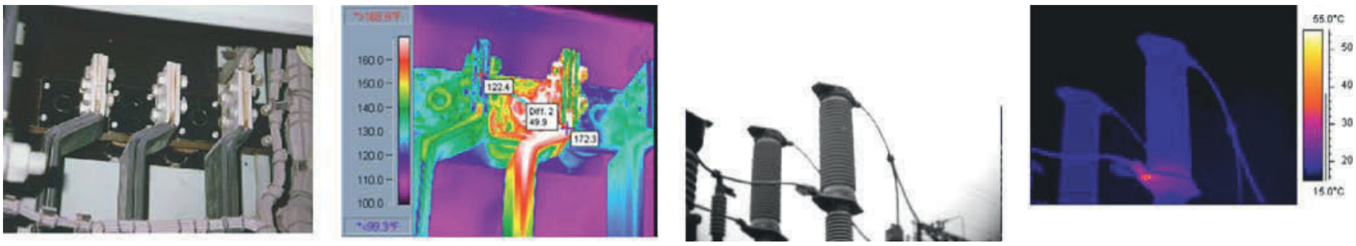

Figure 4 Thermography of faults in one phase of 3Φ connection [16]

4.1.1.2 **Partial Discharge Measurement** – External corona discharge or some form of exposed surface discharge due to contamination can be monitored by using ultrasonic or high frequency current transformer (HFCT) or transient earth voltage probe or antenna sensors in non-intrusive way. A typical low cost HFCTs and the measured PD signals in 20 ms period with 5 sampled data is shown below in Figure 5.

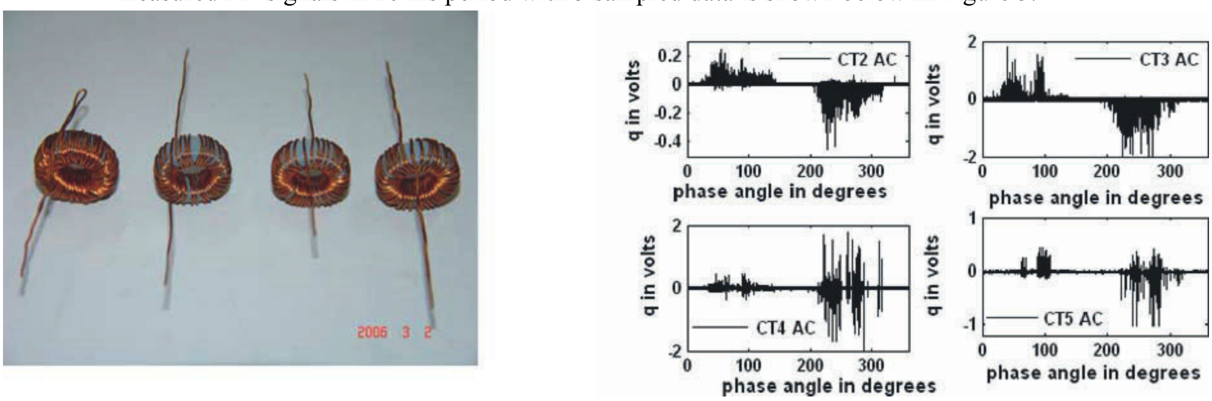

Figure 5 Fabricated 20 MHz HFCTs and its response to air corona [17]

4.1.1.3 **Loss angle measurement** – The leakage current through insulation of bushing is measured and then the ratio of in phase current (Equivalent current thro' resistor in Figure 2) and the quarture capacitive current (Equivalent current thro' capacitor in Figure 2) is determined continuously at 50 Hz operation. If the value exceeds 0.001, the unit will be tested with other additional techniques.

4.1.1.4 **Current measurement** – Load current is continuously monitored to relate with the heating. In addition, it is used to determine zero sequence impedance to identify the earth continuity of the circuit like corroded amour bonds and damaged leads.

4.1.1.5 **Vibration analysis** – Piezo electric sensors mounted at 3 or more locations of power apparatus can identify any non-symmetrical directional operation especially in rotating machine and will help to locate the faults in operating unit in on-line mode. They are widely used in motors and hydraulically /pneumatic operated circuit breakers.

4.1.2 Intrusive methods

4.1.2.1 Electrical methods

In intrusive mode, the measuring sensor will be placed near the HV terminal. It will transmit only the fault high frequency discharges but isolates the very high voltage 50 Hz component. Typical examples are the HV coupling capacitors installed near the line end terminals of generator of 11 to 22 kV rating or slot coupler which transmits the change in resistance (temperature in the slot) in the form of radio-frequency signals. Temperature sensors are mounted near the transformer top end of core and anticipated hot-spot locations. Distributed temperature sensing is done using fibre optics technique using the refraction changes and time domain reflectometry techniques. Pressure changes in long oil/gas -filled cable system are also monitored to identify the faulty location.

Since the signals are obtained without much attenuation, the sensitivity of detection will be high. But the cost of installing the HV capacitor will be considerable.

4.1.2.2 Chemical methods

In oil (or SF_6 gas) insulated system, samples will be taken in from operating transformer and it will be analysed for dissolved gas analysis, moisture content, furan content to relate to degree of polymerisation (DP) of paper, oil dielectric strength, and colour [13] [18]. It integrates the developing faults over time in the form of chemical changes. From the analysed pattern, the type of faults can be identified.

4.2 Off -line diagnostic techniques

Off line condition monitoring techniques have evolved over a period of more than 50 years. It can be classified into destructive and non-destructive measurements.

4.2.1 Destructive method

In this technique, test voltages will be destructive HV in the range of operating voltage.

4.2.1.1 **Hi-pot test -** In the initial period, engineers were using it as an acceptance test formulated in the International Standards [19]. An AC voltage in the range of 1.2 to 1.5 times the rated phase to phase voltage known as HiPot test - is applied to the isolated apparatus using external controllable 50 Hz HV source. The apparatus has to withstand one minute withstand voltage without any flashover or tripping. Since it is destructive test, step-stress Hi-pot test is applied for the aged apparatus. The test voltage is raised at 1 kV step and kept for one minute duration at that level before rising to next 1 kV up-level. Any abrupt rise in current with increase in voltage will indicate the degraded insulation and the increase in applied voltage will be stopped.

4.2.1.2 **Power factor tip-up test** – This is done by applying 50 Hz voltage in steps like step-stress Hi-pot test. Change in power factor or loss angle is measured with increase in voltage. When the ionization starts in the insulation, linearity will change and increase in loss factor will be noticed. Conventional Schering bridge is used to measure the variation.

4.2.1.3 **Partial Discharge test -** Variation of emitted partial discharge (PD) peak magnitude and number with increase in voltage is going to indicate the range of inception voltage to degrade the insulation.

4.2.2 Non- destructive methods

This is the very safe method of identification of fault. It can be classified into DC techniques, AC techniques and Impulse techniques based on the perturbation voltage.

4.2.2.1 DC technique –

- **IR test -** It is basically a megger test. The insulation resistance (IR) of the apparatus is measured with the megger of appropriate voltage rating. It is expected to be more than 100 MΩ. The tested apparatus should be discharged completely as it is DC test. DC test will store interfacial charges with long time constants and it will destroy the insulation gradually if it is not discharged. Also, AC apparatus composite insulating materials will be stressed in different manner with DC voltage.

- **PI test -** An extension of this DC technique is known as the polarization index (PI) test [19] [20]. It is found that the actual model is not as shown in Figure 2. The relaxation/absorption current of defect is shown as one series RC element and the measured current will vary as shown in Figure 6. To identify this relaxation process, the ratio of leakage current at 10 minutes and 1minute is determined to determine the insulation resistance (IR) ratio. PI is the ratio of IR at 10 minutes to 1 minute. If it is greater than 2, the insulation will work satisfactorily without defects.

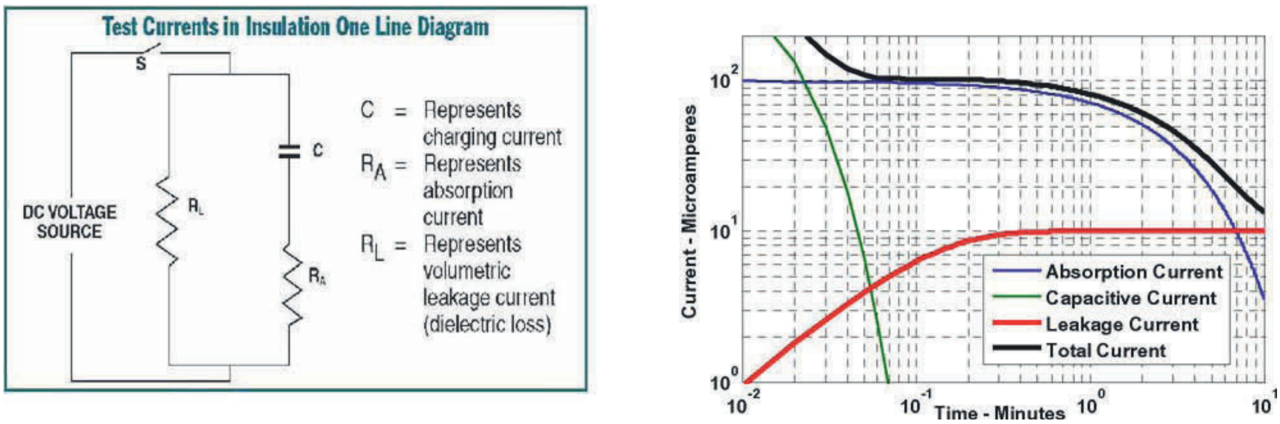

Figure 6 Improved Debye Model of apparatus [20]

Depending on the defects formed, many relaxation elements in the form of serially connected Rpi and Cpi will be existing in the insulation system [2] and the improved model is shown in Figure 7.

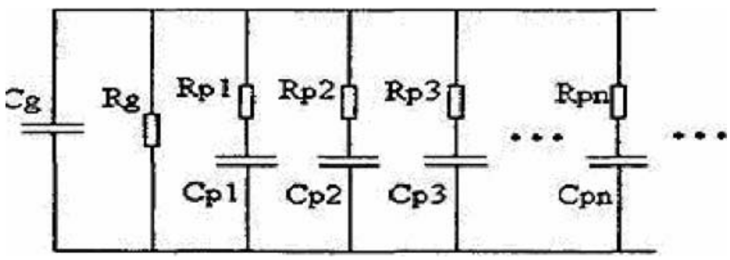

Figure 7 Improved Debye Model of apparatus [2]

- **PC/DP/IRC Test** – This test is known as polarization current (PC) or depolarization current (DPC) or isothermal relaxation current test [6]. Basically, a low DC voltage in the range of 50 V to 1000 V is applied to the system and the resulting polarization current with time will be measured. After that, the polarization source will be short-circuited ad the resulting depolarization current at uniform temperature will be measured. This depolarized current is released by the many relaxation elements shown in Figure 7. Some of them may have relaxation time up to many months. The measured current will be very low and careful measurement technique has to be applied under guarded electrode configuration. It is found to be very sensitive to detect the moisture infiltration into the insulation system.

- **AC technique** – By applying DC perturbation voltage, composite insulation of apparatus will be stressed differently. In addition, the polarized charge due to uni-polar voltage can stay in the interface of different insulations and will enhance the electrical stress at that localized site. To avoid the storage of charge in high insulation system with DC, AC technique is recommended as it simulates the real stressing condition and in each cycle, polarization and depolarization phenomenon occurs. This technique is an extension of Schering bridge technique. The difference is that the applied voltage will be low in the range of 50 to 200 V (rms) and the frequency will be changed.

- **Dielectrometry test** – In this method, the frequency is changed from 1 μHz to 1 kHz [21]. The resulting dielectric real and imaginary parameters are measured. As shown in Figure 7, both capacitance and resistance will change with frequency. At low frequency, a very high loss factor will be obtained to indicate the change in degradation significantly. It is very sensitive test and it requires very costly instrumentation system.
- **FRA test** – In this method, the structural changes in winding can be identified. The applied voltage is very low in the range of 1 to 3 V and the range of frequency used is from 1 kHz to 10 MHz [3][4][22]. A typical change in output is shown below in Figure 8. Significant signal processing and data base can be developed to identify the faults automatically. This technique may be developed to on-line method [3].

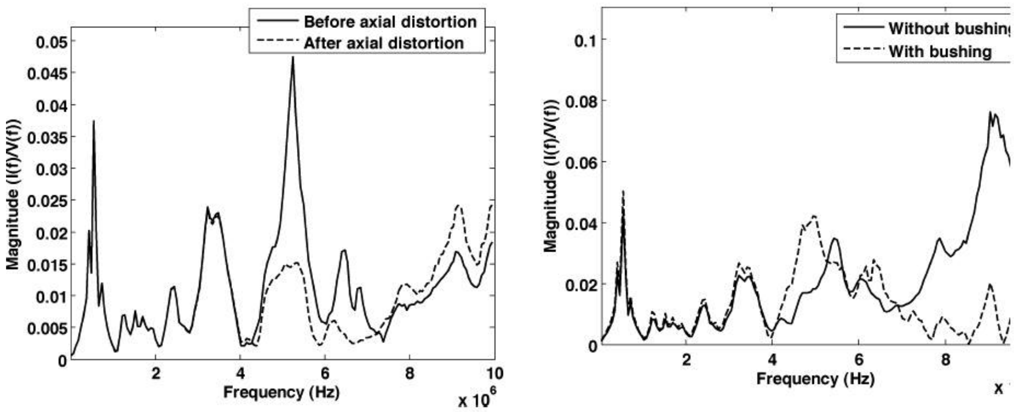

Figure 8 Frequency responses due to axial movement and effect of bushing [22]

4.2.2.2 Impulse technique

The impulse technique is applied in many ways.

- **PD test -** A discharge free 50 Hz HV source is applied to the insulation system. As the HV is increased, the partial discharge signal can be recorded as shown in Figure 4. This is random PD responses with other noises. The distribution of these pulses can be identified by cluster distribution in time and frequency plane as shown in Figure 9. The cluster group lying in the time range 0.6 to 0.8 μs and the frequency range 1.8 to 7.8 MHz is likely due to surface PD and other pulses are noises.

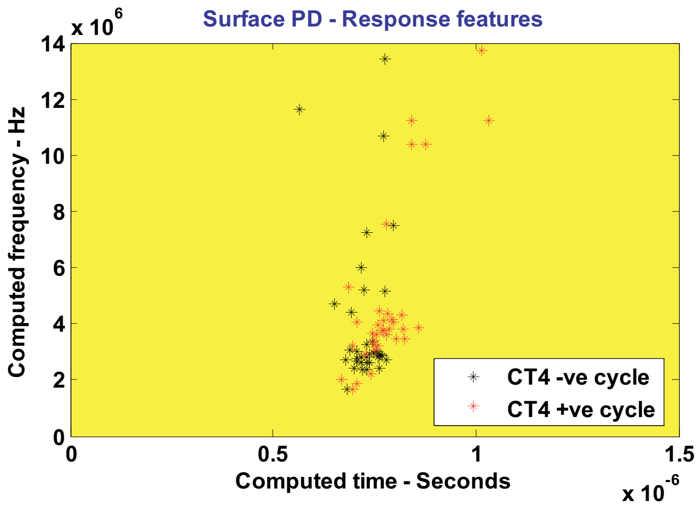

Figure 9 Random occurring single surface PD time and frequency distribution [17]

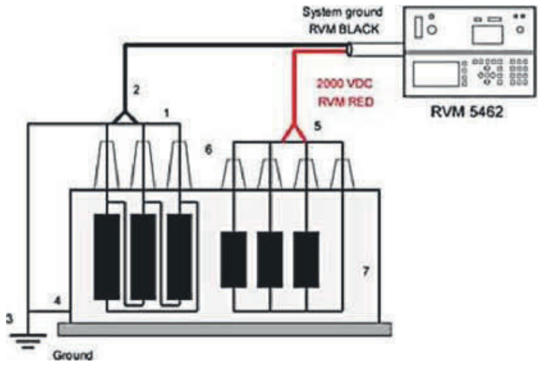
- **RVM Test -** In the industrial apparatus connected to power network, it is difficult to measure depolarization current due to many leakage paths. The new industrial technique known as recovery voltage method (RVM) is introduced [23] [24]. The apparatus will be charged to a finite interval like a step pulse of finite duration and will be discharged to less than the defined finite interval. After that, keeping the circuit open-circuited, the left-over charges stored in relaxation elements will be collected in the geometrical capacitor Cg in Figure 7. By varying the charging and the corresponding discharge interval, it is found that the recovered voltage (y-axis) reaches a maximum voltage at a certain time constant (x-axis) as shown in Figure 10. That time constant is found to be related to the moisture content and the remaining life is determined based on the time constant at which peak RV occurs. It is known as time domain technique to measure the relaxation behaviour.



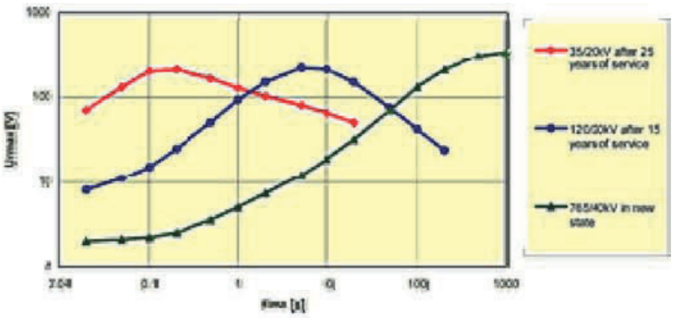


Figure 10 Recovery voltage measurement set up and typical responses [23]

- **LVI Test** – It is also a time domain test equivalent to FRA – frequency domain technique. A low voltage impulse in the range of 10 V with a double exponential pulse of fast rise time and slowly decaying time will be applied and the response current will be measured. Both signals will be transformed to get the transfer function response to identify the faults.

5 DISCUSSION AND CONCLUSION

Asset management of power industry is a billion dollar industry. Electricity has become a part of life these days in all parts of the world and one may not be able to visualize life without electricity, water and air. Recent blackouts in USA, Europe and energy demand in China [25] are a good example of need of more advanced asset management. Even in that assessment management process, social factors will play a dominant role. In a growing urban environment, medical, water, residential housing and transportation industries are looking for alternate energy sources to improve the reliability of electrical power supply. In the competitive energy market, economic factor is the dominant factor. In that price fixation model, models incorporating reliability factors associated with aged apparatus, the effect of failures in power quality and continuity of power supply in network have to be developed.

In the modern information era with good communication facility, static and dynamic technical conditions of operating apparatus can be obtained using web network without visiting any site. Many of the starting failure processes occur in a localized high stress volume of the apparatus. Normally, the failure time from inception of degradation to failure of operation may vary from one month to a few years. Section 4 clearly suggests that many of the condition monitoring techniques can be implemented easily at the site and the cost can be recovered in the form of increased asset life. With the reported condition monitoring methods and other mechanical, physical and chemical diagnosing methods, the developing fault can be identified. Most of the localised faults can be repaired. After repairing and knowing the conditional status of the apparatus, the unit can be put into use again or moved to another location with less demanding load. By this way, the effective use of asset can be extended by knowing the conditional status [26]. The life (book value) of many of the apparatus varies from 15 to 25 years in economical value. But many utilities continue to use the aged apparatus by knowing the operational condition of such apparatus. The knowledge of identifying the conditions and the recorded variation of different critical parameters will become a knowledge base for taking any decision. At present, no steps are taken in the decision process to incorporate it as a static knowledge base since they are not collected and stored properly.

To make a scientific assessment process, knowledge base of different condition indicators indicated in section 4 and by other methods has to be built up. Dynamic instrumentation with good signal processing facilities has to be developed. Dynamic model of the aging apparatus is to be developed for reliable prediction of failure.

Many experienced engineers are retiring with the observed knowledge base of specialist skills and a smart system needs to be developed to collect such human- resource knowledge to blend with ever developing technology, brain-power and new high quality materials used in different modern apparatus [9].

Abstract: This paper reviews the latest trends in the use of intelligent sensors in monitoring applications, including new approaches and computation methods. Sources used emphasise the scientific motivation bringing technological development in the monitoring area, as well as commercial and technological trends.

Key points reviewed include:

- **Parameters and types of sensors currently used**
- **Scientific interest in intelligent sensors**
- **Currently developments in applications in academia**
- **Benefits from using sensors**
- **Processing capacities offered by intelligent sensors**

The state of the art in intelligent sensors capitalises on novel technologies which perform monitoring functions robustly, inexpensively, and at extremely low power.

Key Words: remote sensing, distributed intelligence, wireless, power harvesting

1 INTRODUCTION

The categorisation of a sensor as “intelligent” implies that the sensor incorporates more functionality than merely providing an output measurement. There is some discrepancy governing what makes a given sensor intelligent. There are varying levels of sophistication used by sensors, which have claimed to be intelligent or smart, ranging from merely incorporating an operational amplifier for the output signals, to advanced data modelling techniques for condition monitoring. A “smart” sensor is defined as a sensor that provides functions beyond those necessary for generating a correct representation of a sensed or controlled quantity and having on board advanced processing capability. The intelligent sensors discussed here have built in wireless communication capability. Features required for improving confidence in sensor measurements are defined. This function typically simplifies the integration of the transducer into applications in a networked environment.

The paper introduces possible measurements and available sensors, discusses intelligent sensors in research applications, explaining benefits and advanced possibilities, and finally reviews communication standards used in wireless technologies.

2 PARAMETERS AND SENSORS IN CURRENT USE

In research for the latest applications of intelligent sensors, it will be beneficial to start with an outlook on the applications of conventional sensors. Table 1 lists fields of interest from a scientific point of view [1].

Their applications include:

- "electronic nose" technology, voting systems, telemetry;
- automotive, medical, environmental monitoring and control, consumer, alarm and security, military, nautical, aeronautical and space, robotics and automation;
- sensitive skin systems, sensor-actuators.

Some of the above mentioned applications were designed as intelligent, remotely accessible devices. Development of the technologies introduces a broader need for incorporation of intelligence and remote access. It is expected that in the near future most conventional sensors will be available with upgraded intelligence built into their structure. Such a framework is generic, with the intention of being able to apply the upgraded intelligence to a variety of sensor types, and across civil and military sensor platforms. Standardisation is important to improve portability, and to reduce cost.

Strategies for improving functionality are important, as are features of the sensors themselves, including:

- integration, such as multiple-sensor systems, intelligent sensor arrays (large and high density), sensor buses and distributed networks;
- combined sensors (e.g., electrical & mechanical);
- sensor phenomena and characterization (sensitivity, selectivity, noise, aging, hysteresis, dynamic range, and interference effects).

Table 1: Sensing parameters in intelligent sensing [adapted from 1]

- Mechanical devices and parameters such as: metallic, thin-film, thick film and bulk strain gauges, pressure, accelerometers, angular rate, displacement, force, bulk and surface acoustic waves, ultrasonics, flow;
- Electromechanical sensors over a wide measurement and substrate range;
- Thermal sensors such as: platinum resistors, thermistors, diode and transistors, thermocouples, thermopiles, pyroelectric and piezoelectric thermometers, calorimeters, bolometers;
- Optoelectronic/photonic sensors such as: photovoltaic diodes, photoconductors, photodiodes, phototransistors, position-sensitive photodetectors, photodiode arrays, charge-coupled devices, light-emitting diodes, diode lasers, other quantum devices, liquid-crystal displays;
- Ionizing radiation sensors such as gamma ray, charged particle and neutron detectors;
- Integrated optics/fibre optical devices such as those based on photometry, fluorimetry, interferometry and ellipsometry;
- Microwave/millimetre wave sensors;
- Magnetic sensors such as: magneto resistors, Hall-effect devices, magnetometers, magnetic-field sensors, solid-state read and write heads;
- Chemical and biological sensors, with emphasis on the electronics and physics aspects of transducing chemical and biological signals into information about chemical and biological agents;
- Mass-sensitive devices such as quartz crystal microbalances and surface acoustic wave devices;
- Other sensors such as: thin-film and thick-film gas sensors, humidity sensors, ion sensors (such as pH sensors), radon sensors, carbon monoxide sensors, viscosity sensors, density sensors, acoustic velocity sensors, proximity sensors, altimeters, and barometers.

3 SCIENTIFIC INTEREST IN INTELLIGENT SENSORS

The main interest for the use of wireless intelligent sensors comes from the advanced functionality offered by this type of sensor. Unlike conventional sensors, they are designed to create a complex architecture enabling implementation of advanced measurement strategies. This facility is not present, or is relatively difficult to establish, with conventional sensors. Intelligent sensors do not measure new parameters: the use of them allows measurement of the same parameters but on a different scale. Applications of wireless networks add a new level of sophistication in feature extraction, allowing better monitoring than was previously possible. Additionally, use of distributed intelligence, in the form of local data processing, allows for faster sampling, and reduction of the retained data.

Sensor networks represent a significant improvement over traditional sensors. They are deployed in the following ways:

- Sensors can be positioned far from the actual phenomenon, for example something known by sense perception. In this approach, large sensors that use some complex techniques to distinguish the targets from environmental noise are required. This is in case where the specific measurement is not the main point of concern, but the effects are. For example in the building automation, the wind force will have effect on the stability of the building.
- Several sensors that perform only sensing can be deployed. The positions of the sensors and communications topology are carefully engineered. They transmit time series of the sensed phenomenon to the central nodes where computations are performed and data are fused. This is especially in case of the complex machinery or large objects requiring multiple points of measurement.

An intelligent sensor approach can also be used to improve confidence in the reliability of sensory data in the higher-level sensor management. Onboard condition monitoring and fault detection techniques can be used in preference to reliance on sensor redundancy for ensuring robust measurements. Advanced data based modelling techniques can be used to model non-linear and time-variant sensor systems, avoiding the limitations of linear physical sensor models, and allowing for reconfiguration of the sensor to correct possible errors.

Other functions of an intelligent sensor are autonomous capability, adaptation to changes in the environment, and tolerance to faults.

The principal characteristic of such an intelligent sensor is that it is capable of communicating reliable and self-validated signals or features to higher-level supervision systems, for purposes such as information fusion, tracking and estimation. Poor sensory data can be identified by the sensor itself and flagged for quality problems, together with estimates of the likely cause to enable attempts at sensor reconfiguration. [17]

4 APPLICATIONS IN SCIENTIFIC AREAS

Many research areas benefit from the implementation of intelligent sensors. Applications where wireless sensors have been used range from vibration monitoring, through detection of micro-organisms in food products by sensing the temperature rise of the products, to capacitive displacement transducers which can accurately sense position, speed and acceleration by measuring the (trans)capacitances in multi-electrode structures. Neural networks for local processing are finding many uses, particularly in multi-element sensor arrays such as those found in the "electronic nose".

The range of applications for wireless sensors is very large. A few examples from the literature are presented in Table 2.

Table 2: Wireless sensing applications

- Structural health monitoring (SHM)
  - Vibration measurements are applied for condition monitoring of machines and structures, structural integrity assessment, damage detection and structural failure prediction. Multi-sensor measurement data is essential for SHM. Application of many sensors located on mechanical structures without cables makes the monitoring process more efficient. [2]
  - A chloride sensor and a radio-frequency identification (RFID) chip can be queried remotely both to identify it and to indicate chloride concentration levels; [3]
  - Integrated wireless piezoelectric sensors: Piezoelectric arrays and networks have been suggested as a means to monitor the integrity of composite structures throughout the service life, for instance of an aircraft; [4]
  - Noise reduction in RF cavity wireless strain sensors: monitoring strain in civil structures; [5]
- Passive wireless strain and temperature sensors: approaches to wireless strain and temperature measurements that employ passive sensors based on two types of surface acoustic wave devices, reflective delay lines and resonators; [6]
- Surface acoustic wave devices based wireless measurement platform for sensors: in some applications, a wireless readout is necessary because of the difficulty of fixed connection between sensors and signal processing unit. Wireless surface acoustic wave sensors are being used for sensing some physical and chemical phenomena passively; [7]
- Gaps measurement: a network of small, wireless sensors is helping measure seal gaps in real time; [8]
- Nano-scale gas sensors: microwave carbon nanotube; [9]
- Damage detection and correlation-based localization: demonstration using wireless sensors; [10]
- Passive wireless surface acoustic wave (SAW) sensors based on Fourier transform: application for different physical parameters such as temperature, pressure, and force; [11]
- Continuous monitoring of vital bio-signals; advanced monitor and control medium for healthcare services; [12]
- Agriculture and food production for environmental monitoring, precision agriculture, man-to-machine based machine and process control, building and facility automation and RFID-based traceability systems; [13]
- Microwave moisture sensors: battery powered and capable of communication with the host control system via spread spectrum wireless communications. [14]
- Model analysis: Approaches to wireless hardware and software are suggested that could parallel calculations and thus reduce calculation time and improve data quality by elimination of wires. [15]
- Smart microphone, suitable for outdoor acoustic surveillance on robotic vehicles, incorporating MEMS sensors for acoustic sensing, wind noise flow turbulence sensing, platform vibration sensing. [16]

5 BENEFITS FROM USING INTELLIGENT SENSORS

There are direct benefits from using intelligent sensors. They are able to operate in a task-specific manner with effective data collection techniques. They enable the development and application of more flexible sensor networks which efficiently utilize and coordinate the limited resources of each individual sensor. By focusing resources according to the state of the surrounding environment and on the immediate task, more efficient operation of the sensor is ensured. [18]

- Accuracy: an intelligent sensor will incorporate features which enable it to compensate for systematic errors, system drift and random errors produced due to system parameters or the characteristics of the sensor.
- Reliability: the incorporation of data and sensor validation techniques to detect corrupted data, self-testing of network path connections and sensor operation, as well as calibration of sensor drift, provides yet another level of system reliability in addition to techniques already applied in the network design.
- Adaptability: the processing parameters of an intelligent sensor system should be determined automatically and adopted by a higher level in the system architecture. This enables the optimization of the measuring and processing operations, as well as enabling the sensor to adequately respond to changing environmental conditions.
- Bandwidth reduction: in the case where the number of sensors in a system is expanding, it might cause severe data processing bottlenecks. By localising signal processing and reduction, the data communication bandwidth can also be reduced. [19]
- Advanced data processing: enabling the "intelligence" to be implemented to the sensing strategy - this is perhaps the main advantage of using intelligent sensors above conventional sensors.

6 PROCESSING CAPACITY AND ARCHITECTURE IN INTELLIGENT SENSORS

An important advantage of intelligent sensors is the distribution of advanced processing methods to the point of measurement [20]. The capability of microprocessors is important for performance in smart devices. Digital signal processors (DSPs) are running faster and have improved development tools, making it simpler for designers to employ them in applications which need faster mathematical processing than general-purpose microprocessors can provide. DSPs also make it possible to run more diagnostics. Distributed smart sensors can integrate algorithms which would normally be run on a supervisory system. Local memory allows reference to look-up tables and historical data, allowing adaptable strategies. Local processing allows rapid, frequent measurement establishing good characterisation of both healthy and faulty data without unnecessary network traffic. Fast processors, especially DSPs, are power hungry and this will be an important problem for wireless systems.

A second advantage of intelligent sensors is the opportunity of working together in small or large numbers, and only communicating the results if necessary. A sensor array may be used to enhance reliability by allowing for redundancy. This may detect faults in the sensors themselves and allocate tasks to adjacent sensors. Different analysis tasks may be distributed to different processors within the array, allowing a single system to perform several analyses simultaneously. Recognition and analysis algorithms might be distributed across the array as a whole, creating spatially-distributed sensory fields, which can be particularly advantageous for multivariate monitoring problems and data fusion. Pattern recognition has been widely used off-line for diagnosis of mechanical and system faults, and sensor networks allow an online approach. Systems are likely to use all these possibilities, providing systems with specialised processing and an element of redundancy, providing powerful diagnostic procedures with graceful degradation in the case of individual sensor failure [19,24].

Advanced processing methods, currently only employed by researchers, can be embedded in distributed systems, and this is a key strength of intelligent sensors above conventional devices. The methods available are briefly described in the following sections, and are applications which are described by the data fusion architecture, where the concern is to extract information from data, supported by knowledge, in order to make estimations, classifications or decisions [21].

6.1 Pre-processing: sub-object level

The physical sensing element or transducer produces a response to its environment. The pre-processing stage converts the transducer's response to its input (e.g. temperature) into a more useful engineering quantity which is representative of the raw environmental parameter, such as electric current or voltage. Pre-processing includes software for calibration, which may include linearization, normalisation, and conditioning of the signal to correct for deviations, e.g. those caused by temperature effects or ageing in the sensor and its electronics. [17]

6.2 Information processing: object refinement

Information processing uses filtering and data manipulation for estimation, feature extraction and classification to achieve data reduction and event detection, enhancing and interpreting the collected data [18]. Learning techniques such as fuzzy logic or neural networks may be used to produce a high confidence feature from weak data. Some applications need qualitative (symbolic) characterization of the estimate, for example for rule-based control or diagnostics, where the variables are described by qualitative values for example large, small, increasing, decreasing [23]. The aim is to present the right information to the next level of the hierarchy, with the minimum necessary data. This is an important architectural feature of distributed systems, allowing more local data to be acquired and interpreted, while reducing network traffic – most systems are healthy most of the time.

6.3 Condition monitoring and fault detection: situation and assessment

A condition monitoring system firstly detects change from normal, and then attempts to determine the location, type and severity of a fault. Ideally we could make an estimate of remaining life. Distributed sensors immediately aid the determination of fault location. Local processing, e.g. the fast Fourier transform for feature extraction of a vibration signal, can be used for an indicator of fault type [22]. It is possible to store a look-up table of previous or typical data, to which feature data can be compared to determine severity.

6.4 Sensor modelling, configuration and uncertainty: process refinement

The interpretation of a sensor output depends on the models described in 6.1 and 6.2 above. They are usually simple, linear relationships, and are usually assumed to be constant with time. The rich data acquired from fast, regular sampling allows a better approach to the refinement of models. Non-linear models, such as kernel representations, and other data-oriented models, can allow automatic retraining of the sensor, which may be used to deal with ageing effects. Uncertainty estimates can be returned to a higher level in the hierarchy, which is important for some data fusion algorithms [17]. It is also possible to download new models after comparison with other sensors' behaviour. Compensation may be made to account for variation [18].

6.5 Communications

Intelligent systems require contact with a wider system to report normality and faults, and to be programmed. Traditional sensors are often limited by a lack of standardisation, leading to complex systems, high cost and low flexibility. Standardized transducer interfaces and communications protocols, which are sophisticated in wireless systems, result in autonomous, distributed, re-configurable sensors which are linked in a coherent manner efficient communications and fault tolerance [18].

6.6 Fault Tolerance.

Monitoring of the sensor system itself requires a specially robust architecture to differentiate real parameter changes from sensor faults [17]. Errors arise from behaviour which does not match the expected models, and if they are not detected, they will be introduced into the monitoring system. Fault tolerance issues can be considered at different levels [23]. Real time strategies allow the system to continue its operation with faults present. The fault may be compensated so as to avoid erroneous estimates, or the sensor system may be reconfigured to provide the estimate in another way, e.g. using different sensors. It is also possible to evaluate the system fault tolerance i.e. its ability to accept faults while being still able to run. This depends on the nature of the fault: critical resources e.g. the power supply, can only be tolerated by hardware redundancy.

6.7 Validation

The introduction of erroneous data to the system could cause serious problems, on a wider scale than a single sensor failure. If the data is plausible but wrong, the wrong decision could be made for a component or system, such as allowing an aircraft to fly with an incipient fault. The incorporation of validation into intelligent sensors increases the reliability of the system. The impact of errors can be reduced by redundancy, or at least a dense network where nearby sensors can be compared. Hardware redundancy uses extra sensors, comparing data which appears similarly on the majority of sensors. Analytical redundancy uses a mathematical model to compare the relationship between sensor measurements, computing the difference between an estimate and actual, with either an observer or a residual approach. This can become computationally expensive as complexity increases. The validation can qualify or disqualify the estimation or at least which evaluate the confidence level which can be associated with it [18,23].

A partial data validation approach is technological validation, which checks hardware resources, including power supply checksum of the microprocessor’s memory, and connection to the network. This does not check the data estimation, just the operating conditions [23].

7 RADIO FREQUENCY (RF) STANDARDS

Narrow-band radio technologies are finally disappearing, having limitations for some implementations. Several new technologies are making rapid progress. IEEE 802.11 (WiFi) may have a big impact in industrial markets. Bluetooth technology is still an alternative and a common industrial communication standard. Ultra wide band (UWB), is new to the marketplace and could be a serious option in many applications. This has caused a number of vendors to abandon their own radio systems and cease internal radio development effort in favour of the huge cost and effort saving of low cost wireless standards. This adoption of standard solutions (often created with other markets in mind) has served condition monitoring well before, e.g. in portable computing and instrumentation.

Table 3 shows the existing communication technologies. A short comparison of the most popular technologies and their parameters is presented in Table 4, and their range is illustrated in Figure 1.

Bluetooth still needs consideration as a generic solution. The Bluetooth consortium recently approved an industrial automation working group to address the concerns of the marketplace. Some vendors find it inappropriate for their particular market and applications. There are tradeoffs between cost and reliability in Bluetooth, but the technology should not be discounted just because it is not ideal; it may still be successful. Two spin-offs originating from the Bluetooth standard are Bluetooth enhanced data rate (EDR), with a better bandwidth, and a new protocol in industrial communication, ZigBee. A number of companies, including several new on the market, are actively bringing wireless technologies to market.

8 POWER SOURCES

Power for sensors is important, but for intelligent wireless sensors it is critical. The applications and systems architecture in a distributed system are affected by the performance of the power supply. A typical application uses a battery, which brings a tight restriction on the power consumption and the life of the device without maintenance. To reduce the power consumption, the processor should have three sleep modes: idle, which just shuts the processor off; power save, which leaves an asynchronous timer running; and power down, which shuts everything off except the watch-dog. Power consumption is inversely proportional to battery life. In some applications, up to ten years life is required. Processing, radio, and a typical sensor load can easily consume over 100 mW – compare this with the 30 μW when all components are in sleep mode. The power usage strategy must expedite tasks before returning to sleep mode. This power usage strategy is a key feature of the infrastructure software [25].

Power harvesting opportunities are a natural trend to improve the lifespan and maintenance free time of the installed sensors. Some sensor applications require a high level of self-sufficiency from the device and the harvesting of ambient power enables them to operate without maintenance – specifically a battery changing operation. Alternatives for scavenging power include vibrations, acoustic or millimetre wave energy through use of sensor resonators or piezo-electric devices, solar power and electromagnetic fields. The options increase as the radio range and power consumption diminishes. Sources are compared in Table 5.

Table 3: Figure1: Wireless Standards for Data Application [37]

Standard		Mature	New	Trial	Development
ETSI	2G	GSM GPRS	EDGE		EDGE Ph2
	3GPP	UMTS/WCDMA	TD-CDMA HSDPA	HSUPA	
	3GPP2	CDMA	1xRTT	1xEV-DO	1XEV-DV
IEEE	802.11	Wi-Fi.11b .11a .11g			.11n
	802.15	802.15.3 – UWB		MBOA/DS-UWB	
	Bluetooth	802.15.1 v1.1	v1.2 v2.0+EDR	.15.4(ZigBee)	
	802.16	WiMAX	.16c	.16d	.16e
	802.20	MAN			.20

ETSI standards including: 2G, 3GPP, 3GPP2 are the technologies used in mobile phones.

IEEE standards containing the range 802, are low range wireless.

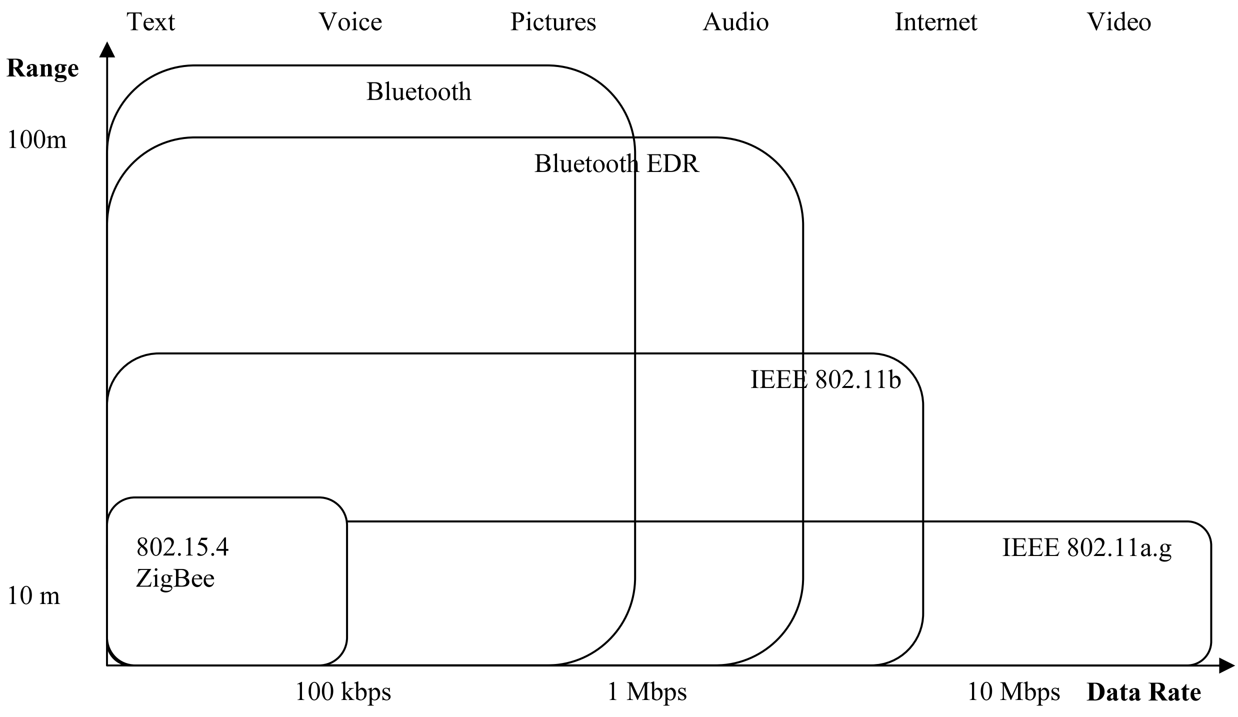

Figure 1: Range comparison at similar power levels [37]

Table 4: Comparison of Wireless Communications Protocols [36]

Parameter	Wi-Fi (IEEE 802.11)	Bluetooth (IEEE 802.15.1)	ZigBee (IEEE 802.15.4)
Range	About 50 m	About 10 to 100 m	About 10 m
Bandwidth/ Throughput	868 MHz/20 kbits/s 915 MHz/40 kbits/s 2.4 GHz/250 kbits/s	2.4 GHz/1 Mbit/s	868 MHz/20 kbits/s 915 MHz/40 kbits/s 2.4 GHz/250 kbits/s
Power consumption	400 mA (TX on) 20 mA (standby)	40 mA (TX on) 0.2 mA (standby)	30 mA (TX on) 1 uA (standby)
Protocol stack size	100 kbytes	100 kbytes	32 kbytes
Battery life	Minutes-hours	Hours-days	Days-years
Relative node physical size	Large	Medium	Small
Relative cost/ complexity	High	Moderate	Low

Table 5: Comparison of power Sources

Power source	Advantages	Disadvantages
Battery powered	• Long lasting source • Cheap solution • Reduced power management • Reliable technology	• Additional cost • Environmentally unfriendly • Limited/uncertain life span • Maintenance required
Online power supply	• No need for energy saving power management • Reduced cost of the device • Maintenance free • Reliable	• Cabling distance restrictions • Closeness to the source • No mobility possible • Reliable on the continuity of external supply
Power harvesting	• Maintenance free - No battery replacement • Enhance lifespan of device • Environmentally friendly • Modern approach with big prospects	• Complicated power management • Additional cost of device • Only applicable in right environment • Need for additional source or power storage when device was stopped

9 CONCLUSIONS

Over the past decade or so, intelligent sensors have risen from being an academic pipe dream into practical and commercial devices. The main reason for their continued success is largely as a result of the major advances in the area of microelectronic technologies. Limitations of conventional sensors can be compensated by the advantages brought by intelligent, miniaturised and wireless sensors.

Like any sensor, an intelligent sensor is primarily aimed at providing estimations of system variables, to be used in control loops, or in decision making for control, maintenance or management of the system. However, intelligent sensors are not components that are just interconnected to the rest of the application. An intelligent sensor should autonomously perform advanced processing functions such as self-validation, self re-calibration, fault detection, and sensory data filtering and feature extraction.

The presented functional view of intelligent sensors shows that features of interest from the scientific point of view are the growth in processing capabilities such as: estimation, characterization, validation and fault tolerance. On the contrary, due to the extra functions they implement, they fully participate in the architecture of complex distributed control systems by offering services at the supervision level.

One of the prime issues with wireless sensor networks is the power consumption of numerous sensor nodes and the requirements to provide periodic maintenance including battery replacement. This issue can be resolved by implementation of the energy harvesting methods, use of which can eliminate the need for battery replacement, making sensors even more independent and their functionality even more distributed.

Future research is likely to focus on advanced data processing directly in the sensor. True distributed data processing opens up new possibilities and future directions from the technological point of view. This shift from the conventional centralised data processing, moving the monitoring task direct to its source will be the main challenge for the future generations of the WINS (wireless intelligent network sensors).

Abstract: For higher recycling quotas of EOL goods, the recycling industry needs economic strategies for optimized reverse supply chains and recycling processes. Especially in the EOL area with a high degree of mixed materials, appropriate systems have to be used for supporting the recycler with decisions during the recycling of products. This paper aims to give an overview on relevant approaches which can help recycling companies to deal with the challenges of this highly dynamic environment. Furthermore, available tools and their application in the plastic recycling area will be presented.

Key Words: Automation, Communication systems, Complex Systems, Computer-aided work, Computer-integrated manufacturing, Decision support systems, Interfaces, Manufacturing processes, Tracking applications.

1 INTRODUCTION

Plastic Recycling Plants are traditionally related on the Small and Medium Sized Enterprise (SME) sector. Here decisions are usually more related on personal knowledge of the staff than on automated decision support systems. This causes insufficient processes because knowledge gained from single recycling processes cannot be reused for new production lots on customer demands. Another important issue, which makes this sector quite complex, covers the uncertainties related to the emergence of recycling material. Although there are predictable scenarios where for instance residuals from production are continuously delivered to recycling, processes are in more or less stable quantities. However, there are many other scenarios where the available material appears in unpredictable quantities. Furthermore the quality and composition of the incoming material can vary dramatically. In any case the recycling facilities are expected to fulfil the demand of their customers.

1.1 Sector description

In general the sector of recycling and especially the recycling of plastics is indicated by various uncertainties. The companies active in this field have to deal with various quantities which are delivered for recycling as well as volatile demands from the customers. These factors make reliable planning strategies very difficult. Another typical problem in the area of plastic recycling is the quality of incoming materials. The deterioration of recycled materials properties as compared to the virgin plastics can be caused by contamination, environmental degradation of the plastics in the course of their application, and thermal and mechanical loads during the recycling process. Examples for such quality indicators are thermal, mechanical or rheological properties of materials such as melting or glass transition temperature, elongation, yield strength, flexural strength, melt flow index etc. [1].

As it is seen from the Table 1 there might be a substantial difference between the properties of virgin and recycled materials that can effect their processing and as a result properties of end-use products. Thus today companies in the recycling sectors aim to react to different situations as flexible as possible. In many cases the proper reaction depends on the experiences of few people. In this context, a decision support system would be desirable which supports the decision maker and furthermore offers new potential for optimisation of the often complex recycling processes. At the end, such systems could help to make the whole process more transparent and thus traceable.

Table 1

Some properties of typical recycled polyethylene terephthalate (PET) compared with virgin PET

Properties	Virgin PET	Recycled PET
Melting point, °C	241	252
Recrystallisation temperature	176	193
Tensile modulus, MPa	2321	2367
Creep deformation in 0.5 min (at 100 °C and 0.05 MPa tensile load), %	2.1	3.2
Viscosity(temperature 270 °C, shear rate 25 1/s), Pa s	100.7	37.4

1.2 Decision support systems - State-of-the-Art

Depending on the application field there are different approaches for decision support systems (DSS). Each of them comes along with its own strengths and weaknesses and thus is applicable only for certain areas. However, keeping in mind the diversity of the decision problem, it is absolutely necessary to be aware of the main problem areas related to recycling. In this paper three problem areas in the recycling process are considered as the main ones:

1. Uncertainties regarding material quantities and qualities
2. Material treatment
3. Production, warehousing and logistics

For all of these areas particular approaches can be identified supporting the decision maker. The most important ones are listed below together with a reference to the problem area:

- Simulation (1, 3)
- Formal (mathematical) approaches (3)
- Expert Systems, Neural Networks (2, 3)
- Benchmarking (2, 3)
- Specific methodologies (2)

The list above shows that none of the methods is able to cover all of the problem domains. Thus a combination of several is desirable. Although all of the concepts mentioned are well defined and have been used for decision support in various areas, none of them are available in the form of user friendly tools. In particular, formal approaches like mathematical programming (e.g. integer / mix-integer programming) are used for problems related to production warehousing and logistics. However, significant knowledge is required in order to apply them which makes them unusable for domain experts as decision makers usually are. Methods from artificial intelligence, like neural networks or expert systems, usually suffer in this context from the necessity to train them or to specify complex knowledge bases. Their application is therefore often limited to certain scenarios. An extension requires significant effort. Benchmarking approaches require a significant number of cases / scenarios in order to be useful. The main problem in this context covers the willingness to deliver internal data.

Thus the most promising candidates for effective decision support systems in the field of plastics recycling are simulation-based approaches as well as certain methodologies which have been specified for particular problem domains together with accompanying tools in order to simplify their application for domain experts. In addition to the requirements regarding applicability as well as user-friendliness previously mentioned, an important issue in this context covers the integration of these approaches / environments into the value creation chain. Existing solutions will be shortly presented in the following chapter.

1.3 What can innovative technology offer?

An interesting question in this context covers the application of innovative concepts – like the concept of Product Embedded Information Devices (PEID) - which is considered in the PROMISE project (see section 3).

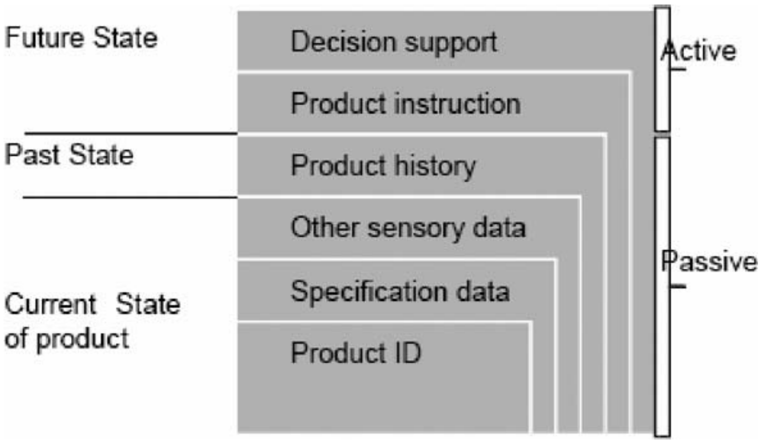

Figure 1. Product Information Model Enabled by Auto-ID [2].

In fact such technologies offer considerable potential to be exploited for decision support. As shown in Figure 1, the active behaviour of product entities could be utilised in order to develop completely new environments or enhance existing ones by making them more responsive due to the pervasive availability of product related information anytime and nearly everywhere. In particular available model-based solutions (like simulation) can benefit from such technologies because their main deficiency is in the timeliness of the information kept by the underlying model. Appropriate concepts exploiting the available information can reduce the costs and time for solution finding dramatically.

2 DSS INTEGRATION

With respect to the integration of the simulation-based DSS – ONE (see section 3) into the current scenario, the main goal is to provide real-time data for incoming materials and goods on the basis of the required specifications for PEIDs and RFIDs within the scenario. Real-time data will be provided for all of the relevant process steps within the scenario for the support of back-end systems such as Warehouse Management Systems (WMS) and Production Planning Systems (PPS). Afterwards the planning system will be able to simulate basic processes like purchasing and sales planning taking into account the availability of materials, maintenance costs, etc. on the basis of real-time in-formation provided by PEIDs.

All the real-time data information logistics which are offered by the PROMISE solution will be handled by the middleware. That means, the PROMISE middle-ware needs to be capable of managing the data flows among the recycling machines, transport systems, and control systems. Furthermore, it must provide the links between the software embedded in the PEIDs, PEID readers and back-end systems and should be based on platforms used in PROMISE and is compatible with other application scenario implementations.

In order to handle the potentially vast amount of product information generated within the scenario, the middleware must furthermore provide suitable filtering mechanisms for the data flow between the system components and especially toward back-end systems. To that end, it should include mechanisms such as plausibility checking, duplicate data avoidance, data persistence monitoring, etc. In that context, depending on the design and specification of both the middleware and the DSS, it is possible for the middleware to incorporate DSS functionality where suitable. Last, but not least, the middleware is expected to integrate suitable security mechanisms for protection of personal and process relevant data.

For the integration of the ONE tool with the PROMISE environment a pure data-based interface should be considered (at first) for the first step. Although more or less manual, this approach would allow the connection for less costs and efforts than for a more direct coupling which can be looked at a second step. Thus the exchange of data will be conducted via file creation, transmission and import into the ONE system. Especially for file creation internal mechanisms provided by the PROMISE platform will be applied in order to generate the right format and content. The import process is shown by the following screen shot (Figure 4). For each variable the system allows the specification of a constant value, according to a certain distribution function or in the form of a file where the data will be taken from. The example below shows the specification of a certain user demand.

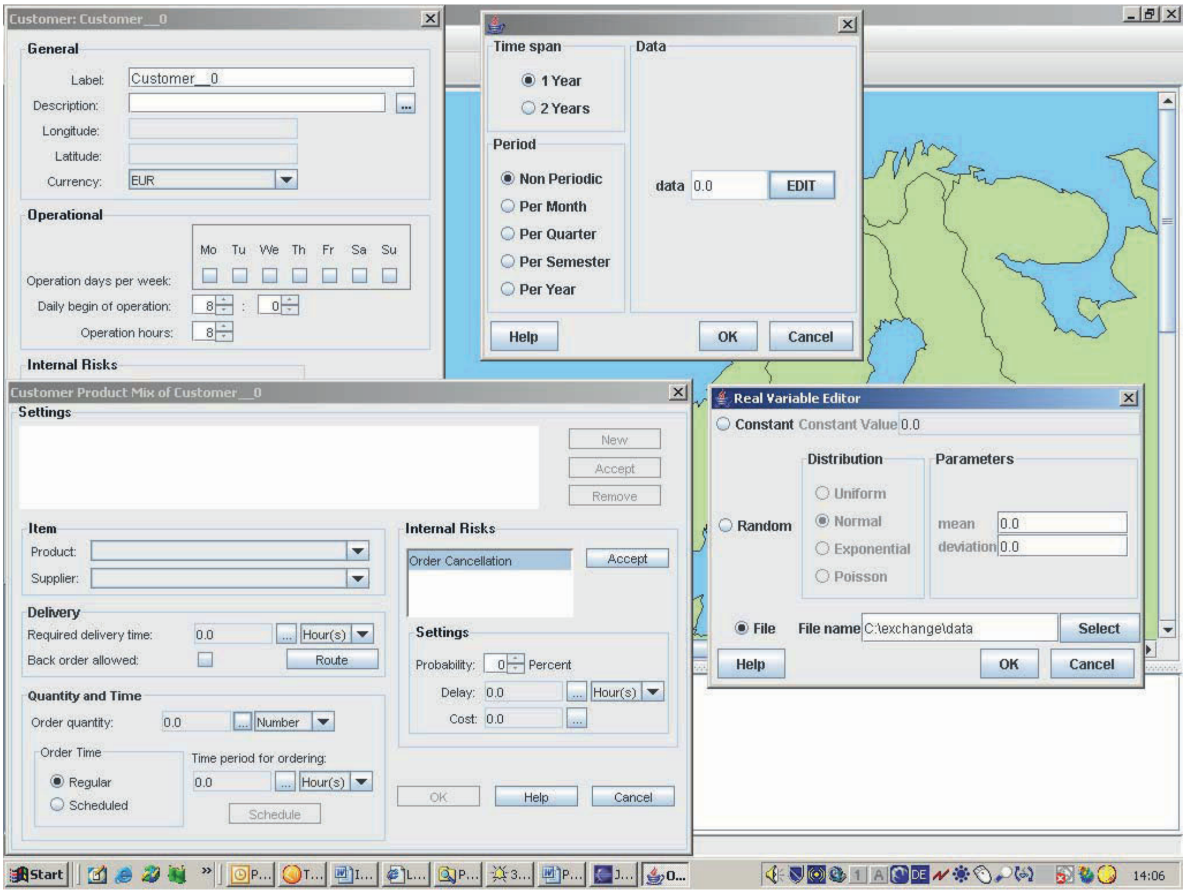

Figure 2. Data import in ONE.

After the import of the data representing customer demand for a certain period in time the DSS can support purchase planning as well as sales in determining available materials and sales planning. In addition, logistics solutions (distribution networks, etc.) can be planned and evaluated before being implemented in reality with the simulation component. Thanks to this component it is also possible to consider uncertainties regarding customer demand or the quantity of material available for recycling. Additionally, process related risks can be investigated, e.g. regarding the impact of delays of deliveries due to accidents or the technical breakdowns during the recycling process.

3 RESEARCH BACKGROUND

The described integration concept is based on different research projects, which will be shortly described in this chapter.

3.1 Product Lifecycle Management and Information using Smart Embedded Systems (PROMISE)

PROMISE is an international research project in the IMS (Intelligent Manufacturing Systems) program with industry and academia consortia in Australia, Europe, Japan and the United States (see Figure 3). The project concerns the whole information flow from Design, Production, Use-Service-Maintenance or MOL (Middle-of-Life) and Retirement or, as most commonly is called, EOL (End-of-Life). The European part (funded by the European Commission) will develop Information Models, Architecture and Implementation concepts for the PEID technology. This includes also models for decision making.

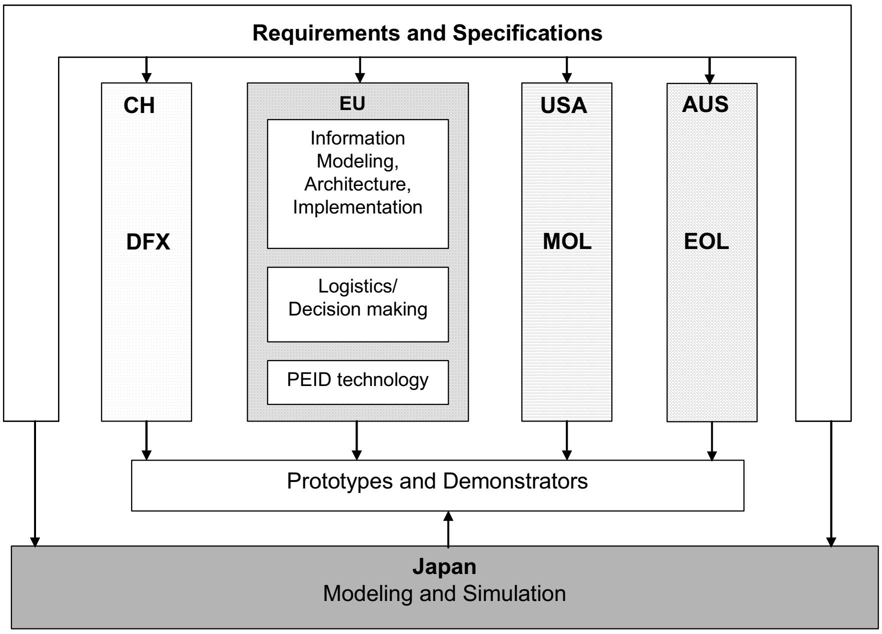

Figure 3. IMS PROMISE regional cooperation [3].

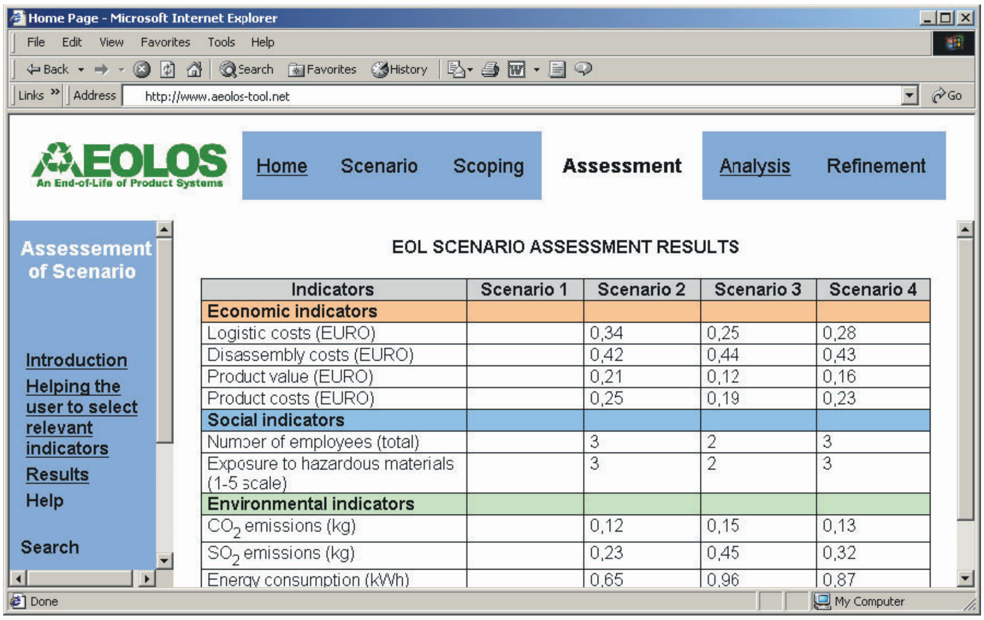
3.2 An End-of-Life of Product Systems (AEOLOS)

The methodology and toolset developed in AEOLOS will provide support to decision-makers both within the public sector and in industry. Stakeholders addressed by the AEOLOS are:

- Society"
    - as a heterogeneous group, and including future generations
    - as particular communities or interest groups
    - as represented by government at all levels
- Manufacturers
- Remanufactures
- Reclaimers
- Recyclers
- Incinerator operators
- Landfill operators
- Title owners of product and
- Distributors.

Decision-makers in all of these areas formulating policy at local authority, regional, national and EU levels will be supported with the means by which to determine, analyse and evaluate the most appropriate EOL treatment option from an environmental, economic and social perspective for their geographical areas of concern. Similarly, resource recovery/recycling companies and original equipment manufacturers (OEMs) will be provided with decision support as to the choice of EOL treatment options, based on a set of environ-mental, economic and social criteria. The solution is progressing with a methodology and a web-based toolset supporting it's application (see Figure 4 below).



EOL SCENARIO ASSESSMENT RESULTS

Indicators	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Economic indicators				
Logistic costs (EURO)		0,34	0,25	0,28
Disassembly costs (EURO)		0,42	0,44	0,43
Product value (EURO)		0,21	0,12	0,16
Product costs (EURO)		0,25	0,19	0,23
Social indicators				
Number of employees (total)		3	2	3
Exposure to hazardous materials (1-5 scale)		3	2	3
Environmental indicators				
CO_2 emissions (kg)		0,12	0,15	0,13
SO_2 emissions (kg)		0,23	0,45	0,32
Energy consumption (kWh)		0,65	0,96	0,87

Figure 4. AEOLOS web-based toolset [4].

3.3 Optimisation methodologies for Networked Enterprises (ONE)

The project ONE (Optimisation methodologies for Networked Enterprises) developed an integrated decision support tool for the evaluation and optimisation of existing as well as the planning of new supply chain networks. In this context not only monetary aspects were considered but also environmental and social impacts, along with certain network specifications. Furthermore, the tool supports risk assessment which means the analysis of the robustness of supply chain networks against unpredictable events such as accidents, bankruptcies or natural disasters. As another important issue, the tool is able to deal with uncertainties like volatile customer demand. The ONE-System encompasses the following components:

- A network modelling module providing user friendly support for graphical, interactive development of supply chain networks.
- A statistical data miner allowing the analysis of existing data material and the extraction of information (e.g. in the form of specific probability distributions for customer demand) in order to make network descriptions more realistic.
- A set of optimisation tools each of which supports the optimisation of certain aspects within a network model.
- In order to prove the impacts of changes or network configurations proposed by the optimisation module, ONE includes a simulation engine for the emulation of a network model.

Especially the consideration of uncertainties as well as risk together with the combination of optimisation methodologies and simulation makes the ONE system an interesting approach for decision support while dealing with today's highly dynamic supply chain network planning and optimisation. The combination of these functionalities make ONE a prime candidate for integration with new technologies like the one which is proposed by the PROMISE project.

4 CONCLUSIONS

The paper gives an overview about the specific requirements in the field of plastics recycling. Furthermore, different approaches for decision support within this area were discussed. It was shown that different concepts come along with their own strengths and weaknesses. Due to the requirements regarding applicability, user-friendliness and integration into the value creation process most of these concepts are not suitable. On the other hand, even promising environments – namely simulation as well as specific methodologies and the accompanying toolsets - are not able to cover all end-users needs on their own. Thus a combination of both concepts would be desirable. Furthermore it was detected that the most challenging requirement clearly concerns the integration of DSS tools into "real life". In this context the paper gave an overview about a possible approach demonstrated along the simulation-based DSS tool ONE. In addition, the potential benefits coming along with innovative concepts like the one which is considered by the PROMISE project were addressed. In this context major improvements regarding the accuracy of the results from available DSS solutions can be expected due to the improvement of the underlying model (information).

The PEID concept perfectly fits to the concept of GRID computing for the globally distributed topology comprising product entities and the associated information. Formerly more utilized in the field of high performance computing, GRID computing is nowadays investigated regarding it's suitability for other application fields, e.g. distributed enterprise networks. However, the integration of PEID and GRIDs can be an interesting approach, especially for the development of a new generation of decision support systems which are able to consider global environments for solution finding.

CONDITION BASED RISK MANAGEMENT (CBRM) – ENABLING ASSET CONDITION INFORMATION TO BE CENTRAL TO CORPORATE DECISION MAKING

D Hughes[1] G Dennis[1], J Walker[1] and C Williamson[2]

[1]EA Technology – UK [2]Thew & Mc Cann Pty Ltd - Australia

Abstract: CBRM is a process developed by EA Technology in conjunction with several major electricity companies [1-4] to assist with the tasks of defining, justifying and subsequently targeting spending to achieve defined levels of performance. The process has already delivered major benefits. If fully embraced, it can become the basis for effective asset management programmes that address the critical issues of renewing networks and maintaining reliability within an ever more challenging regulatory and financial environment

Key Words: CBRM, asset condition

1 THE CBRM PROCESS

The essence of CBRM is the provision of a structured framework that enables available engineering knowledge and experience of network assets to be readily and transparently linked to corporate decision making. Application of the process results in the fundamentally important decisions, relating to both operational and capital spending, being directly linked to asset condition and future performance.

One of the great strengths of distribution network owners and operators is the wealth of available asset specific and generic knowledge and experience relating condition, performance, degradation and failure mechanisms, operating context, maintenance regimes etc. CBRM enables this to be effectively utilised to deliver corporate objectives.

To understand the mechanics of CBRM it is useful to define the process by a number of sequential steps as listed below. A more complete understanding and appreciation of the potential of the process can then be obtained from discussion of its application and examples of the output in later sections.

1. **Define asset condition**. Derive 'heath indices' for individual assets and build health index profiles for asset groups. Health Indices on a scale of 0-10, 0 indicating the best condition, 10 the worst.
2. **Link current condition to performance**. Calibrate the health index against relative probability of failure (POF). Match the health index profile with current failure rate to determine health index/POF relationship.
3. **Estimate future condition and performance.** Use knowledge of degradation processes to 'age' health indices, ageing rates dependent on initial health index and operating conditions. Calculate future failure rates from aged health index profiles and previously defined health index/POF relationship.
4. **Evaluate potential interventions in terms of POF and failure rates**. Factor in the effect of potential replacement, refurbishment or changes to maintenance regimes, modify future health index profiles and recalculate future failure rates.
5. **Define and weight consequences of failure (COF)**. Construct and populate a consistent framework to evaluate consequences in significant categories, safety, network performance, environmental, financial etc.
6. **Build a risk model**. Combine POF and COF for asset groups to quantify risk. Total risk can be separated into previously defined categories. Total risk and risk within each category related to tangible quantities, £, CMLs, frequency of fatalities or serious injuries etc.
7. **Evaluate potential interventions in terms of risk**. Factor in the effect of potential replacement, refurbishment or changes to maintenance regimes, recalculate POF and COF and quantify risk reductions
8. **Review and refine information and process**. Learn from applying the process, identify opportunities to improve asset information and refine models and algorithms. Define and progressively build an improved asset information framework.

2 APPLICATION OF CBRM

2.1 Generating short term results

It is important to emphasis that CBRM has been developed as a result of working with individual electricity companies to achieve specific, short term objectives. In particular to assist companies to prepare for regulatory submissions. To define asset condition and create the framework for evaluation of potential investment plans within a relatively short and clearly defined timescale necessitated an approach that did not involve major information gathering. Therefore the initial applications were based on the principle of maximum utilisation of existing information.

Within every electricity company we have worked with (on CBRM projects or in other areas) we have encountered extensive knowledge and experience of almost all asset classes.

In addition to the specific internal information, there is also extensive knowledge and experience of degradation and failure processes for most asset groups. There is a good understanding of the critical issues that relate environment, duty, maintenance etc to the condition and performance of assets and huge body of generic (type specific) experience within individual asset groups.

CBRM is about using all this engineering knowledge and experience to maximum effect, creating a consistent framework to utilise this to define condition and link to current and future performance. It is about putting engineering knowledge and experience right at the centre of asset management decision making.

Our experience is that for major asset groups, including substation assets, overhead lines and cables from 11kV upward, health indices that provide a reasonable definition of condition and can be justifiably related to POF, are viable. Clearly, the nature of information available is quite variable and it is accepted that these initial health indices are not 'perfect', but based on the extent of engineering knowledge available they are deemed to be a credible definition of condition and performance.

A very important aspect of CBRM is that it requires a critical assessment of available information and identifies omissions that, if addressed, would greatly increase the confidence in the health index. It also clearly illustrates how information could be defined and collected in a manner that enhances future asset management processes. This creates opportunities to systematically improve asset information as discussed in later sections.

Having completed projects with many companies we have realised the value of working within a common framework relating health indices to POF. This had led to use of standard curves that are fitted to specific health index profiles and failure rates for each population. This enables direct comparison between different assets or similar assets in different locations and enables health index values to relate to consistent definitions of condition and performance. In essence, we now 'calibrate' each set of results against a common definition of condition and performance. By cross referencing results for similar assets in different locations with different performance levels we can greatly increase the confidence in the results.

A feature of the health index, POF and ageing methodologies used in CBRM is that at all stages they are related back to physical condition and degradation and failure processes and assessed in light of the practical experience of the assets. In this way there are a number of 'reality checks' that can be applied to the results and the predictions of future performance.

In the same way, the assessment of consequences and building of the risk model is based on practical experience and calibrated against tangible values. In most cases the actual total risk in a specific category (safety, financial, network performance) can be defined in real terms. Thus the final 'risk figure' for an asset group and the benefit in terms of risk reduction resulting from a particular investment programme can also defined using the same real values.

The CBRM process has been successfully applied to the full range of assets that make up distribution and transmission networks. The value obtainable in the short term is illustrated by example in the following section.

2.2 Examples of CBRM output

Health indices, POF and failure rates. The first output and the foundation for the rest of the process is the definition of asset condition in the form of a health index derived for individual assets. These are built into a health index profile, a distribution of health indices, for a population.

As described earlier, considerable thought has gone into the relationship between the health index and POF. An exponential relationship was initially identified as a reasonable description and subsequently this has been used to derive and calibrate health indices. The form of the basic relationship is shown schematically figure 1.

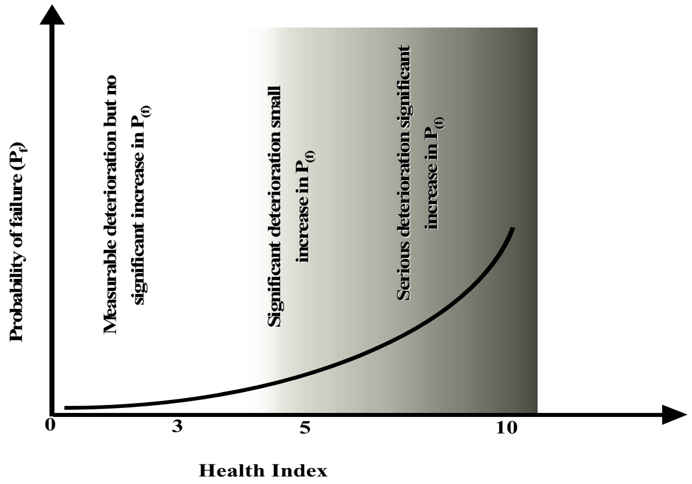

Figure 1

By adopting a consistent basis for the relationship between health index and POF, a health index profile gives an immediate appreciation of the condition of assets in a group and an understanding of the implication for future performance.

A health index derived for a population of HV OHLs based on a combination of condition and design information is shown in the profile in figure 2. Ageing this profile and factoring in the improvements in performance that would be obtained by rebuilding lines enables an estimate of the overall improvement in performance for different levels of investment, as summarised in tables 1 and 2.

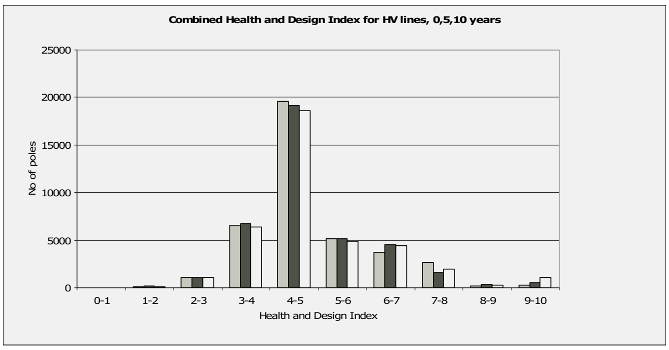

Figure 2, Combined condition and design index for HV OHLS

	Condition and design	3rd Party	Total
Current rate	0.064	0.028	0.092
Year 5	0.072	0.028	0.100
Year 10	0.085	0.028	0.113

Table 1: Fault rates (per km) assuming no rebuild

Table 2: Fault rates in year 10 for different levels of rebuild

Another example (figures 3&4) shows the health index profiles for a population of large transformers. In this case, different ageing algorithms are applied to transformers based on loading and environment.

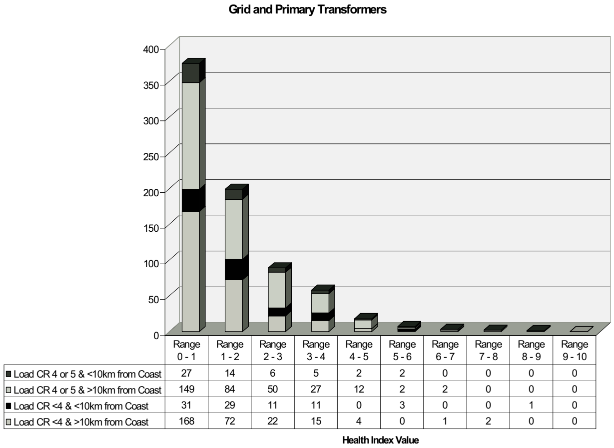

Figure 3, Current profile for population of grid and primary transformers

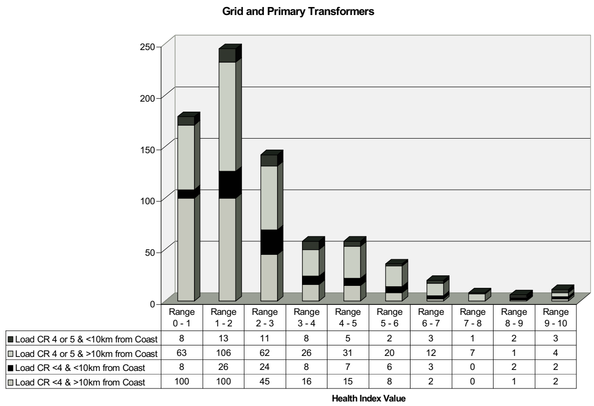

Figure 4, Profile in year10, assuming no significant intervention

Applying the calculated HI/POF relationship to the Year 10 profile indicates a 3 fold increase in rate of failure. Factoring in interventions reveals that to maintain the current (acceptable) failure rate would require 92 (out of 850) transformers to be replaced over the 10years. By considering the relevance and effect of refurbishment/remedial measures on an individual transformer basis and factoring these in, the same overall result can be obtained by a significantly cheaper option involving replacement of 45 transformers and refurbishment/remedial work on 70.

Risk calculations. The initial applications used health indices and POF calculations to define investment requirements to achieve a specified level of failure rate. More recently risk models (combining COF with POF) have been populated to provide a more complete means of optimising investment.

Risk is evaluated in 4 basic categories (financial, safety, network performance, and environmental). In each category the consequence of failure (the range and the distribution) are determined by consultation with experienced engineers and is calibrated against real values wherever possible, i.e. the number of CMLs resulting from failures of the asset group.

The relative weighting between each category is determined by relating each consequence to a common framework, value in monetary terms, e.g. the monetary value of a CML. This enables the overall risk for any scenario (with or without an investment package) to be calculated as a single number (of risk units, RUs). The total number can then be split down into the 4 categories and the effect (reduction in risk) achieved by different investments packages can be compared, as illustrated by the example in table 3 below.

A risk summary for a population of fluid filled cables.

Base Case, at the end of next regulatory period with no significant investment.

Option 1, including a programme to replace short sections, install additional stop joints and remake terminations at a cost of £12m.

Option 2, Option 1 with increased cable replacement at a cost of £16.5m

Table 3, Summary of risk for fluid filled cables

Risk Category	Base Case	Option 1	Option 2
Network performance	1,893	759	670
Safety	584	352	292
Financial	18,510	6,308	5,552
Environmental	21,653	6,980	6,114
Total	**42,640**	**14,399**	**12,628**
Benefit		28,241	30,012
Cost		£12m	£16.5m
Cost Benefit		424£/RU	549£/RU

1RU ≡ 1500CML,   1RU ≡ £70 OPEX,

50,000RU ≡ 1 fatality, 1000litres of oil ≡ 140RU

This risk model is still in the development stage and needs some refinement, nevertheless the results we are achieving provide an effective means of defining a complex and rather abstract quantity (risk) in a manner that can be related to tangible values. Encouragingly where the results have been presented and discussed with asset managers there has been a high level of satisfaction, both in terms of the relative values between asset groups and the overall presentation of risk, in a manner that can be directly related to engineering knowledge.

3 SHAPING THE FUTURE

3.1 Building CBRM into business as usual

The initial impetus to develop CBRM came from the need to define and justify spending plans in regulatory submissions. Great success has been achieved but it has been a labour intensive process to provide a one off snapshot of asset condition and risk. The potential value of building CBRM into everyday activities such that asset managers routinely have access to well defined asset condition information that can be used to actively manage asset is clear. Indeed the ability to target spending (both OPEX and CAPEX) to achieve defined benefits will be essential to maintain acceptable reliability while working within strict financial restraints.

'Built in' CBRM would give asset managers the ability to direct resources to achieve specific performance objectives, something that is absolutely essential in the increasingly demanding regulatory and financial environment.

3.2 Improved asset information – the key to future success

The key to implementing CBRM is access to appropriate asset information and therefore the key to building CBRM into business as usual is the creation of an information framework that gives asset managers access to appropriate information routinely. Improved asset information to enhance asset management decision making is seen as the key to success. Discussion of improved asset information usually leads to thoughts of huge IT projects, which involve mammoth cost and have very distant deliverables (probably the last thing electricity companies need at present). Contrary to this, the experience of implementing CBRM has revealed a real opportunity to achieve this objective (routinely available, quality information) relatively painlessly, incurring only modest initial costs with overall cost savings in the medium term!

During the development and application of CBRM, a real understanding of the nature and quality of information currently held by electricity companies has been obtained. This has highlighted the present deficiencies and provided an insight into the means of progressively improving the quality, relevance and consistency of asset information in an economic and practical manner.

A central feature of the CBRM process is the critical review of the information current available. This inevitably leads to identification of additional or alternative information that could be particularly useful in improving the ability to define condition and future performance.

Furthermore, activities involving extracting data from various sources and combining it to give a numerical value of health index, has demonstrated the difficulty of working with data in the variety of different forms currently available. The potential value of adopting a system that defines the results of all inspection or tests by a relatively simple numeric condition rating system then becomes clear.

The CBRM process, and some of the work to optimise maintenance that preceded it, also demonstrated the significance and importance of maximising opportunities to obtain critical condition information, in particular to integrate the information collection across the inspection and maintenance activities. This leads to significant opportunities to optimise the whole management process and generates significant OPEX savings, better targeted inspection leading to less invasive maintenance and the collection and storage of less (but more useful) data.

Another feature of the CBRM process is the principle of progressive improvement. The aim has always been to produce the best result possible with the currently available information and then define the means to progressively improve the output by improving the information. Improvements in information are obtained not with large expensive condition assessment activities, but by identifying potential useful information that can be obtained during existing, routine inspection and maintenance activities.

This is perhaps the most critical lesson. Distribution assets are visited frequently. By careful consideration of the information that will enhance decision making processes it is possible to define inspection protocols, using simple numeric condition ratings that will rapidly lead to a data resource that can routinely enable much more effective decision making. By targeting the information to meet specific requirements, the volume of data and the whole inspection and maintenance regime can be rationalised.

All this should be possible using existing IT infra structure. Creating an improved information framework is an engineering issue not a major IT project!

Applying the principles discussed above therefore provides electricity companies with a significant opportunity to inexpensively create an information framework that will enable targeted spending to deliver specific network performance at minimum cost. This is critical to future success. For UK companies this will enable delivery of DPCR4 targets and be excellent preparation for DPCR5!

Much of the development of CBRM has been in conjunction with UK electricity distribution network operators, initially in preparation for their last price review (2004). Subsequently several companies have embraced the principles of CBRM and are currently building them into their routine asset management activities both to provide the cornerstone of their next price review submission.

In recent months significant CBRM projects have been undertaken with major transmission companies in locations that include, China, Far East and Middle East. It appears that CBRM is an effective asset management tool in any language!

4 CONCLUSIONS

CBRM provides an effective means of linking the extensive engineering knowledge and experience of network assets, available in most companies, to corporate decision making.

Implementation has demonstrated it can deliver significant short term benefits.

The CBRM experience offers the opportunity to build an improved asset information base that would greatly enhance decision making capability. It would enable future spending to be defined, justified and targeted to deliver specific levels of network performance at minimum cost.

CBRM is a vital component of successful asset management in the ever more demanding regulatory and financial climate.

5 ACKNOWLEDGEMENTS

The authors are indebted to the many colleagues at EA Technology who have contributed significantly to the development of CBRM and to the numerous ‘partners’ in the participating electricity companies. CBRM only works if there is effective collaboration between all those who share knowledge and experience of the assets.

THE SOCIETY FOR MAINTENANCE & RELIABILITY PROFESSIONALS (SMRP)

C Armbruster [a] & T Byerley [b]

[a] SMRP Chair, www.smrp.org, / Corporate Reliability Engineer Manager,The J. M. Smucker Company

[b] SMRP Vice Chair, www.smrp.org / Director, The Maintenance & Reliability Center, The University of Tennessee

Abstract: The Society for Maintenance & Reliability Professionals (SMRP) is an organization formed by practitioners, for practitioners. SMRP is committed to and an advocate for excellence in Maintenance and Reliability professionals.

SMRP is incorporated as an independent, not-for-profit professional society. As such, SMRP Bylaws state the Society is organized and operated exclusively for educational, scientific and charitable purposes.

The Society has grown to international status with its vision to become *the* global organization best known for creating value through improved physical asset management

Key Words:maintenance practitioners,

1 INITIATIVES FOR MAINTENANCE PRACTITIONERS

1.1 Our History

SMRP was formed and chartered in 1992 to network those in the maintenance & reliability profession. SMRP continues that dedication, instilling excellence in Maintenance and Reliability in all types of manufacturing, service, and educational organizations.

1.2 Our Mission

SMRP will be the global leader:

- Promoting and supporting Maintenance and Reliability education for people, production and quality processes to improve the work environment.
- Supporting Maintenance and Reliability as an integral part of business and asset management.
- Presenting a collective voice on Maintenance and Reliability issues and advancing innovative reliability practices.
- Facilitating information exchange through a structured network of Maintenance and Reliability professionals.

2 MEMBER BENEFITS

-Educational Workshops

-Benchmarking and Standards

-Quarterly Newsletter

-Local Chapters

-Networking Database

-Advertising Opportunities

-Web Site and Discussion Boards

-Annual Conference

-Executive Member Meetings

-Membership Directory

-Speaker's Bureau

3 TYPES OF MEMBERSHIPS

Individual: at $125/person. Classifications include: practitioners, suppliers, consultants, students, military, academic, government, and non-profit trade organizations.

Executive: at $1,250/year. Include full membership privileges to five designated individuals. Executive memberships include free participation in Annual Benchmarking program, one vote at Annual Business Meeting, access to job posting program and other key benefits.

4 GOVERNANCE

The governing body is as depicted below:

2005-06 Board of Directors

Officers		**Directors**	
Chair	Chuck Armbruster	Define Body of Knowledge	Ramesh Gulati
Vice Chair	Tom Byerley	Education	Chad Sayle
Treasurer	Tim Goshert	Certify & Set of Standards	Dane Brooks
Secretary	David Staat	Improvce Members Services	John Schultz
Past Chair	Larry Cote		

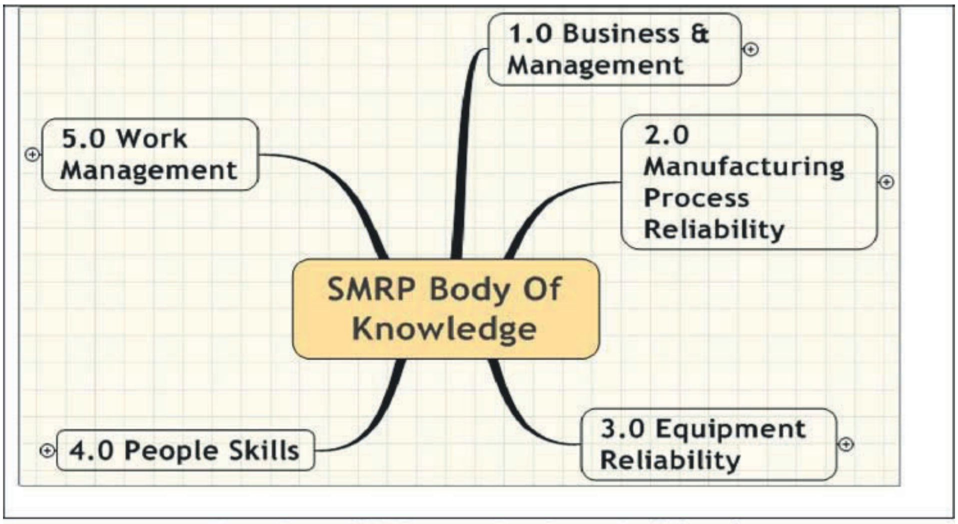
5 SMRP INITIATIVES

SMRP's leadership is comprised primarily of Maintenance & Reliability practitioners whose dedication and commitment to facilitating networking and the exchange of knowledge is impressive and unquestioned. Individually and collectively, the leadership is responsible for ensuring that SMRP's strategic initiatives are tied to our mission, purpose and vision, and that they are being implemented with the utmost sensitivity to quality, usefulness, timeliness and relevance.

These current initiatives include these four areas:

5.1 Define the Body of Knowledge

- Benchmarking- Seeking out the best practices that can be adopted to improve performance
- Best Practices- Developing Maintenance and Reliability metrics utilizing common terminology
- Body of Knowledge- Defining the Maintenance and Reliability professional. The subject areas include the areas found at the top of page:



Body of Knowledge Initiative

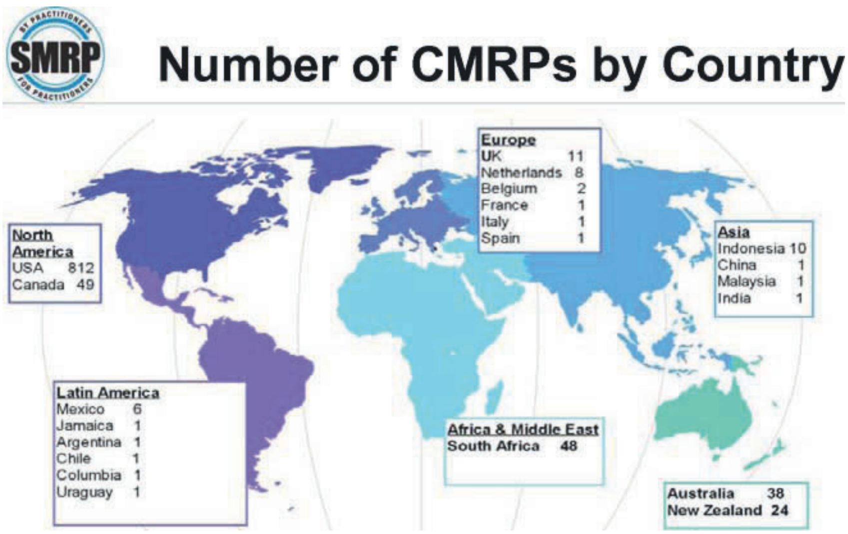
5.2 Educate

- Providing workshops and Executive Member Meetings
- Acting as a liaison between the private sector and educational institutions
- Executing outstanding annual conferences
- Developing the SMRP web site as the go-to resource for Maintenance and Reliability content

The SMRP Home Page (www.smrp.org) is shown below:

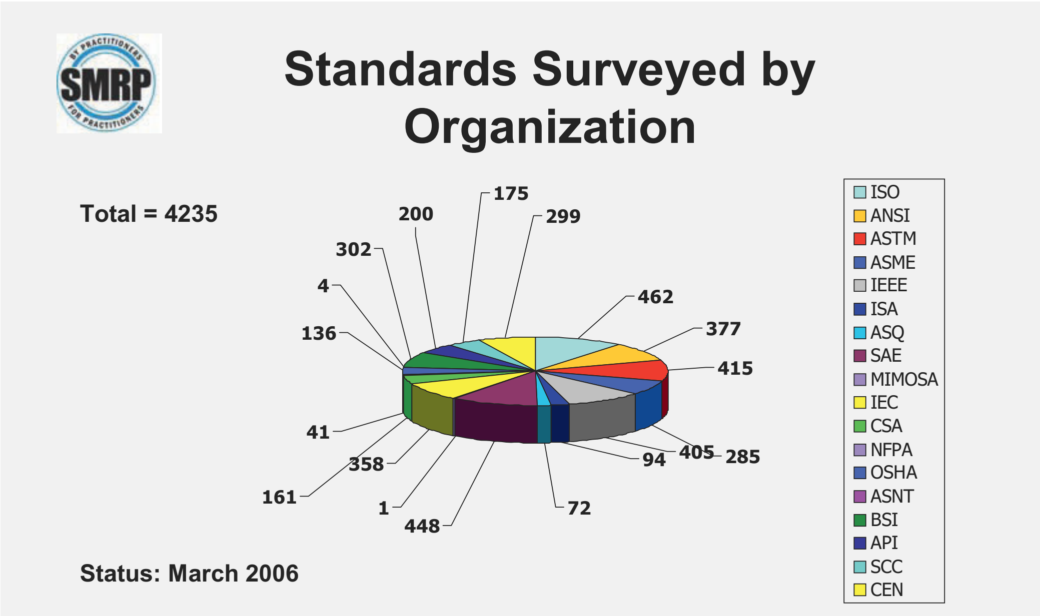
5.3 Certify & Set Standards

- SMRP Certifying Organization (SMRPCO)
  ** Prepares and conducts examinations for Certified Maintenance & Reliability Professional (CMRP) recognition
  ** The SMRPCO exam covers the five subject areas of BoK
  ** The Exam questions are developed by practitioners and statistically analyzed



5.4 Standards Committee

** Reviews, catalogs, and develops standards that affect the Maintenance and Reliability community
** Applying to ANSI for accreditation as a Standards Development Organization



5.5 Improve Member Services

- Enhancing membership value
- Promoting membership growth
- Establishing local chapters

MODELING RAIL WHEEL-FLAT DYNAMICS

NS Vyas & AK Gupta

Indian Institute of Technology, Kanpur 208 016, India

Abstract: Development of flats on the wheels of railway engines and wagons is one of the major causes of track and ride quality deterioration. Wheel flats are flat zones on the wheel tread caused by unintentional sliding of the wheel on the rail when the brakes lock. A fresh wheel-flat has the shape of a geometric chord on the wheel circumference. Forces from the wheels with flats can be up to four times higher than those from normal wheels. In this paper, wheel-flat and rail interaction dynamics is modeled through a finite element model. Typical wheel flat loading patterns are generated and response is computed for various cases of rigid and flexible rail supports and damping.

Key Words: Dynamics, Rail Wheel, Finite Element Model, Damping.

1 INTRODUCTION

A wheel flat is caused by the brake or some other mechanism, interfering with the normal angular velocity of the wheel. When brakes do not function properly, the wheel ceases to rotate and a flat develops due to plastic deformation. The dimensions of the wheel flat, its form and position on the tread depends on length of the wheel skid, axle loading, running speed, shape of rail profile, position of the wheel on rail, wheel material and the material coefficient of adhesion between the wheel and the rail material.

Wheel flats cause large dynamic forces on the rail. According to popular practices, flats on wheels should be restricted to a length of 60 mm and a depth of 0.9-1.4 mm. In this range the dynamic wheel load increases by approximately, 30 kN/mm for timber sleepers and 50 kN/mm for concrete sleepers. Wheel flats are also known to inflict very high acceleration levels (about 500g) on the track. These high vibrations get transmitted to the rolling stock, which induce forces much larger than permissible values and cause damage to the suspension system, frame and the body of the rolling stock.

The general problem of rail-wheel interaction attracted attention as early as the year 1847, when a British commission was appointed to study dynamic effects on railway bridges. The differential equation of deflection was established by neglecting inertia of the bridge and by considering the moving load as a concentrated mass. An exact solution of the equation was obtained by Stokes [1]. Timeshenko [2] solved the problem of a pulsating forces moving with uniform velocity along a beam. Lowan [3] studied the case with variable velocity of traversing force. These investigations pertained to single span structures. Ayre, Ford, and Jacobsen [4] studied transverse vibration of a two - span beam under action of a moving constant force. Some of the more recent works include a study carried out by Cai, Cheung and Chan [5] who analysed the dynamic response of an infinite continuous beam subjected to a moving force. For multi-span beams most researchers have used Finite Element methods. Nielsen and Igeland [6] have investigated the vertical dynamic behaviour for a railway bogie moving on a rail by use of an extended state-space vector approach in conjunction with a complex modal superposition for the track. Effects of imperfections on the running surface of wheel and rail were studied by assigning irregularity functions to these surfaces and contact forces were calculated for moderate vehicle speed in the presence of wheel flat. Thambiratnam and Zhuge [7] developed a simple finite element model to analyze simply supported beams on an elastic foundation of any length, where the foundation has been modeled by springs of variable stiffness. Abu Hilal and Zibdeh [8] investigated vibration of elastic homogeneous isotropic beam with general boundary condition traversed by moving force. Wu and Shih [9] have studied dynamic response of railway and carriage under the high speed moving loads. Dynamic response of the rail and carriage due to action of multi-roller carriage was determined by means of the finite element method. Wu, and Thompson [10] have investigated vibration analysis of railway track with multiple wheels on the rail.

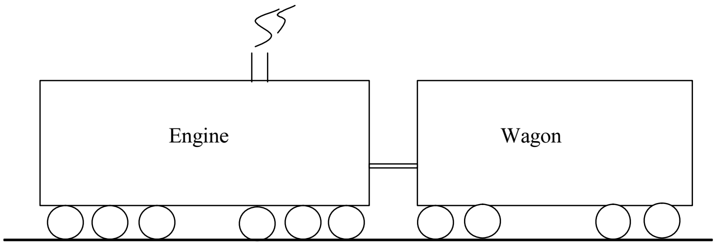
In this paper wheel-flat and rail interaction dynamics, modeled through a finite element model is described. Typical wheel flat loading patterns are generated and response is computed for various cases of rigid and flexible rail supports and damping.

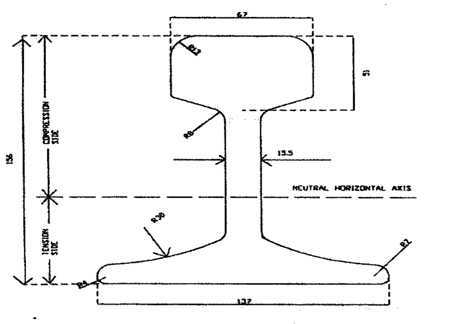
2 MODEL AND ANALYSIS

Rail vibration under loading due to normal wheels is estimated initially and then modeling is extended to incorporate loading due to wheels, which have developed flats. Modeling is done through the Finite Element package NISA and the wheel loads are treated as moving loads.

2.1 Rail Data

Analysis is carried out for typical data obtained from Indian Railways. A railway train comprising of an engine and one wagon is considered. A schematic of the train is given in Fig.1 (a). The engine has 12 wheels (six wheels on either side). The wagon has eight wheels, four on either side. Analysis is carried out for only one side of the railway track. The rail cross-section is shown in Fig. 1 (b). The data employed for the analysis is listed below:





(All dimensions are in mm)

Fig 1 (a) Schematic diagram of test train

Fig 1 (b) Rail section

Cross section area of rail	66.15 x 10-4 m^2
Moment of inertia	2158 x 10-8 m^4
Distance between two-sleeper pads	0.6 m
Young modulus of rail	2.0678 x 1011 N/m^2
Density of rail	7600 Kg/m^3
Speed of train	36 km/h (=10m/s)
Wheel diameter	1 m
Load on each wheel of engine	92214 N
Load on each wheel of wagon (empty)	29062.125 N
Total Number of wheels in the engine	12
Total Number of wheels in the wagon	8
Damping ratio of rail (rigid support)	0.05
Stiffness of sleeper pads	2.5 x 108 N/m
Damping ratio of rail (flexible support)	0.1

The weight of the engine and wagon is taken to act on the rail through the wheels as point forces. The respective weights of the engine and wagon are assumed to be equally distributed among the wheels. At the initial time instant the first wheel of the engine is assumed to be at node 1 of span number 1 of the rail. Table 1 gives the wheel loading data for all the ten wheels (6 from engine and 4 from the wagon).

Table 1

Wheel loads, distances and arrival times at node 1 (Train velocity =10 m/s)

Wheel No.	Arrival time at node 1 (s)	Wheel load (kN)	Distance from first engine wheel (m)
1	0.00	92.214	0.0
2	0.21	92.214	2.1
3	0.42	92.214	4.2
4	1.05	92.214	10.5
5	1.26	92.214	12.6
6	1.47	92.214	14.7
7	1.79	29.062	17.9
8	1.99	29.062	19.9
9	2.44	29.062	24.4
10	2.64	29.062	26.4

Total time taken to cross rail by train = (rail length + train length) /velocity = (9 + 26.4)/10 = 3.54 s

2.2 Finite element model

Two models of rails are developed - (i) rail with rigid supports (ii) rail with flexible supports. A rail track of 15 spans is considered. The length of each span is 0.6 m. Different scenarios with wheel flat falling on the supports and in-between supports, are discussed. Details of the FE model are given below:

(i) Rail with rigid support

Type of element	2-D beam
Order of element:	1 (linear)
Degrees of freedom per node	3 (u_x,u_y,r_z)
Number of nodes per element:	2
Total number of elements in rail	118
Total number of nodes in rail	119
Total length of rail	9 m

u_x = 0 is taken at all nodes of rail and u_y = 0 at supports only

(ii) Rail with flexible supports (in addition to the data of case (i))

Type of element of spring	2-D translation
Order of spring element	1(linear)
Degree of freedom spring element	2 (u_x,u_y)
Number of nodes per spring element	2
Total number of spring elements	15

u_x =0 is taken at all nodes of rail and u_y =0 at one end of spring element only. The above models are shown in Fig 2 (a) and Fig 2 (b) respectively.

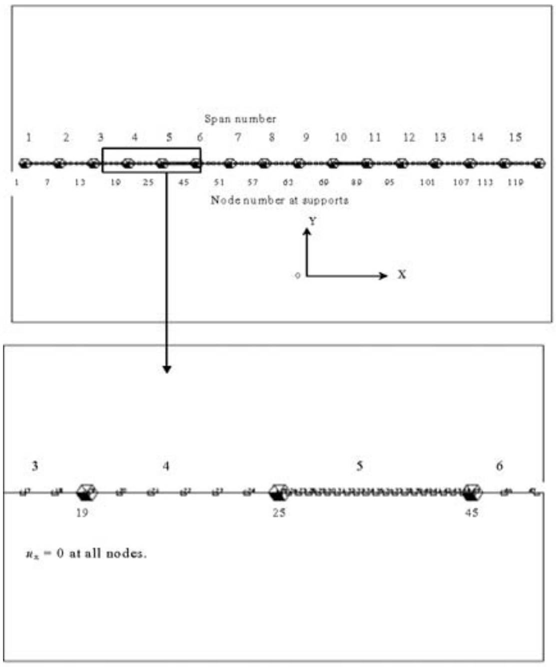


Fig 2(a) Finite Element model of 15-span rail-rigid supports

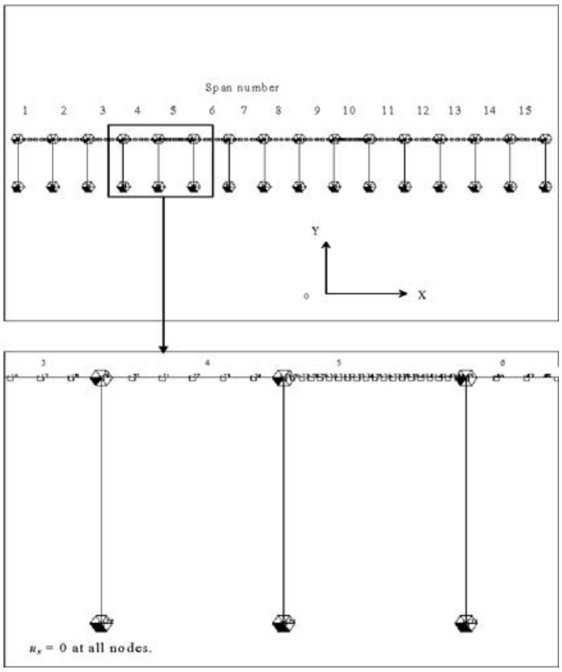

Fig 2(b) Finite Element model of 15-span rail-flexible supports

2.3 Free vibration characteristics of rail

Eigenvalue analysis of the rail was carried out in NISA using conventional subspace iteration and consistent mass formulation. Table 2 gives the first five natural frequencies of rail for the rigid support and flexible support models. The corresponding mode shapes are given in Figs. 3 (a) and (b).

Table 2

First five natural frequencies of rail (rad/s)

Mode No.	Rigid support	Flexible support
1	7842.73	2854.00
2	7941.44	2854.11
3	8230.34	2862.73
4	8690.14	2891.54
5	9295.03	2955.22

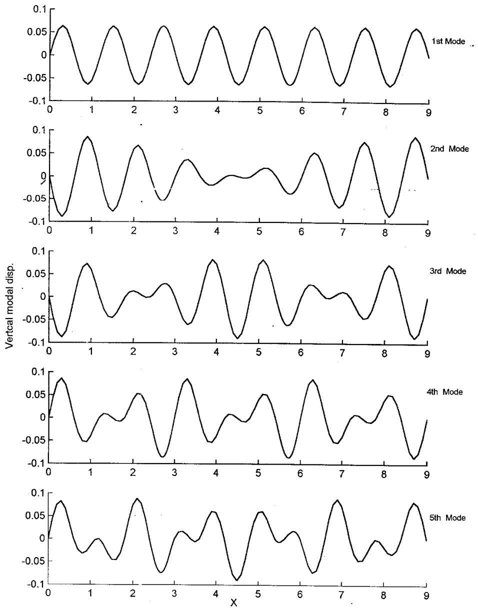

Fig 3(a) Mode shapes of rail – rigid supports

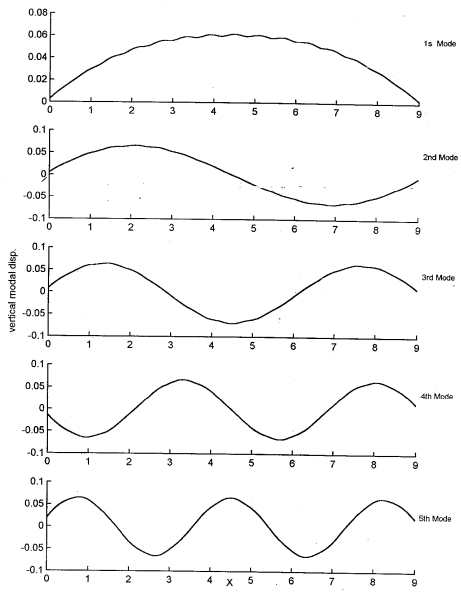

Fig 3(b) Mode shapes of rail – flexible supports

2.4 Wheel flat loading

The loading pattern caused due to out-of-roundness of the wheel depends on the severity and shape of the damage on the wheel. The out-of-roundness is however idealised by a flat on the surface, which would be seen as a chord on circular profile of the wheel. Such a flat results in loss of contact between the wheel and the rail for a short time and then regaining of contact. This idealised lift and hit phenomenon is shown in Fig. 4. When there is no contact, the wheel rises above the rail. Recovery of contact results in a large impact force. However, due to the bogie suspension system, the loss of contact between the wheel and the rail is not total, since the wheel moves downwards and the rail moves upwards. The overall effect is that the contact surface initially decreases and later, due to inertia, the wheel continues downward motion resulting in an increase of contact force.

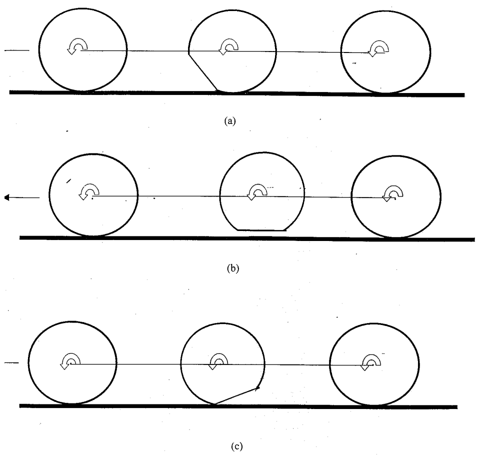

Fig 4 Lift and hit phenomenon of wheels

2.5 Rail vibration under moving train

Deflection and acceleration are computed for point loads from the ten moving wheels for the following cases:

(i) Undamped System (a) without flat (b) with flat
(ii) Damped System (a) without flat (b) with flat.

The wheel flat is assumed to be present on the 10th wheel of the train. Chord length of the flat is taken as 60 mm. Forced vibration analysis is carried out in NISA and 30 modes are taken under consideration. The wheel-flat hits the rail on the 5th and then on the 10th span. In order to improve accuracy 20 elements are taken on these spans, while on the remaining spans the number of finite beam elements are 6. Thus, the response is computed for 119 nodes on the rail. The loading patterns for cases with and without wheel flats are shown in Fig.5 for 10th span. The flat wheel looses contact at node 33 and regains it at node 35. Again, it looses contact at node 82 to regain it at node 84.. The nodal distances and arrival time of the 10th wheel at these nodes along with the tenth node (which sees normal wheel behaviour) are listed in Table 3.

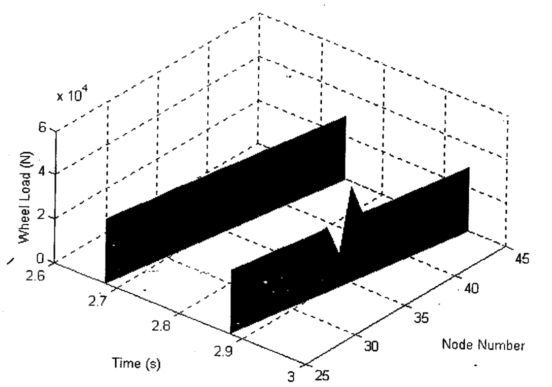

Fig 5 Load pattern of 10th span under 9th, 10th wheels

Table 3

Nodal distances and arrival time of 10th wheel

Node Number	Distance from Node 1 (m)	Arrival time of the 10th wheel (s)
10	0.90	2.730
33	2.64	2.904
34	2.67	2.907
35	2.70	2.910
82	5.79	3.219
83	5.82	3.222
84	5.85	3.225

Node 35, where the hit occurs for the first time, lies in the centre of a beam span (number 5). Node 84, where the hit takes place for the second time is close to a support (i.e. a sleeper). The vibration of rail is expected to be more due to the first hit, in comparison to the second hit. For the undamped system with rigid supports the displacement response at nodes 10, 33 and 35 is shown in Figs. 6 (a)-(c). It corresponds to the normal case (without flat). Figs 7 (a)-(c) give the response in the case of a wheel with flat. The corresponding acceleration responses are shown in Figs. 8 (a)-(c) and 9 (a)-(c). It can be seen that while each wheel causes distinct deflection as it passes through each node, the acceleration response does not provide a clear picture since it comprises of a large number of frequency components. It can be said that measurement of displacement response through strain gauging techniques can provide better information than that obtained through measuring acceleration, using accelerometers.

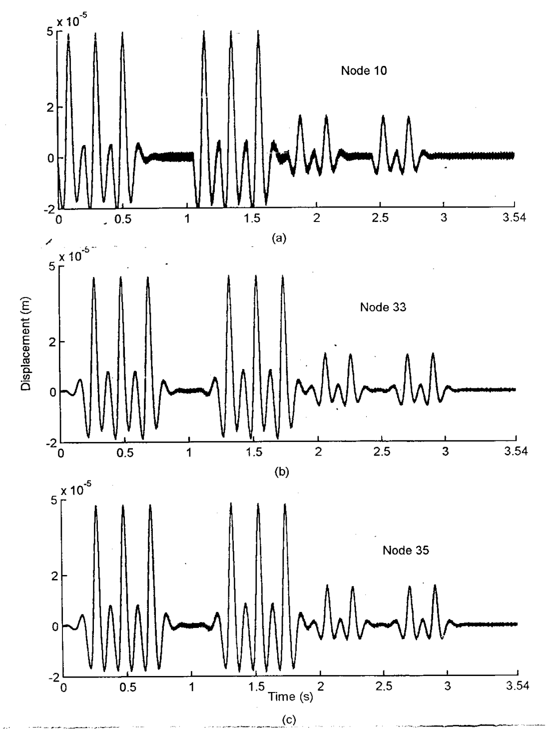

Fig 6 Rail response for Case 1(a) Rigid supports (a) node 10, (b) node 33 and (c) node 35

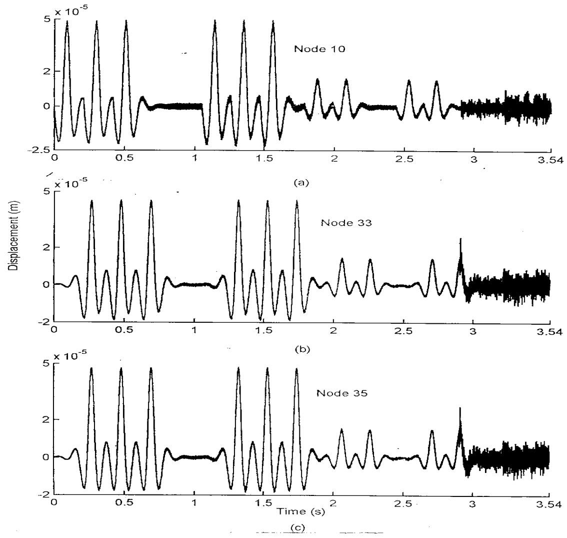

Fig 7 Rail response for Case 1(b) nRigid supports (a)node 10, (b) node 33 and (c) node 35

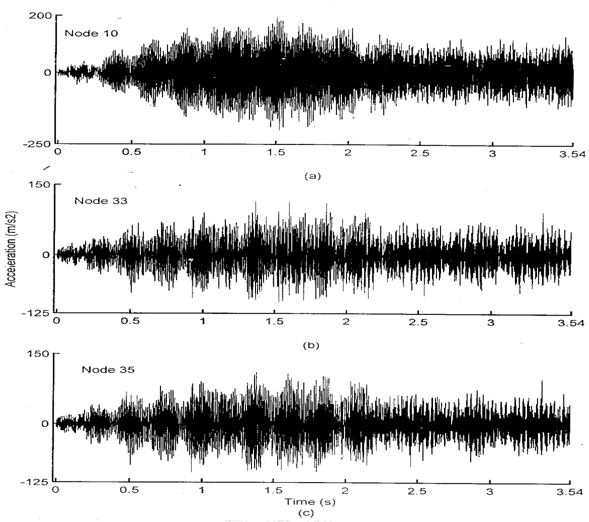

Fig 8 Acceleration response for Case 1(a)Rigid supports (a) node 10, (b) node 33 and (c) node 35

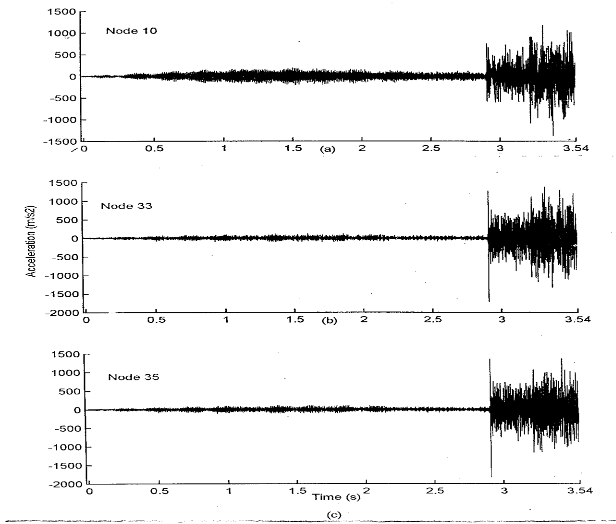

Fig 9 Acceleration response for Case 1(b) Rigid supports (a) node 10, (b) node 33 and (c) node 35

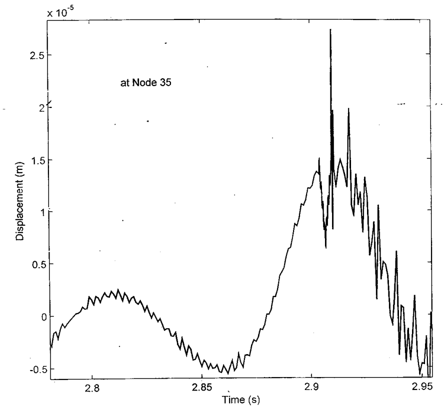
From the plots of Figs. 7 (b), the impact caused by the wheel flat is clearly visible. The maximum deflection due to the engine wheels is 47.82 μm at node 35. Maximum deflection, at node 35, due to the wagon wheels is 15.59 μm in the absence of any flat, while it rises to 27.35 μm, when a flat is present. Occurrence of this increase in the maximum deflection can serve as an effective tool for wheel-flat detection. The zoomed picture of the response under wheel flat loading is depicted in Fig.10, which clearly indicates the lift and hit mechanism of the wheel flat discussed earlier.



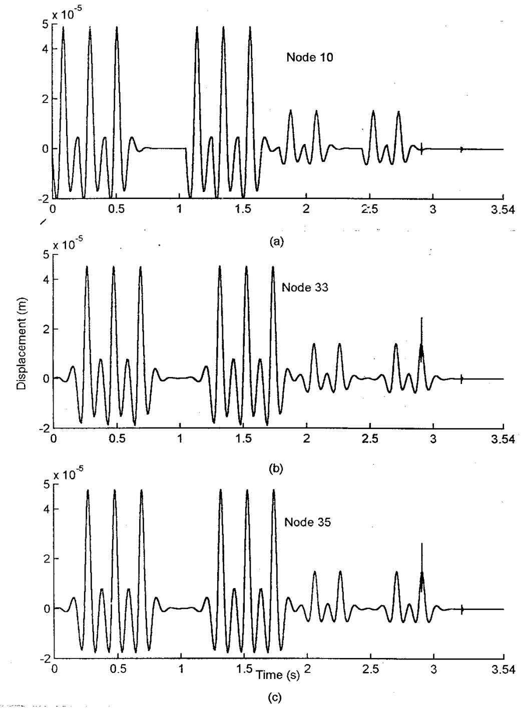


Fig 10 Zoomed view of response for Case 1(b) Rigid supports

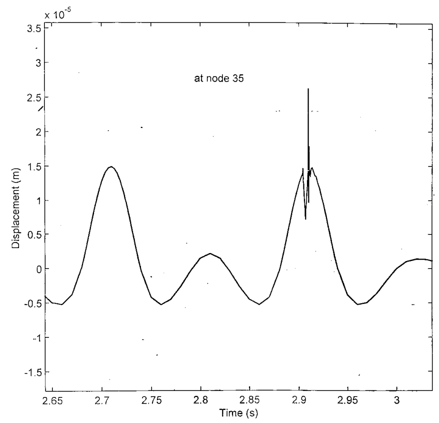
Fig 11 Rail response for Case 2(b) Rigid supports (a) node 10, (b) node 33 and (c) node 35

The response for the damped system is shown in Figs. 11 (a)-(c). The inclusion of damping in the analysis, as can be seen, removes the free vibration components, from the response plots. The zoomed picture of the response under wheel flat loading is given in Fig.12. Computation is also carried out for cases where the rail support has been taken as flexible. The response in this case is shown in Figs. 13 (a)-(c). As expected, deflection is higher in this case than with rigid supports. The response at nodes 82, 83, 84 (for rigid supports and with damping) is shown in Figs. 14 (a)-(c). Comparison with the response at nodes 33, 34, 35, discussed earlier reveals that the deflection levels are lower and the impact due to wheel flat is also less pronounced. This is due to the fact that while nodes 33,34,35 lie in the centre of a beam span, nodes 82, 83, 84 are closer to a support (i.e. sleeper).



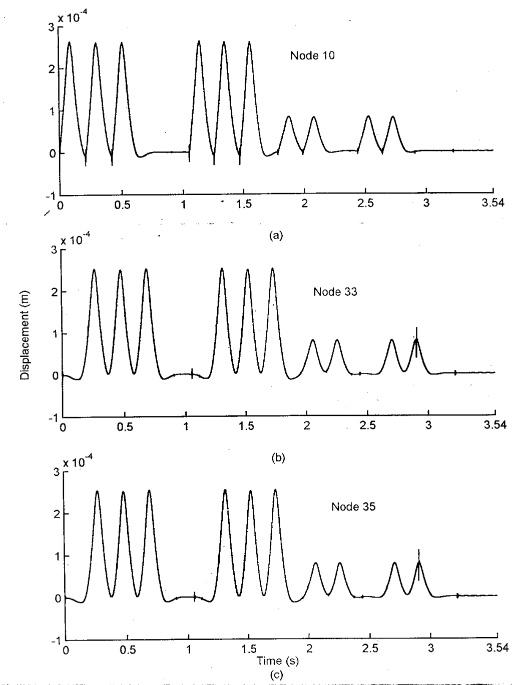


Fig 12 Zoomed view of response for Case 2(b) Rigid supports

Fig 13 Rail response for Case 2(b) Flexible supports (a)node 10, (b) node 33 and (c) node 35

The maximum deflections caused by the wagon wheel, in various cases discussed above are listed in Tables 4.

Table 4

Maximum deflection due to wagon wheel (at node 35) in μ m

Type of support	Without flat		With flat	
	Undamped	Damped	Undamped	Damped
Rigid support	15.59	14.89	27.35	26.26
Flexible support	221.26	79.67	203.00	109.75

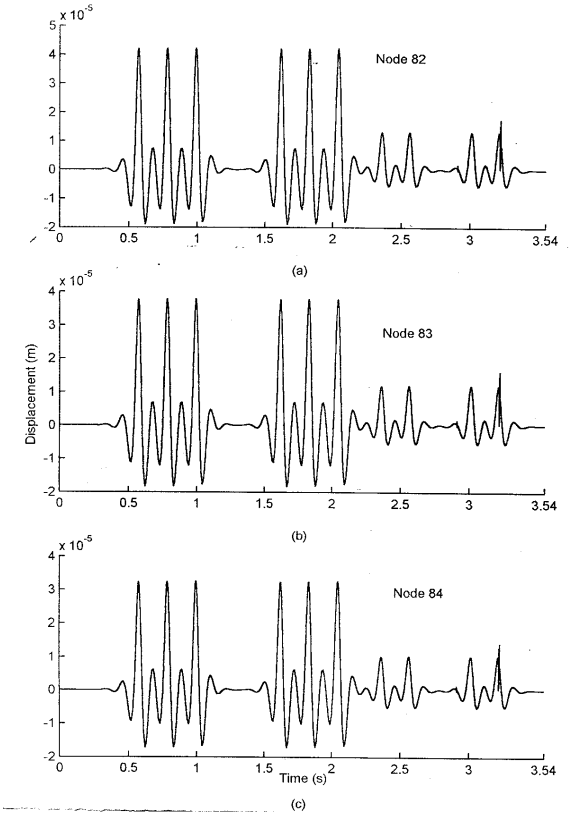

Fig 14 Rail response for Case 2(b) Flexible supports (a) node 82, (b) node 83 and (c) node 8

3 CONCLUSION

The analysis reveals that flat zones on the rail wheel periphery cause impacts on the rail with a magnitude nearly twice as much as the normal rolling force. It is important to identify these deformities and isolate such wheels quickly in order to prevent rail fractures.

TOWARDS AN ASSESSMENT TOOL FOR THE STRATEGIC MANAGEMENT OF ASSET CRITICALITY

D Anderson [a] P Keleher [a] and Peter Smith [a]

[a] *Faculty of Sciences, Engineering and Health, Central Queensland University, Queensland, Australia*

Abstract: Many organisations in both the private and public sectors rely on engineering assets to provide products and services. The failure of these assets, or their components, can have undesirable consequences for the organization. Failure consequences can be measured in terms of their impact on the safety of personnel, the public and the environment, and on their impact on desired levels of service or output. Existing decision tools for determining the criticality of asset failure are typically rigorous and detailed. They are necessarily time consuming methodologies. A strategic management approach seeks to focus the effort and cost of such detailed analysis more appropriately. It recognises the value of the expert knowledge of those directly engaged in operations and maintenance functions in supporting a strategic approach to the assessment of asset criticality. The purpose of such a tool is to quickly and effectively identify critical assets within a facility to assist strategic decision making. The assessment tool being trialled is to support the Maintenance function of organisations and therefore it is focussed on the Operations and Maintenance phase of the asset life cycle. This paper presents an overview of the alternative methodology being trialled and some examples of its practical application.

Key Words: Asset, Failure, Consequence, Criticality, Probability, Risk, Methodology

1 INTRODUCTION

Expert knowledge based assessments of asset criticality are necessarily qualitative. They are best supported by a systematic and standardized methodology that underpins qualitative rigor and enables assessment to be open to external audit. This paper (a) explores the concept of asset criticality, (b) describes the systematic approach to qualitative assessment that is being piloted, (c) outlines the results of the pilot study series completed and (d) draws some conclusions and makes some suggestions about future steps in the further development of expert knowledge based assessment tools of asset criticality.

2 THE CONCEPT OF ASSET CRITICALITY

Asset criticality can be determined asset by asset as part of a complete quantitative diagnosis of current state of the asset, its potential for future failure and the consequences of such failure. It may also be assessed in order to choose or sort assets into a priority list. The consideration of asset criticality in this paper is in the context of this latter, triage like, approach with a focus on prioritizing maintenance work to support asset operation and safety.

Asset intensive organisations rely on physical assets to produce products or services for end users or customers. The physical assets used by these organisations include industrial assets (plant and equipment) and infrastructure assets (drainage, water and sewer systems, bridges, roads, tunnels, and dams).

There are similar objectives identified for asset intensive organisations typified in statements by Rio Tinto [1] and Shell [2]:

- To operate profitably or economically
- To provide desired or agreed levels of service
- To operate safely in terms of consumers, the public and employees
- To operate safely with regard to the environment.

Asset performance in asset intensive organisations directly impacts on the ability of the organisation to meet objectives. The loss of asset capability through degradation or failure can impact significantly on the degree to which an organisation is able to meet their objectives. The Maintenance Engineering Society of Australia's Capability Assurance Model [3] draws a direct relationship between asset capability (function) and the achievement of organisational objectives. Kelly [4] describes the loss of asset function affecting the production and safety performance of a facility.

Asset criticality is defined in literature in different forms. Moteff and Parfomak [5] draw on numerous US sources to identify critical assets as those assets whose 'incapacity or destruction would pose a threat to security, national economic security, or public health or safety'. This definition is a more general view of asset criticality and less focussed on the physical failure of assets, rather a loss of asset function by any means.

An operations and maintenance view of critical assets is defined in the International Infrastructure Management Manual [6] as:

Assets for which the financial, business or service level consequences of failure are sufficiently severe to justify proactive inspection and rehabilitation.

This definition of critical assets is focussed specifically on decisions surrounding preventive maintenance actions arising from perceived modes of asset failure.

There are potentially many possible viewpoints of asset criticality. Examples of these viewpoints derive from the lifecycle phase of the asset [7] and organisational function that perceives asset criticality [8]. Models that describe asset criticality from all possible perspectives could be complex. The scope of the assessment in this paper is concerned with a perspective of the Operations and Maintenance phase of the asset life cycle and a view from the perspective of the Maintenance function of the organisation.

For the purpose of the initial study, the following definition of asset criticality is proposed:

A relative measure of the impact of the loss of asset function on the objectives of the organisation from the viewpoint of operations and maintenance.

This definition allows for asset criticality to be modified according to local business rules. A range of vulnerabilities is possible within the scope of the definition. This is considered to be a working definition. It is expected that this definition will be refined with experience of assessing criticality and feedback from industrial facilities.

3 CURRENT METHODS FOR IDENTIFYING CRITICAL ASSETS

There are few published methodologies for identifying critical assets. A search of current literature has identified frequent references to the need to identify critical assets, but little on a methodology for identifying critical assets [4, 5, 9, 10, 12].

International Standard IEC 60300-3-14 [9] advocates a preliminary 'Operation Use Study' as a precursor to developing maintenance policy. This study is to determine:

- items and systems that are important to meet process objectives
- items and systems that involve safety considerations
- operational patterns
- environmental conditions
- expected service life

There is no methodology or reference within the standard that describes how such a study might be performed or documented.

Kelly [10] describes a 'Top-Down' approach to identifying critical assets as a precursor to developing maintenance policy. The following steps to ranking critical assets are identified:

a) Construct a process flow diagram and establish a plant inventory
b) Understand the plant operating characteristics and the production policy
c) Rank units is order of their importance (criticality)

Kelly does not provide a methodology or reference that describes how such a study might be performed or documented.

There is evidence of asset criticality being based purely on failure consequence as used by Shell Brunei [11] to rank asset criticality. It is more common for a risk based analysis based on an assessment of asset failure consequence and probability [12] to be applied. Where failure probability is considered at component and failure mode level, as typified by Failure Modes and Affects Analysis (FMEA) [13], estimates of probability are valid. It is otherwise considered difficult to assess how probable a loss of asset function event is without a rigorous analysis of the way in which such a loss of function might occur.

Where an underlying principle is provided in support of the consequences of the loss of asset function, it is usual that criteria based assessment is applied. These criteria vary between approaches. A review of methods [8, 10, 9, and 11] identified the following criteria for assessing the consequences of loss of asset function:

- Repair costs
- Loss of income

- Loss of service
- Loss of life or injury
- Damage to property
- Failure to meet statutory requirements
- Third party losses
- Loss of image
- Location of asset
- Environmental Impact

There are two distinct categories of criteria identified from this list. These are 'mandatory' criteria dealing with Safety, Environmental and Statutory requirements and 'economic' criteria dealing with loss of income, service or damage to property.

The method of ranking asset criticality within the criteria is also varied across the methods reviewed. This is summarised by Jay [8], who identifies three common approaches to ranking asset criticality:

- High, medium, low;
- Scoring (e.g. 1,2,3,4,5);
- Weighted scoring.

Jay regards weighted scoring as being a more discriminatory and favoured method.

There is not one single approach in the methods reviewed that is considered to meet the requirements of defining critical assets as defined in this paper. There is an opportunity to draw on the strengths of current methods to create an alternate methodology for identifying critical assets.

4 AN ALTERNATE METHOD FOR IDENTIFYING CRITICAL ASSETS

4.1 General Description

The aim of developing an alternate method for identifying critical assets was to draw on individual features of existing methods to create an approach to:

- Identify assets;
- Rank critical assets;
- Be easily applied and reproduced;
- Take an operations and maintenance perspective of critical assets.

The following elements of a methodology were developed:

Asset Identification – a means of identifying and representing assets for the purpose of criticality analysis.

Criteria – a list of factors against which asset criticality could be measured.

Weighted Scoring – a means of allocating scores to achieve a total score indicating asset criticality.

Scoring Guides – templates for the application of scoring against each of the identified criteria.

Application – a means of applying the scoring to the criteria within an organization.

These elements are explained in more detail in the following sections.

4.2 Asset Identification

Assets were identified visually and models prepared. Assets were clustered in groups according to logical units or process function. This satisfied the layout of the facility, and also assisted with segregating assets for analysis purposes, described in more detail in section 4.5. Asset identification is demonstrated in the block model of Figure 1. In this example assets are represented as blocks interconnected with lines representing logical process flows or operational or reliability relationships.

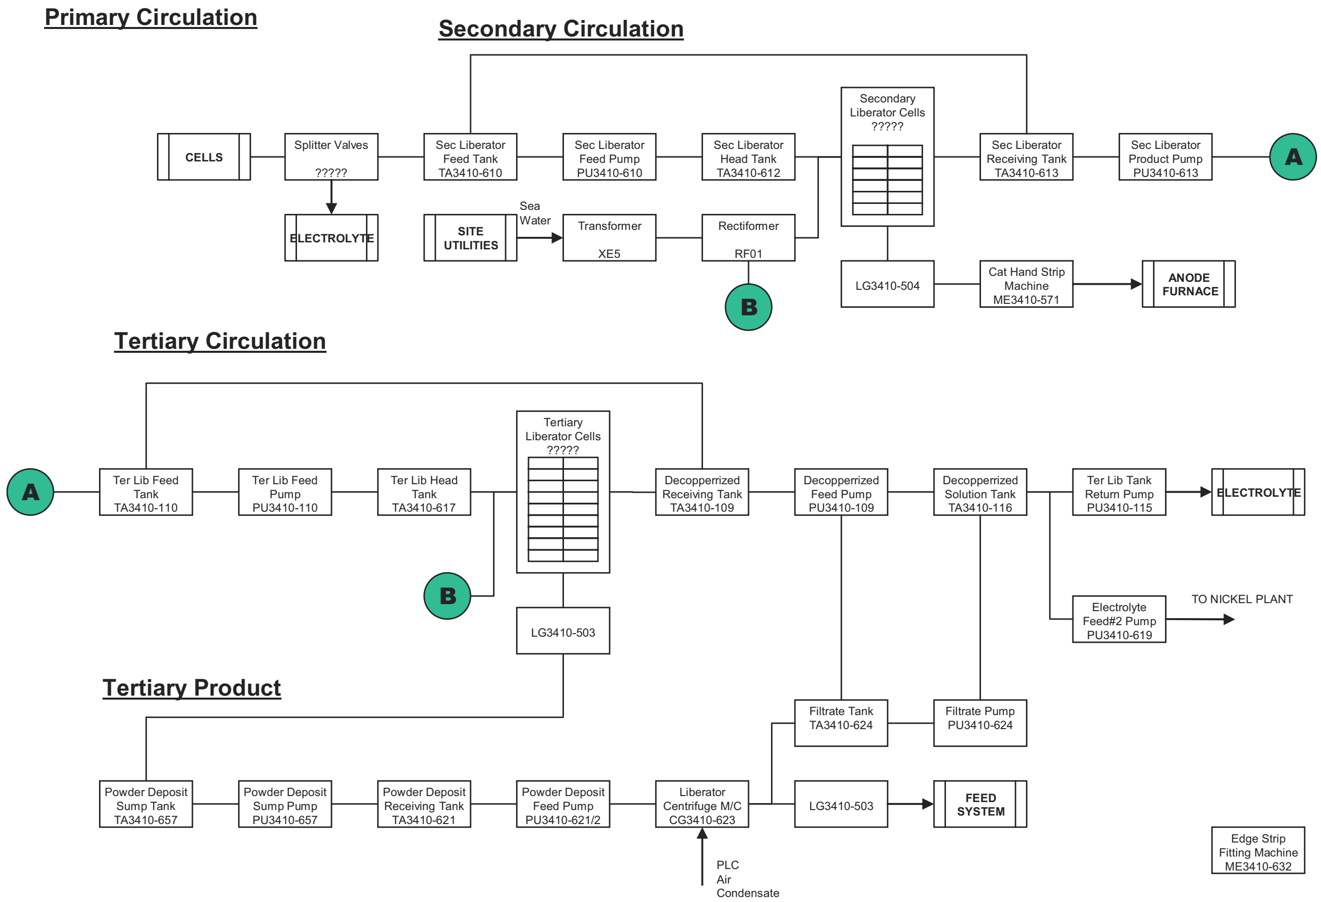

Figure 1- Asset Representation

Initial modelling of assets was performed based on recognising logical groups of components with a clear input and output or a definable function. It was also considered important to clearly identify stockpile or storage areas, inputs and outputs to the assets and links to other systems within the scope of the assessment.

4.3 Criteria

A criteria assessment using a weighted scoring method was selected for trial based on current methods. Initial criteria were based on the key business drivers of Health, Safety and Environment (HSE) and Output were readily identified from the function of maintenance. There was little logical basis for a ranking on two criteria. Additional criteria to assist in ranking based on probability were added to the criteria set. The criteria initially selected were:

Safety / Environment (mandatory) - the consequences of loss of asset function on the safety of personnel, the public, consumers or the environment.

Output (economic) - the consequences of loss of asset function on the loss of service levels, or the loss of revenue through termination of production, lost opportunity, loss of product or cost of reproduction or reparation.

Severity - the potential rate that the environment, process conditions or constituents can deteriorate assets.

Condition - the actual or assumed condition of the plant as determined by actual historical performance where possible.

Existing Maintenance - the actual or assumed quality of preventive maintenance actions carried out on the asset.

Complexity - the complexity of the asset according to the number of maintenance causing items that make up the asset.

A system of weighted numerical scoring was developed to indicate the degree of impact that each criteria had on the perceived criticality of each asset.

4.4 Weighted Scoring

An arbitrary scale of 1 to 10 for scoring and weighting was selected. It was assumed that a factor of more than 10 would be unnecessary to discriminate between critical assets, and that any less than 10 would be insufficient to achieve the desired spread of results.

Criteria weighting was varied to suit local business rules. This depended on the emphasis of the organisation (e.g. relative safety vs. process criticality) and the reliability of information used to conduct the assessment so that the results are not greatly influenced by information from unreliable or biased sources. Weighting was maintained separately to scoring so that results could be compared across facilities or sensitivity analysis performed.

Low scores indicate a less serious outcome within the criterion. A score of 1 indicated a low criticality against a criterion while a score of 10 indicated the highest. A weighting of 1 indicated the lowest importance of a criterion to the ranking, while a score of 10 represented the highest. Scores and weightings in between 1 and 10 indicate relative scales for comparison purposes.

The final ranking of the criticality of assets is determined by the total weighted score. The sum of each score multiplied by the criterion weighting for all criteria provided the total weighted score for a single asset. The magnitude of the total weighted score for the asset determined its overall ranking within the facility.

4.5 Scoring Guides

Scoring guides were developed to apply consistent application of scoring to the criteria. Although not covering every possible description of a criterion outcome the guides are intended to maintain a consistent scoring across a facility with regard to exposure and consequences.

Table 1- Scoring Guide - Safety / Environmental Criterion

Score	Description
1	No impact on environment or safety of personnel if failure occurs.
2	Nuisance impact on employees and no impact on environment if failure occurs e.g. noise, additional rectification required.
3	Nuisance impact on employees and impact on environment recoverable at minimum cost.
4	Failure results in an obvious hazardous situation but contained by equipment. e.g. Oil spill within bunded area.
5	Failure results in obvious hazardous situation, but not contained by equipment. Hazard can be seen and avoided or approached with caution. e.g. Dust leak.
6	Failure results in hidden unsafe equipment or working environment (Hazard is not visible).
7	Serious hazard to individual employee or release of environmentally sensitive substance.
8	Potential fatality of individual employee or release of environmentally sensitive substance. e.g. Lifting device failure.
9	Serious hazard to multiple personnel or wide spread environmental impact. Hazard cannot be contained or controlled. e.g. Fire.
10	Potential for fatality of multiple personnel or widespread environmental consequences. e.g. Major Chlorine Gas Leak.

Table 2- Scoring Guide - Output Criterion

Score	Description
1	No affect on production within repair time
2	Reduction in production capacity short time frame (without affecting ability to meet orders).
3	Loss of equipment with some contingency and buffer storage
4	Loss of equipment with significant contingency and buffer storage.
5	Loss of equipment with 100% capacity backup.
6	Failure of equipment without sufficient back up to ensure that production requirements can be met. 25% loss of facility output or equivalent loss.
7	Significant impact on ability to meet customer order quantities. 50% loss of facility output or equivalent loss.
8	Significant impact on ability to meet customer orders for specific product with no backup. 75% loss of facility output or equivalent loss.
9	Significant impact on multiple equipment or process lines. Equivalent 75% loss of output of facility.
10	Stops entire output of facility. Contributes to long outages of facility. e.g. Loss of power.

Similar scoring guides were developed for the remaining four criteria. These scoring guides are omitted from this paper due to size consideration.

4.6 Application

The preliminary steps in the application of the criticality assets were performed by a facilitator with input of management stakeholders and the assistance of a facility representative. This included:

1. Identifying and documenting asset models;
2. Building an asset list;
3. Establishing the criteria;
4. Establishing and ratifying scoring guides;
5. Weighting criteria.

Once the preliminaries had been performed, the scoring was applied in a facilitated meeting by knowledge workers from the facility under analysis. The mix of individuals in the team was sometimes varied during the application; particularly on larger sites where broad expertise was not available within individuals.

Scores were applied to the criteria for each asset. A pessimistic application of the scoring guides was applied, based on the knowledge and understanding of the participants. Discussion and consensus were sought before each asset was considered to have been assessed. The outcome of the scoring was captured as indicated in Table 3. Initial analyses were captured manually, but this was soon replaced by a computer aided data collection process.

Table 3 - Scored Asset

UNIT - COMPRESSOR
ASSET - SEAL OIL SYSTEM

	Weight	*Score*	*TWS **	*Comments*
Safety / Environment	10	10	100	Potential for multiple fatalities
Output	8	10	80	Stops Entire Output of Facility
Severity	7	2	14	Seal Oil
Condition	6	4	24	Good condition
Existing Maintenance	5	4	20	Formal maintenance program in place
Complexity	3	3	9	Simple rotating machinary
TOTAL			247	* Total Weighted Score

5 RESULTS

Raw data was collected across a number of sites following the methodology outlined in Section 4. Three sites were selected as a pilot study series. The data displayed in Figure 2 represents the raw data collected during the application of the methodology. Raw data collected included:

- Asset identification;
- Score for each asset against each of the six criteria;
- Description against each criterion – this was defaulted to the scoring guide description but over written as appropriate.

The results of three sites are presented and compared in this section. These sites were:

1. Site 1 – Food Processing Plant - 454 Assets Scored
2. Site 2 – Brewery – 333 Assets Scored
3. Site 3 – Petrochemical Plant – 217 Assets Scored

Summarised results of the application of the methodology include:

- Numbers of safety critical assets (safety / environmental score greater than or equal to 7 indicating potential fatality or reportable environmental consequence);
- Number of output critical assets (Output score greater than 5 indicating a degree of loss of output or loss of service);
- Top 10 Critical assets for each site;
- Histogram of total score relative frequency of total weighted score for each site;
- Histogram of scores relating to output for each site.

All results presented were calculated with Safety / Environmental, Output, Severity, Condition, Existing Maintenance and Complexity weightings of 10, 8, 7, 6, 5 and 3 respectively.

5.1 Site 1 – Food Processing Plant

454 assets in total were scored for Site 1. 31% of assets were identified as safety critical with a Safety / Environmental score of 7 or over. 23% of assets were identified as output critical with an Output score of 5 or over. The top ten highest total weighted scores are shown in Table 4.

Table 4- Top 10 Critical Assets for Site 1

	UNIT	*ASSET*	*TWS*
1	PRODUCT FILL/PACK	FILLER	323
2	PRODUCT BLENDING	SCRAPE SURFACE HEAT EXCHANGER	322
3	STEAM	SERVICES BRIDGE (ADJ. PROD A)	310
4	LIQUID PACKAGING	LIQUID FILLER	294
5	PREPARATION	MIXER #2	284
6	PREPARATION	MIXER #1	284
7	COOKING	RETORT COOKERS #1 - #16	280
8	PRODUCT C	KETTLE	278
9	PRODUCT D	THERMOFORMING MACHINE	277
10	PRODUCT D	KETTLE	277

The relative frequency of total weighted scores is shown in Figure 2.

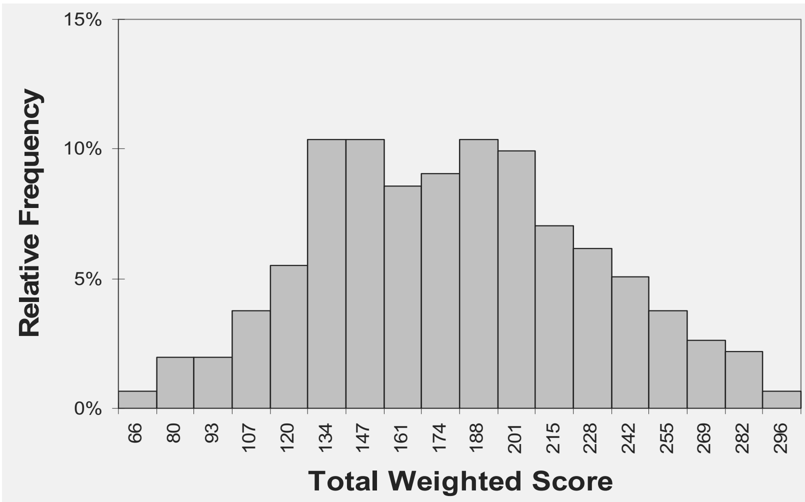

Figure 2- Relative Frequency of Total Weighted Scores for Site 1

The relative frequency of total output scores is shown in Figure 3

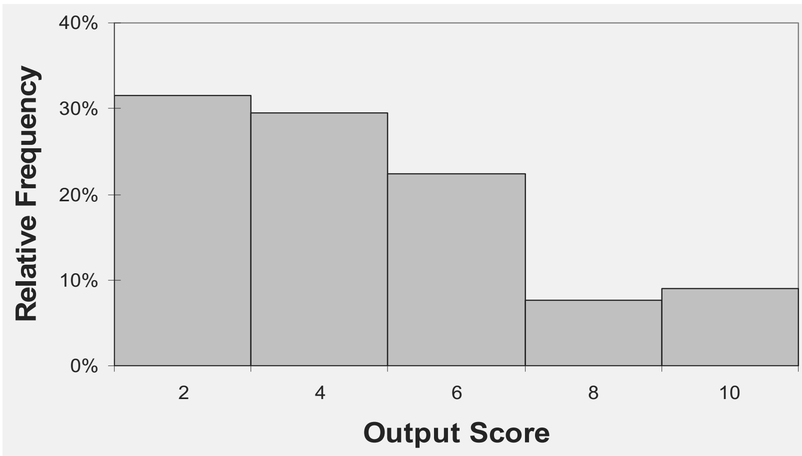

Figure 3- Relative Frequency of Output Scores for Site 1

5.2 Site 2 – Brewery

333 assets in total were scored for Site 2. 26% of assets were identified as safety critical with a Safety / Environmental score of 7 or over. 24% of assets were identified as output critical with an Output score of 5 or over. The top ten highest total weighted scores are shown in Table 5.

Table 5- Top 10 Critical Assets for Site 2

	UNIT	ASSET	TWS
1	GENERAL	PIPE BRIDGE	292
2	CIP SYSTEM	CIP CAUSTIC STORAGE	246
3	CIP SYSTEM	WORT COOLER CIP TANK	240
4	CIP SYSTEM	BREW VESSELS CIP TANK	240

The relative frequency of total weighted scores is shown in Figure 5

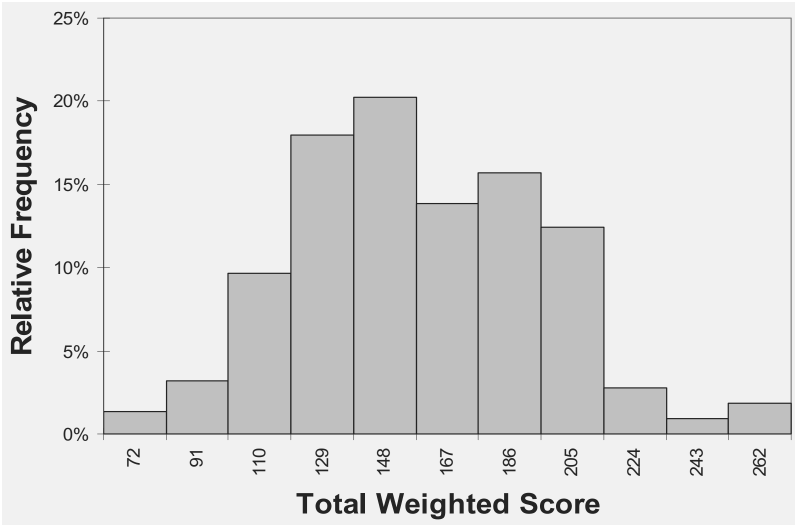

Figure 6- Relative Frequency of Total Weighted Scores for Site 3

The relative frequency of total output scores is shown in Figure 6

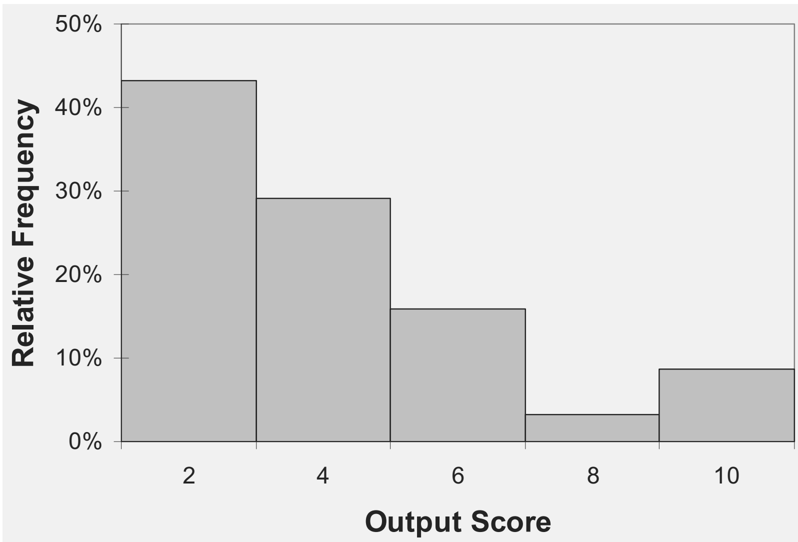

Figure 7 - Relative Frequency of Total Weighted Scores for Site 3

5.4 Discussion of Results

There are similarities between the results across the three sites studied. The following observations are made based on the results:

1. The results from the application of the methodology were well received by both the participants and other stakeholders. In the majority of cases, disagreements with the final ranking were not upheld after closer scrutiny of the criteria scoring.

2. There is variability in the Total Weighted Scores across the three sites supporting validity in the assumption of diversity of asset criticality across a facility.
3. The top ranked critical assets were dominated mainly by safety /environmental consequences. Although there were relatively high numbers of assets identified with safety / environmental consequences it was revealed that he number of maintainable items within the asset with a safety functionality were low.
4. Assets associated with the provision of facility services (air, water, steam etc.) featured prominently in the critical asset ranking. This was counter intuitive for many of the participants who expected the largest production assets to be the most critical.
5. There was a higher than expected percentage of assets assessed as having no measurable impact on the output of a facility. This was consistently demonstrated across all sites in the study series.

There were a number of lessons learned from the application of the methodology across the study series. This information was provided by participants in the application or subsequently by stakeholders or other observers. These lessons provided opportunities to modify the approach and apply additional work. These issues were:

1. Critical assets can disappear in the ranking. Assets with a high safety / environmental criticality with a low output criticality (or vice versa) could be significantly down the ranking. Separate lists should be maintained to segregate critical and non critical assets according to the ranking of the Total Weighted Score.
2. There is a need to improve the definition of an asset. Identification of assets is arbitrary and this method is not well described or defined.
3. Current criteria do not reflect the vulnerability of an asset to accidental damage or acts of vandalism. The criteria should be modified for subsequent applications.
4. There is an opportunity to document the methodology so that it can be successfully applied by others.
5. Computerisation of the data collection process greatly improved the efficiency and effectiveness of the application. Improvements to the current database would greatly enhance future applications.

Additional future work is warranted to satisfy these opportunities.

6 CONCLUSION

A systematic and standardized methodology was developed to identify critical assets. It was demonstrated in application that this methodology could be applied effectively and efficiently using the expert knowledge of those directly engaged in operations and maintenance functions. An assumption of diversity in asset criticality was supported by the application of this methodology. A variety in both ranking and relative criticality of assets was demonstrated consistently across the facilities included in the study series. The application of the developed methodology identified opportunities for future steps in the further development of expert knowledge based assessment tools of asset criticality.

PROFESSIONAL SKILLS TRAINING IN INTEGRATED ASSET MANAGEMENT: HOW TO DEVELOP AND IMPLEMENT THE ESSENTIAL ORGANISATIONAL ASSET MANAGEMENT FUNCTIONS

RF Stapelberg

Education and Training Manager The Cooperative Research Centre for Integrated Engineering Asset Management - Australia

Abstract: Asset management in the context of physical infrastructure and industrial assets is the process of organising, planning and controlling the acquisition, use, care, refurbishment, and/or disposal of an organisation's physical assets to optimise their service delivery potential and to minimise the related risks and costs over their *entire life*. Asset management on national and international scales is extremely wide and complex, and consequently has either fallen short of specific requirements, or lacks application of the essential principles. There is therefore an emerging need for a significant increase in the level of competency and technological sophistication through *integration* of asset management decision-making across all public and private sectors. This competency includes the concept of *knowledge management decision-making* in integrated asset management, with due consideration of the essential differences of approach by the different public and private sectors; yet with a standardized implementation of education and training in integrated asset management that would have the widest reach and applicability on a national (and international) scale for each sector. This paper specifically considers standardized professional skills training in integrated asset management with particular reference to meeting industry needs of how to develop and implement the essential organizational asset management principles, themes, frameworks and functions, and to establish an *integrated knowledge-based framework* in which *knowledge-based decision-making* can be optimized.

Key Words: Infrastructure and industrial assets, asset management, integrated asset management, knowledge management decision-making, integrated knowledge-based frameworks, professional skills training.

1 INTRODUCTION

Integrated Asset Management (IAM) involves integrated processes of managing physical assets during their useful lives, and requires a certain level of management insight and expertise from diverse organisational disciplines. IAM is a systematic, structured process covering the whole life of physical assets whereby the underlying assumption is that an organisation's assets exist to support the organisation's delivery strategies. The principal objective of IAM is to achieve the best possible match of assets with an organisation's delivery strategies to achieve the desired outputs and outcomes. This is done through the appropriate development and implementation of the essential organizational asset management principles, themes, frameworks and functions as researched in current literature of the status of asset management world-wide [1].

2 ASSET MANAGEMENT PRINCIPLES, THEMES, FRAMEWORK, AND FUNCTIONS

The key starting point, to ensure assets support an organisation's delivery strategy, is to establish a link between delivery objectives and the assets. Corporate objectives are then translated into delivery strategies, outputs and outcomes. An organisation's delivery strategies consequently combine with information systems, personnel, and financial resources. Asset management strategy on the other hand, is not simply a summation of the individual plans developed for each phase of an asset's life-cycle. It must be consistent with corporate objectives and integrated with other management strategies [2].

It should therefore relate to specific organizational requirements that will ensure the correct establishment of certain asset management *principles*. The general concepts or *themes* of asset management in turn must relate to these *principles*. Furthermore, asset management decisions should not be made in isolation. They should be part of an overall *framework* of decision-making in an organisation. Asset management objectives can thus be translated into principles, themes, and frameworks. Once the asset management objectives have been translated into principles, themes, and frameworks, a concept map for the development of asset management *functions* can be developed in accordance with these objectives. A schematic presentation of such a concept map is indicated in Figure1:

Concept Map Stages of Developing Asset Management Functions:

Identify and generalise asset management ***principles***

⬇

Establish the relevant asset management ***themes***

⬇

Develop a comprehensive integrated asset management ***framework***

⬇

Initiate a first attempt at building a theoretical framework for asset management ***functions***

Figure 1. Concept Map of Developing Asset Management Functions [1]

2.1 Asset Management Principles

The *principles* of asset management common to most organisations are [1]:

- Asset management is driven by corporate/business objectives and goals:
- Assets exist to meet some identifiable service delivery. Asset management provides clearly assigned managerial accountabilities and responsibilities for service delivery:
- Asset management places emphasis on managing assets (what, why, where, how much):
- Asset management provides effective recognition and life cycle management of risks:
- Asset management places emphasis on optimising existing asset utilisation and performance to maintain or reduce overall service delivery cost to a sustainable level:
- Asset management considers the use of engineering solutions and management techniques for organising, planning and controlling the acquisition, use, care, refurbishment, and/or disposal of an organisation's physical assets.
- Asset management takes a total life-cycle cost approach and utilises “whole of life cycle” techniques for assets to optimise their service delivery potential and to minimise the related risks and costs over their *entire life*:
- Asset management focuses on performance measurement, monitoring and matching assets to organisational delivery strategies:

The *general principles* of asset management can thus be summarised as:

- An effective framework can be established for asset management;
- Asset management decisions are integrated with strategic planning;
- Asset planning decisions are based on the 'life-cycle' of assets;
- Asset ownership/stewardship bears risks that are assessed and evaluated;
- The appropriate tactical planning considers asset condition and use;
- Financial accountability is established for asset performance and residual life.

These principles are not definitive but are consistent with trends in improving asset management in the public and private sectors. Each principle reflects a fundamental notion of best practice and continual improvement, although they are not widely practiced in most industry sectors.

2.2 Asset Management Themes

The basic *themes* of asset management represent current thinking with national asset owners as well as professional organisations representing asset owners [1]. Underlying these themes is the assumption that assets exist to support program delivery, and relate to the following:

- Asset strategic planning;
- Asset ownership/stewardship;
- Asset service delivery and risk;
- Asset life cycle costing and budgeting;
- Asset usage, maintenance, and performance;
- Asset information and decision-making.

2.3 Asset Management Frameworks

So far, various asset management principles have been considered from the perspective of their related themes, and these themes have been used as a basis for comparison – which in effect can be presented in the form of an asset management structure or *framework*. Such a framework would include the following [1]:

- Strategic planning and decision-making;
- Ownership/stewardship and governance;
- Service delivery and risk analysis;
- Life cycle costing and budgeting;
- Engineering and economic analysis;
- Data management and information;
- Condition monitoring and modelling;
- Usage life-cycle and maintenance;
- Performance measure and financial management.

It is the various themes to which the general principles of asset management relate that can be presented in the form of an asset management structure or framework.

A study of various asset management frameworks developed by the public and private sector for both infrastructure and industrial assets revealed a fairly consistent adherence to the general asset management principles and themes. Although asset management requires a *framework* to support both short and long term organisational *delivery strategies*, the actual integration process was not explicitly defined up until the formalisation of an Integrated Asset Management Framework by the Cooperative Research Centre for Integrated Engineering Asset Management [3]. This integration process was reviewed by CIEAM from an adaptation of a Strategic and Tactical Asset Management framework developed by Stapelberg, (2000).

2.4 Integrated Asset Management Frameworks

Such an integrated framework includes the following modules [1]:

- Strategic planning of assets;
- Asset management decisions;
- Asset ownership/stewardship;
- Asset service delivery and risk analysis;
- Asset life cycle costing and budgeting;
- Asset data management;
- Asset condition monitoring;
- Asset engineering and economic analysis;
- Operating and maintaining assets;

- Asset usage information and feedback;
- Performance measure of assets;
- Assets financial management.

The Integrated Asset Management (IAM) Framework was adapted from the asset management integration approach developed by Stapelberg (2000) which is divided into five areas:

- Strategic planning and risk integration.
- Budgeting and costing and financial management integration.
- Data management and information systems integration.
- Condition monitoring and performance measure integration.
- Tactical planning and asset usage life-cycle integration.

The approach considers a 'top-down/bottom-up' systems integration from key strategies and higher order asset management needs, through the appropriate budgeting and costing and financial management integration, to data management and information systems integration. It is specifically the data management and information systems level that forms the bridge between strategic planning and tactical planning, whereby the bottom-up approach progresses from tactical planning and asset usage life-cycle integration, through condition monitoring and performance measure, to data management and information systems integration. This 'top-down/bottom-up' integrated process appears linear, although it is in effect cyclic and follows the asset life-cycle from conceptualization through establishment to disposal.

The Stapelberg (2000) asset management model shows an effective asset management framework of ten core modules or functions which incorporate an asset management strategy integration concept and an asset management tactics integration concept that optimizes asset value over the complete asset life cycle. This is illustrated in Figure 2. This model divides the asset management system integration approach into two main concepts namely:

The strategy integration concept: The objective of this concept is to provide a strategic planning model that incorporates all the higher order asset management systems within the organization such as the overall asset management plans, assets risk management, budgeting and costing and assets financial management. This provides a consistent view of the organization's *strategic business model* across all asset management systems and serves as a basis for the integration of these systems. The products of this approach include high level business strategies.

The tactics integration concept: This concept identifies the *operational functions* of each system in the entire asset management program. It helps to establish the integration requirements of all systems at their process level. The tactics integration concept also considers three distinct integration phases: a Data Management - Information Systems Integration Phase; a Condition Monitoring - Performance Measures Integration Phase; and Tactical Planning - Assets Usage Life-Cycle Integration Phase.

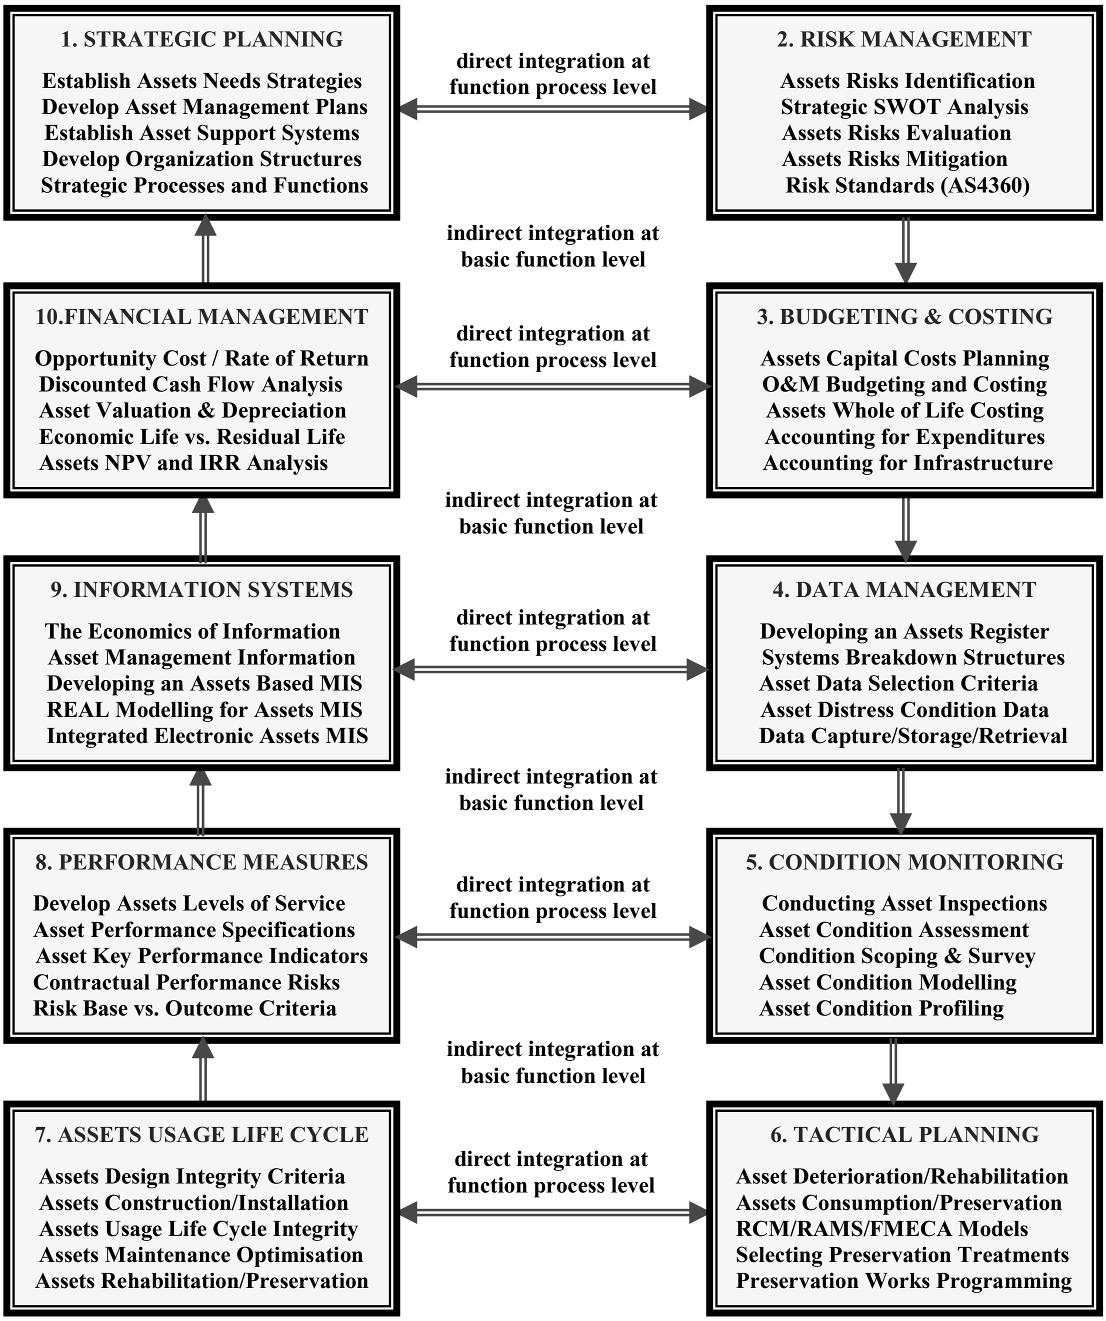

Figure 2. Integrated Asset Management Integration Concept [4]

The Stapelberg (2000) asset management model seeks to integrate an organization's *strategic business model* across all asset management systems with the *operational functions* of each of these systems through a process of *knowledge management decision-making*. The model provides an effective framework for the development of various functions and sub-functions of each core module, as well as the integration of these sub-functions through related operational processes and appropriate decision-making.

3 ASSET MANAGEMENT FUNCTIONS

The development of various ***functions*** of each core module of an Integrated Asset Management Framework as developed by the Cooperative Research Centre for Integrated Engineering Asset Management [3], and adapted from a Strategic and Tactical Asset Management framework developed by Stapelberg, [4], includes the following:

- Strategic planning;
- Asset ownership;
- Risk management;

- Budgeting and costing;
- Data management;
- Condition monitoring;
- Tactical planning;
- Human resources;
- Assets usage life-cycle;
- Performance measure;
- Information systems;
- Financial management.

The building of a theoretical framework for ***asset management functions and sub-functions*** is presented in modular format in Figure 3 [1].

1. STRATEGIC PLANNING **Establish Assets Needs Strategies** **Develop Asset Management Plans** **Establish Asset Support Systems** **Assets/Corporate Purpose Links** **Strategic Processes and Functions**	2. ASSET OWNERSHIP **Assets Ownership/Stewardship** **Ownership Responsibilities** **Strategic Governance** **Stakeholder Relationships** **Assets Alliances**	3. RISK MANAGEMENT **Assets Risks Identification** **Strategic SWOT Analysis** **Assets Risks Evaluation** **Assets Risk Mitigation** **Risk Standards (AS4360)**
4. BUDGETING & COSTI NG **Assets Capital Costs Planning** **O&M Budgeting and Costing** **Assets Whole of Life Costing** **Accounting for Expenditures** **Accounting for Technology**	5. DATA MANAGEMENT **Developing an Assets Register** **Systems Breakdown Structures** **Asset Data Selection Criteria** **Asset Distress Condition Data** **Data Capture/Storage/Retrieval**	6. CONDITION MONITORING **Conducting Asset Inspections** **Asset Condition Assessment** **Condition Scoping & Survey** **Asset Condition Modelling** **Asset Condition Profiling**
7. TACTICAL PLANNING **Asset Deterioration/Rehabilitation** **Assets Consumption/Preservation** **Assets Diagnostics and Prognosis** **RCM/RAMS/FMECA Modelling** **Selecting Preservation Treatments**	8. HUMAN RESOURCES **Assets Education and Training** **HR Strategic Planning** **Assets Systems Utilisation** **Employment Relations** **Teams & Virtual Teams**	9. ASSETS USAGE LIFE CYCLE **Assets Design Integrity Criteria** **Assets Construction/Installation** **Assets Usage Life Cycle Integrity** **Assets Maintenance Optimisation** **Assets End of Usage / Disposal**
10. PERFORMANCE MEASURE **Develop Assets Levels of Service** **Asset Performance Specifications** **Asset Key Performance Indicators** **Contractual Performance** **Risk Base vs. Outcome Criteria**	11. INFORMATION SYSTEMS **The Economics of Information** **MI Access/Validity/Dispersion** **Developing an Assets Based MIS** **REAL Modelling for Assets MIS** **Integrated Electronic Assets MIS**	12. FINANCIAL MANAGEMENT **Funding / Discounted Cash Flow** **Basis for Asset Valuation** **Assets Opportunity Cost / ROI** **Economic Life vs. Residual Life** **Assets Depreciation / Disposal**

Figure 3. Diagrammatic Structure of a Theoretical Framework [1]

This framework incorporates core modules or functions, as well as their sub-functions. These are listed as:

- **Strategic planning** – Establish assets needs strategies; develop asset management plans; asset support systems; asset/corporate purpose links; strategic processes and functions.
- **Asset ownership** – Asset ownership/stewardship; ownership responsibilities; strategic governance; stakeholder relationships; assets alliances.
- **Risk management** – Assets risks identification; strategic SWOT analysis; assets risks evaluation; assets risk mitigation; risk standards (AS4360).
- **Budgeting and costing** – Assets capital costs planning; O&M budgeting and costing; assets whole-of-life costing; accounting for expenditures; accounting for technology.

- **Data management** – Developing an assets register; systems breakdown structures; asset data selection criteria; asset distress condition data; data capture/storage/retrieval.
- **Condition monitoring** – Conducting asset inspections; asset condition assessment; condition scoping and survey; asset condition modeling; asset condition profiling.
- **Tactical planning** – Asset deterioration/rehabilitation; assets consumption/preservation; assets diagnostics and prognosis; reliability modeling; selecting preservation treatments.
- **Human resources** – Assets education and training; HR strategic planning; assets systems utilization; employment relations; teams and virtual teams.
- **Asset usage life-cycle** – Assets design integrity criteria; assets construction/installation; assets usage life-cycle integrity; maintenance optimization; assets end-of-use/disposal
- **Performance measure** – Develop Level-Of-Service; asset performance specifications; key performance indicators; contractual performance; risk base versus outcome criteria.
- **Information systems** – Economics of information; MI access/validity/dispersion; developing an assets MIS; REAL modeling for assets MIS; integrated electronic MIS.
- **Financial management** – Assets funding/DCF; assets valuation; assets opportunity costs/ROI; economic life versus residual life; assets depreciation/disposal.

It is in accordance with these functions that a schema can be developed for professional skills training in Integrated Asset Management. However, in addition to the application of these functions and sub-functions of asset management in a structure or framework, it is essential to determine whether they are indeed applied with the necessary knowledge and insight through an integration of the various organisational disciplines involved in asset management. From such an approach, the fundamentally unique concept of **Integrated Knowledge-based Asset Management** can be developed [5].

4 INTEGRATED KNOWLEDGE-BASED ASSET MANAGEMENT

Integrated Knowledge-based Asset Management involves *integrated* processes and disciplines for managing organisational physical assets, and requires a certain level of *knowledge management* and *decision-making insight* from diverse organisational functions. It is therefore a systematic, structured process covering the whole life of an organisation's physical assets, whereby the underlying assumption is that the concept of *knowledge-based decision-making* in regard to these assets forms the basis of the organisation's delivery strategies. The principal decision objective of Integrated Knowledge-based Asset Management is thus to achieve the best possible match of assets within an organisation's delivery strategies. This could however pose an essential reliance upon an *integrated knowledge framework for decision-making* in the implementation of such delivery strategies, additionally to establishing an effective integrated framework for asset management. The following application of *knowledge management* and *decision-making* to the principles of asset management thus represents a *new thinking paradigm* amongst asset owners and asset management organisations for the implementation of Integrated Asset Management.

4.1 Integrated Knowledge-based Asset Management Principles

The principles of integrated knowledge-based asset management can be summarized as [5]:

- A total *integrated knowledge framework* can be established for asset management;
- Knowledge management decision-making is integrated in asset *strategic planning*;
- Strategic planning decisions are based on *life-cycle knowledge* of physical assets;
- Asset ownership and/or stewardship bears *risks* that can be assessed and evaluated;
- Asset tactical planning considers *specific knowledge* of asset conditions and safety;
- Financial *accountability* is based on asset performance and residual life knowledge.

Each principle now reflects a fundamental notion of dependency upon knowledge management and decision-making in IAM in the public and private sectors.

4.2 Knowledge Management in Integrated Asset Management

Knowledge management (KM) is concerned with the exploitation and development of the knowledge assets of an organisation with a view to furthering the organisation's objectives. The knowledge to be managed includes both explicit, documented knowledge, and tacit, subjective knowledge. Organisations that succeed in knowledge management are likely to view knowledge as an asset and to develop organisational norms and values, which support the creation, and sharing of knowledge [6]. Historically, KM has been aimed at managers through what has been generally referred to as an executive information system aimed at supporting managerial decision-making. More recently, however, KM systems are increasingly designed for entire organisations. As organisations are being driven toward KM to meet organisational delivery strategies and create value, they are increasingly finding that use of existing knowledge and the creation of new knowledge inevitably allows for better decision-making within an integrated asset management framework. In addition, KM technology is ideally suited for organisational groups such as Asset Management Groups (AMG's).

5 CONCLUSION: A SCHEMA FOR PROFESSIONAL SKILLS TRAINING IN IAM

With the development of the essential functions and sub-functions that can be applied with the necessary *knowledge* and *insight* through an *integration* of the various organisational disciplines involved in asset management, a schema can now be developed for professional skills training in IAM. Such a schema is referenced in Figure 4 [4].

Abstract: As a result of aging and wear, the performance of machine and equipment deteriorates, which leads to a decrease in performance reliability and increase in the potential for faults and failures. To ensure proper functionality of complex systems, an ever-increasing number of increasingly sophisticated sensors and measurement devices have been employed for the purpose of performance diagnosis and control. Nevertheless, sensors themselves degrade, just as any other dynamic system. Therefore, to improve the reliability and performance of the system, it is essential to track and monitor the health conditions of the sensors as well. Without imposing requirements for redundant sensing equipment, the method developed in this paper utilizes the fact that sensor readings depict dynamic characteristics of the measured phenomenon in the plant as well as the dynamic characteristics of the sensor itself, which enables detection and quantification of sensor performance degradation as well as its isolation from degradation processes in the monitored or controlled plant. The method assesses sensor performance based on identification and tracing of time-constants and gains-changes associated with the sensor, which are obtained from using the subspace model based system identification method and that based on Auto-regressive Moving Average model with eXogeneous variables (ARMAX model), respectively. The method was verified through high-fidelity simulations of an automotive electronic throttle system.

Key Words: Sensor Performance Assessment, Subspace Model Based System Identification Method, ARMAX Modelling, Confidence Value (CV)

1 INTRODUCTION

The performance of machines and equipment degrades as a result of aging and wear, which decreases performance reliability and increases the potential for faults and failures [1]. To ensure proper functionality of complex systems, advanced technologies for performance diagnosis and control are incorporated into engineering designs, especially in the case of sophisticated, expensive and safety critical systems, such as manufacturing equipment, computer networks, automotive and aircraft engines, etc. Reliable performance diagnosis and control functionalities necessitate the use of an ever-increasing number of increasingly sophisticated sensors and measurement devices that are capable of delivering data about the key indicators of system status and performance. Nevertheless, sensors themselves degrade, just as any other dynamic system. Incipient failures such as bias, drift and precision degradation in the sensors can lead to errors in system condition diagnosis and ineffective control because the sensors are no longer able to deliver accurate information about the system's health condition. Therefore, to improve the reliability and performance of diagnostic and control systems, it is essential to ensure the health of the sensors as well, which places great importance on the problem of sensor performance monitoring.

The reliability of sensor readings can be improved by introducing redundant sensing hardware into the system. Such an approach is regularly used in safety-oriented applications such as aircraft and nuclear-power plant monitoring and control. However, the use of redundant sensing devices may not always be feasible due to cost and space constraints.

In this paper, we utilized the fact that the sensor readings depict dynamic characteristics of the measured phenomenon in the plant or system as well as the dynamic characteristics of the sensor itself. The aim of the method presented in this paper is to capture dynamic characteristics of the sensor within the sensor readings and separate them from those of the monitored phenomenon in the monitored or controlled system, thus enabling one to track the key dynamic indicators of the sensor and statistically assess the significance of their changes, without explicit need for redundant sensing hardware.

The reminder of this paper is organized as follows. A brief literature state-of-the-art review on the techniques on sensor reading validation is given in Section 2. A detail description of the sensor performance assessment method is presented in Section 3. To verify the developed method, several degradation scenarios of an automotive electronic throttle system in the simulation environment are conducted in Section 4. Finally, conclusions and possible future work of the current research work are given in Section 5.

2 STATE-OF-THE-ART REVIEW

Monitoring of sensor performance is becoming increasingly important as on-board system control, condition-diagnosis and performance prediction are being implemented in an ever-increasing number of dynamic systems. A conventional engineering method for ensuring sensor validity is to check and recalibrate the sensors periodically by following a set of predetermined procedures [2]. Although it is effective in dealing with bias problems, such method is not capable of continuously assessing the sensor performance and detecting small degradation and drifts in sensor performance. As more and more electronic components and sensors are being utilized, periodic checking of the sensors is no longer sufficient, especially in the case of sophisticated, expensive, and safety critical systems. Therefore, two alternatives are pursued in assessment of sensor performance: hardware redundancy approach and analytical redundancy approach [3].

The general idea of the hardware redundancy method is to measure the same key variables using two or more sensors. It is widely used in safety critical applications, such as aircrafts, submarines or space vehicles. Checking of the consistency of the redundant measurements of key process variables readily yields the faulty sensor, which can be picked out, for instance, by employing majority vote algorithm or by conducting the correlation analysis. Through the use of such a method, a monitoring system with higher measurement precision can be implemented using a group of sensors with comparatively lower precision [4]. Nevertheless, although the hardware redundancy method is effective and simple to implement, the redundant sensors increase the cost and impose larger space requirements on the entire system.

On the other hand, analytical redundancy approach builds up the static and dynamic relations between the multiple sensors based on a known or empirically obtained mathematical model of the corresponding system. Then, in order to detect the faulty sensor, residuals are generated by comparing the actual sensor readings and the readings estimated through the model. Fewer sensors are needed to pursue analytical redundancy than hardware redundancy. However, such method requires a significant amount of prior knowledge about sensor and plant dynamics and behaviour in order to detect sensor degradation and decouple it from degradation of the plant that is being measured.

In recent years, neural network based estimators are used to observe the critical sensor by taking the measurements of its neighbouring sensors as inputs. In [5], an approach is proposed to detect the defective sensor by checking whether its reading is far from the established value estimated by a Cerebellar Model Articulation Controller (CMAC) neural network from the measurements of its correlated sensors. In addition, the reading of the defective sensor can be reconstructed as the estimated value from the CMAC neural network. The problem of network architecture and appropriate training was not addressed. G. G. Yen *et al.* proposed a Winner Take All Experts (WTAE) network based on a ‘divide and conquer’ strategy, which significantly reduces the computational time required to train the neural network [6]. M. R. Napolitano *et al.* evaluated the robustness of the on-line learning neural networks and Kalman filters based approaches by applying both approaches for several different types of faults [7]. S. Wang *et al.* presented an online fault detection and diagnosis and sensor reconstruction scheme with an application of central chilling systems. The method is based on the Principal Component Analysis (PCA) to build the model that captures the correlation between the different sensors [8]. G. Kerschen *et al.* presented a procedure based on PCA to detect, isolate and reconstruct a faulty sensor for structural health monitoring [9]. Pablo *et al.* presented an algorithm for intelligent sensor validation in real time environment with a second Bayesian network that represents the dependencies and independencies between different sensors [3]. With such Bayesian network, the trade-off between the decision accuracy and time can be handled.

Nevertheless, the aforementioned work did not consider the possibility of the monitored plant degrading along with the sensor, and the subsequent need to decouple sensor dynamics from the remainder of the system in order to detect sensor dynamics degradation. The aforementioned problem will be addressed in this paper.

3 SENSOR PERFORMANCE ASSESSMENT METHOD

The problem of sensor performance assessment considered in this paper is based on the system structure shown in Figure 1, where sensed quantity contains the dynamics of the monitored or controlled system and the sensor, as well as the influence of process disturbances $w_p(t)$ and measurement noise $w_n(t)$. Sensor performance will be assessed using the observed control signal $u(t)$ and measured signal $y(t)$ without the use of redundant sensing equipment. The following assumptions will be introduced:

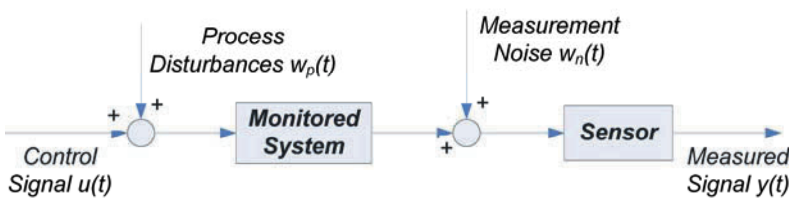

Figure 1. Structure of the compound system

a) There is no nonlinearity involved in the monitored system and the sensor.

b) The dynamics of the sensor is much faster than that of the monitored system. This assumption is not very restrictive because the dynamics of the sensor should be at least 2-5 times faster than that of the monitored system, which ensures accurate measurements and capturing of the dynamics of the monitored system.

c) The process disturbances and measurement noise are white noise.

Due to its linearity and causality of the compound system, the measured signal $y(t)$ cab be described in terms of the known input $u(t)$ and the unknown external disturbances $w_p(t)$ and $w_n(t)$ with the relationship in Equation (3.1).

$$y(s) = G_p G_s (u(s) + w_p(s)) + G_s w_n(s) \tag{3.1}$$

where G_p and G_s contain the dynamics of the monitored system and the sensor, respectively. Transfer functions $G_p(s)$ and $G_s(s)$ can then be represented as

$$\begin{aligned} G_p &= \frac{K'_p N_p(s)}{D_p(s)} = \frac{K_p(s+z_{p_1})(s+z_{p_1})\dots(s+z_{p_{n_p}})}{(\tau_1^p s+1)(\tau_2^p s+1)\dots(\tau_{m_p}^p s+1)}, n_p < m_p \\ G_p &= \frac{K'_s N_s(s)}{D_s(s)} = \frac{K_s(s+z_{s_1})(s+z_{s_1})\dots(s+z_{s_{n_s}})}{(\tau_1^s s+1)(\tau_2^s s+1)\dots(\tau_{m_s}^s s+1)}, n_s < m_s \end{aligned} \tag{3.2}$$

where K_p and K_s denote the gain of the monitored system and sensor, and τ^p and τ^s are the time constants associated with the poles of the monitored system and sensor, respectively.

Dynamic characteristics of the sensor can be generally described by the gain and the time constants of its transfer function poles, indicating the magnification capability and the response speed of the sensor. A sensor generally will respond slower or have deteriorated magnification capability as it degrades, which corresponds to the increasing time constant and changing (usually decreasing) sensor gain. Similarly, the performance of the monitored system can also be described by its gain (magnification capability) and time constant (speed). Thus, to identify the degraded sensor and distinguish the degradation source, the gain and time constants of the sensor and the plant should be tracked and monitored.

3.1 Detecting degradation in dynamic sensor parameters

Due to its superior performance in dealing with signals with dramatic changes, the subspace model based method is proposed to identify the linear compound structure of the sensor and the monitored system [9]. Based on the control signals and measured outputs, the subspace model based method estimates a state space model of the compound system in the form

$$\begin{aligned} x(t+T_s) &= Ax(t) + By(t) + Ke(t) \\ y(t) &= Cx(t) + Du(t) + e(t) \end{aligned} \tag{3.3}$$

where T_s denotes the sampling time, A, B, C and D are system matrices and K is the Kalman gain obtained by solving the corresponding Riccati Equation. The first line in Equation (3.3) is the state equation and the second is the output equation.

The subspace model based method provides an efficient and numerically reliable way to determine the predictors by projections directly on the observed data sequences [10]. With such predictors, all states $x(t)$ in Equation (3.3) can be obtained as a linear combination of the k-steps ahead predicted outputs (k = 1, 2, ……, n). Thus, if time sequences of state vectors $x(t)$, output vectors $y(t)$, and input vectors $u(t)$ are known, Equation (3.3) is actually a linear regression model and C and D can be estimated using the least square method, yielding error vector $e(t)$ from the output equation in (3.3). Given $e(t)$, the state equation in (3.3) becomes another linear regression in A, B, and K. (for more details, see Section 7.3 and 10.6 in [10] for details)

Transformation of the state space representation into a transfer function and tracking of the poles of the resulting transfer function readily yields the temporal behaviour of all plant and sensor poles and their corresponding time constants. Since the monitoring system should have much faster dynamic response than the monitored system in order to ensure rapid and accurate measurements, the time constants of the monitored system can be identified as much larger than that of the sensor. Thus, the degraded sensor with changes in its dynamics can be detected and its degradation can be distinguished from that of the monitored system.

Since the time constant of the degrading sensor changes gradually, the compound system is actually a time varying system which can be represented by a state space model with time varying matrices A, B, C, D, and K. To capture the time varying matrices, subspace model based method is used to fit a proper state space model to the data within a moving window. The flow chart shown in Figure 2 summarizes the procedures to detect and isolate the degradation in sensor dynamic parameters.

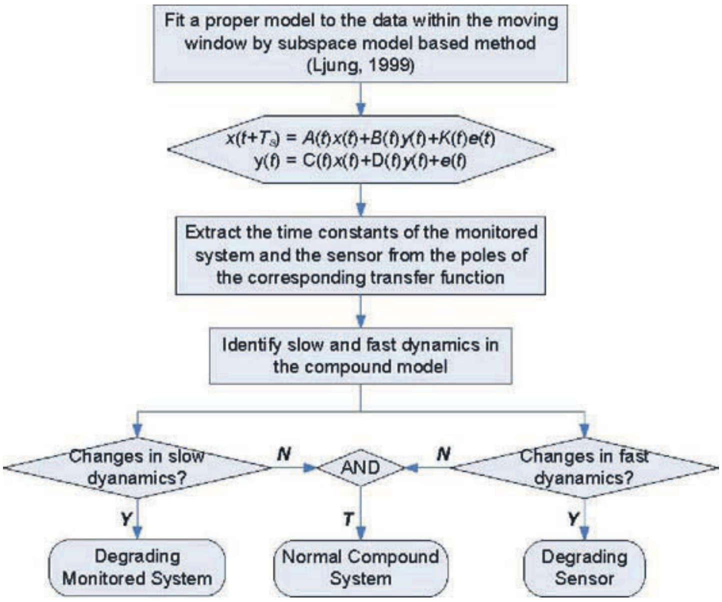

Figure 2. Flow chart of the procedures to detect degraded sensor with dynamic changes

3.2 Detecting degradation in sensor gain

The ARMAX model, a generalization of AutoRegressive Moving Average (ARMA) model, is able to incorporate an external input variable, thus establishing the relationship between the observed inputs and outputs. The form of the ARMAX model is

$$A(q)y(t) = B(q)u(t-nk) + C(q)e(t) \tag{3.4}$$

where *nk* denotes the input delay, and $u(t)$, $y(t)$ and $e(t)$ are the inputs, outputs and residuals, respectively. $A(q)$, $B(q)$ and $C(q)$, which represent the AutoRegressive (AR), eXogeneous (X) and Moving Average (MA) parts of an ARMAX model of order [*na*, *nb*, *nc*], can be expressed as

$$\begin{aligned} A(q) &= 1-\Phi_1 q^{-1} - \Phi_2 q^{-2} - \ldots - \Phi_{na} q^{-na} \\ B(q) &= \gamma_1 - \gamma_2 q^{-1} - \gamma_3 q^{-2} - \ldots - \gamma_{nb} q^{-nb+1} \\ C(q) &= 1-\Theta_1 q^{-1} - \Theta_2 q^{-2} - \ldots - \Theta_{nc} q^{-nc} \end{aligned} \tag{3.5}$$

As described in [11], the set of parameters of an ARMAX model is estimated by minimizing the sum of squared residuals. As the model becomes more complex, the associated sum of squared residuals decreases, however, the number of estimation parameters also increases. To achieve reasonable modeling accuracy with necessary complexity, either Akaike Information Criterion (AIC) or F-test criterion can be used to determine the order of the ARMAX model.

By comparing Equation (3.1) and (3.4), the relationship between the transfer of the compound system and the corresponding ARMAX model can be concluded as follows

$$\begin{aligned} A(q) &\leftrightarrow D_p(s)D_s(s) \\ B(q) &\leftrightarrow K_p^{'}K_s^{'}N_p(s)N_s(s) \\ C(q) &\leftrightarrow N_s(s)(K_p^{'}N_p(s)\frac{W_p(\omega)}{W_n(\omega)} + D_p(s)) \end{aligned} \tag{3.6}$$

where both sides of the operator ↔ can be derived from each other.

Consequently, by analogy, the AR part of the properly fitted ARMAX model between the control signal and the measured outputs contains the dynamics of the compound system.

$$e(t) = K_s' w_n(t) \Rightarrow std(e(t)) = K_s' std(w_n(t)) \tag{3.7}$$

$$K_{s_0}' = \frac{std(e_0(t))}{std(w_{n_0}(t))} \quad K_{s_k}' = \frac{std(e_k(t))}{std(w_{n_k}(t))} \Rightarrow K_s = \frac{K_{s_k}'}{K_{s_0}'} = \frac{std(e_k(t))}{std(e_0(t))} \bullet \frac{std(w_{n_0}(t))}{std(w_{n_k}(t))} = \frac{std(e_k(t))}{std(e_0(t))} \tag{3.8}$$

Furthermore, a proportional relationship in Equation (3.7) exists between the measurement noise $w_n(t)$ and the residuals of the adequate ARMAX model, which leads to their proportional statistical relationship. Thus, the sensor gain over a time window k and a reference window *0* can be defined according to Equation (3.8). Since the standard deviation of the white noise over any time window equals, the normalized sensor gains K_s over time can be obtained as the ratio between the standard deviations of the ARMAX model residuals over a time window and a reference window.

Based on the transfer function of the compound system identified by the subspace model based method, the product of the normalized gain of the sensor and the monitored system can be derived. Therefore, the normalized gain of the monitored system can be tracked, which enables the detection and isolation of the gain degradation in the compound system. Figure 3 summarizes the procedures to detect the degrading sensor with gain changes.

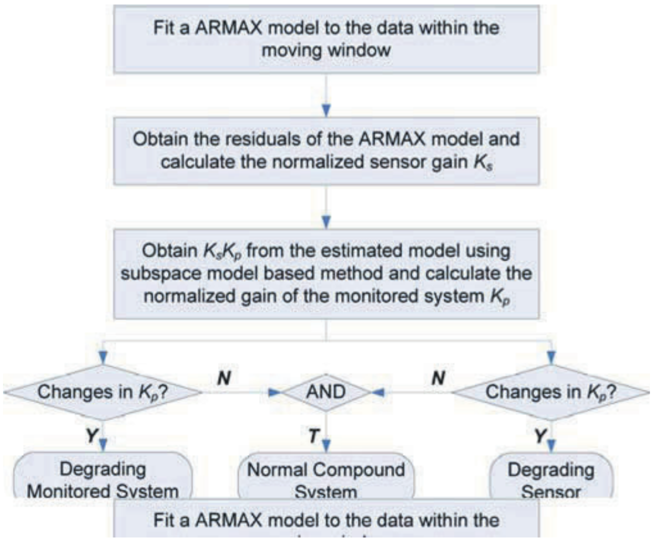

Figure 3. Flow chart of the procedures to detect degraded sensor with gain changes

3.3 Detecting degradation in sensor gain

Due to assumptions of Gaussianity of process $w_p(t)$ and $w_n(t)$, the changes in the identified time constants and gains of the sensor could be statistically interpreted, with severity of those changes being expressed through the overlap of distributions describing behaviour of parameters of the sensor during its normal and degraded operations. Following [12], this overlap between distributions of sensor dynamic parameters under normal and degraded conditions will be referred to as the sensor performance confidence value, ranging between zero and one, with higher CVs signifying a high overlap, and hence performance closer to normal.

4 SIMULATION SCENARIOS – ELECTRIC THROTTLE SYSTEM

To validate the methodology for sensor performance assessment, an electrical throttle system in the simulation environment is introduced. The throttle system is a primary controller that controls the power output in an automobile by controlling the airflow and fuel input to the engine that is actually constrained by the opening and closing of the throttle valve.

Figure 4 shows the simulation model for the compound system with the nominal values of their parameters, which includes an electric throttle as the monitored system and a sensor measuring the throttle angle. In the simulation, the electric throttle is simplified as a 2nd order system, while the angle sensor is modeled as a 1st system with a much smaller time constant than that of the throttle system. Two simulation scenarios for the gradual degradation of the compound system are exampled. 1) The gain of the monitored system and the sensor drop gradually by 40% and 40% simultaneously, respectively. 2) The gain and time constant of the sensor gradually and simultaneously drop by 40% and 40%, respectively.

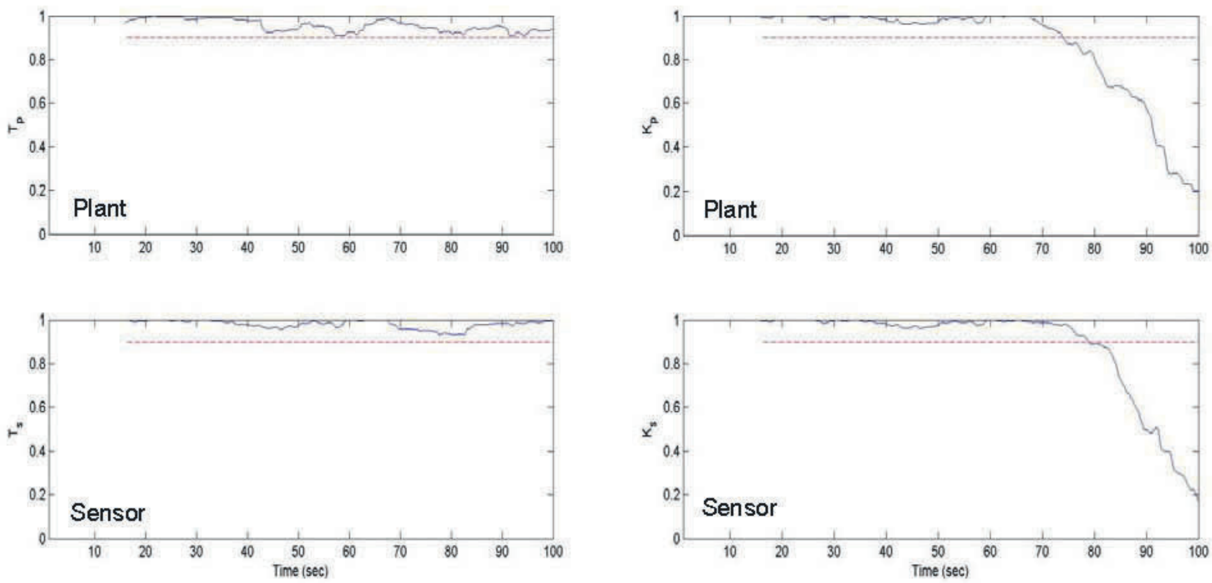
* *K_p – normalized gain of the monitored system; K_s – normalized gain of the sensor;*



(a) Estimated Time Constants (b) Normalized Gains

Figure 6. Confidence values of the estimated time constants and normalized gains

As shown in Figure 5(a), the two series of time constants estimated from the data set have mean values at 0.22 *sec* and 0.028 *sec*. According to our assumption that the time constant of the monitored system should be much larger than that of the sensor, we can consider the estimated time constants with mean value of 0.22 *sec* as the time constants of the monitored system, and assigned the other to the sensor. Thus, when degradation occurs in the gains of the throttle system and the angle sensor, the estimated time constants of the monitored system and the sensor oscillate around their mean values without any obvious increasing or decreasing trends. On the other hand, the normalized gains of the monitored system and the sensor, illustrated in Figure 5(b), both show decreasing trends at the end. As shown in Figure 6, the performance CVs associated with the normalized gains drop significantly, while those associated with the time constants indicate normal performance. By setting an ad hoc threshold value as 0.9 in this paper, the performance CVs of the normalized gains of the throttle system and the sensor break through the threshold value, while those of their time constants stay above the threshold.

Limits beyond which changes of dynamic sensor parameters are considered significantly can be set using standard Statistical Process Control (SPC) techniques applied directly to the extracted features including the time constants and normalized gains [13]. In this paper, *X* chart is applied with their upper and lower control limits as

$$ULC_x = \overline{X} + 2\sigma_x \qquad LCL_x = \overline{X} - 2\sigma_x \tag{4.1}$$

As shown in Figure 5(a), majority of the estimated time constants of the sensor and the monitored system stay between the upper and lower limits, thus indicating that the dynamic properties of the compound system are under normal conditions. On the other hand, the normalized gain of the sensor and the monitored system, as illustrated in Figure 5(b), consistently break out the low control limit after 75 *sec*, which further verify the diagnostic conclusion that the gains of the compound system are under degradation.

When the gain and time constant of the sensor were changed, the time constants and normalized gains of the throttle mechanism oscillate around their mean values in Figure 7. On the other hand, the time constants of the angle sensor increase and its normalized gains decrease at the end. As shown in Figure 8, the performance CVs associated with the angle sensor drop significantly, while those associated with the throttle system indicate normal performance. Consequently, the performance CVs associated with the angle sensor break through the threshold value, while those associated with the throttle system stay above it.

In addition, as *X* chart is applied to their estimated time constants and normalized gains in Figure 7, the estimated time constants and normalized gains of the sensor consistently break through the control limits after 80 *sec*, which also indicates the degradation of the sensor and verified the conclusion derived from their associated confidence values plots in Figure 8. Thus, the method introduced in this paper is able to detect the degrading sensor and distinguish sensor degradation from that of the plant.

Figure 8. Confidence values of the estimated time constants and normalized gains

The area under the Receiver Operating Characteristic (ROC) curve, often called AUC, is used to evaluate the discrimination ability of the mainly proposed algorithm for sensor performance assessment. Since the ROC can be represented by plotting the fraction of true positives (TP) vs. the fraction of false positives (FP) for a binary classifier as its discrimination threshold is varied, AUC is generally taken as a summary statistic to evaluate detection accuracy. The AUC of a perfect detector is one because it is able to achieve 100% TP rate and 0% FP rate. On the other hand, the closer the value of AUC comes to 0.5, the less accurate the detector is.

The AUC values in Table.1 are calculated under different degradation modes with step changes in the time constants and gains of the monitored system and the sensor at the levels of 5%, 10%, 15%, and 20%. Since the nominal value of the normalized gain should be one, the normal behaviour of the normalized gains of the monitored system and the sensor are generated according to a Gaussian distribution with mean value of one and standard deviation of the parameters estimated under normal operating conditions. As shown in Table.1, the AUC values for the different degradation modes increase as the degradation level increases, which indicates the intuitively plausible fact that the detection accuracy of the developed algorithm improves as the performance of the monitored system or the sensor deteriorates. In addition, the developed algorithm is able to achieve higher accuracy in detecting changes in the dynamics.

Table 1 : AUC values calculated for four single degradation modes

Degradation Level	*Gain Change*		*Dynamics Change*	
	Monitored System	Sensor	Monitored System	Sensor
5%	0.86778	0.61637	0.99187	1.0000
10%	0.96587	0.85823	0.99996	1.0000
15%	0.99363	0.97445	1.00000	1.0000
20%	0.99839	0.99959	1.00000	1.0000

5 CONCLUSIONS

The method introduced in this paper is able to identify the dynamics of the compound system consisting of a sensor and a monitored plant, and separate the sensor dynamics from that of the monitored plant. As a result, the method is capable of detecting and quantifying senor performance degradation in the compound system without the use of redundant sensing equipment, where either the plants or the sensors monitoring those plants could undergo degradation of their dynamic properties. In addition, the method accomplishes identifying sensor and plant dynamics using inputs observed during normal system operations rather than using special inputs. Consequently, such method is capable of assessing sensor health condition as the system operates, rather than off-line.
