Proceedings of the 1st World Congress on Engineering Asset Management (WCEAM)
Conrad Jupiters, Gold Coast, Australia
11 – 14 July 2006

PREFACE

It is with great pleasure that we welcome you to the inaugural World Congress on Engineering Asset Management (WCEAM) being held at the Conrad Jupiters Hotel on the Gold Coast from July 11 to 14, 2006. More than 170 authors from 28 countries have contributed over 160 papers to be presented over the first three days of the conference. Day four will be host to a series of workshops devoted to the practice of various aspects of Engineering Asset Management.

WCEAM is a new annual global forum on the various multidisciplinary aspects of Engineering Asset Management. It deals with the presentation and publication of outputs of research and development activities as well as the application of knowledge in the practical aspects of:

- strategic asset management
- risk management in asset management
- design and life-cycle integrity of physical assets
- asset performance and level of service models
- financial analysis methods for physical assets
- reliability modelling and prognostics
- information systems and knowledge management
- asset data management, warehousing and mining
- condition monitoring and intelligent maintenance
- intelligent sensors and devices
- regulations and standards in asset management
- human dimensions in integrated asset management
- education and training in asset management and
- performance management in asset management.

We have attracted academics, practitioners and scientists from around the world to share their knowledge in this important emerging transdiscipline that impacts on almost every aspect of daily life.

All full papers published in these proceedings have been refereed by specialist members of a peer review panel for technical merit. It should be noted that some papers may contain grammatical errors in their current published state. Given timing constraints in the publication process, the Editors elected not to edit these papers to this level of detail. Nevertheless, the Review Panel has accepted these papers based on technical merit.

The vision for the WCEAM originated from the CRC for Integrated Engineering Asset Management (CIEAM) in 2004 during free form discussions at the closing of the 2004 Asia Pacific Conference on Systems Integrity and Maintenance (ACSIM) held in New Delhi, India. It was recognised that the ACSIM forum needed to expand its scope to include the research and development outputs from this growing transdiscipline. To facilitate rapid uptake for an inaugural event and in a spirit of collaboration, several international conference organising committees were approached to combine their efforts for this 1st WCEAM. These included the International Conference on Maintenance Societies (ICOMS 2006) hosted by the Maintenance Engineering Society of Australia (MESA), the International Maintenance Systems (IMS) Conference hosted by the IMS Centre, USA, The Condition Monitoring Conference hosted by the British Institute for Non-Destructive Testing (BINDT) and ACSIM hosted by CIEAM.

WCEAM Sponsorship
We would like to gratefully acknowledge the support of **Transfield Services** as Gold Sponsor of the ICOMS conference since 1994, which is being held jointly with WCEAM, the **Queensland Government through the Department of State Development and Innovation** as Silver Sponsor, and the **Beenleigh Merrimac Pimpama Alliance** as Bronze Sponsor of 1st WCEAM.

1st WCEAM is also hosting a **state-of-the-art exhibition** providing an excellent opportunity for suppliers of equipment and services in EAM to showcase their offerings in this growing market.

Vote of Thanks

We would like to thank all the members of the WCEAM Organising Committee for the enormous effort they have contributed to making this conference a success. Thanks are also due to members of the WCEAM International Steering Committee and Industry Advisory Group for their efforts in both reviewing papers as well as promoting the congress to their contacts.

In particular we note the importance of the local asset management bodies that we team with to make these international events a success. In this case the invaluable role of MESA and its Brisbane Chapter which are manned by volunteers was essential in achieving the successful outcome that this first WCEAM has become.

In closing, we would like to invite you to enjoy 1st WCEAM on Australia's Gold Coast and we encourage you to take this opportunity to network with your colleagues from around the world. Our social events have been carefully selected to maximise opportunities for you to do so. We look forward to your participation in making this a most memorable event for you and your fellow delegates.

We trust you will also sample some of the delights of this region by taking time out after the congress to enjoy what it and the state of Queensland has to offer.

Once again, welcome, and thank you for being a part of 1st WCEAM.

FAULT SELF RECOVERY OF INDUSTRIAL PLANTS -VISION AND STATE OF THE ART

GAO Jinji

Diagnosis & Self-recovery Engineering Research Center
Beijing University of Chemical Technology, Beijing 100029 China)

Abstract: Machine faults can be contained or even eliminated by the machine system itself during operation, i.e. machines with "fault self-recovery" function can be built. Engineers have always aspired to invent such machines. The scientific basis, its connotations, theory, and several applications of fault self-recovery technologies are discussed in this keynote presentation. FSR (Fault Self-recovery Regulation), RCIMS (Reliability Centered Intelligent Maintenance System) and ASSR (Abnormal Situation Self-recovery Regulation) that integrates information, diagnosis, artificial intelligence, and active control technologies, are introduced. By FSR based design, the responsibility of maintenance duty can be shifted from users to the manufacturers, and the safe operation period of machines can be prolonged. The concepts presented in this keynote are important to the development of Intelligent Maintenance Systems.

Key Words: industrial plant, fault self-recovery, fault self-recovery regulation (FSR), reliability centered intelligent maintenance system (RCIMS), abnormal situation self-recovery regulation (ASSR)

1 INTRODUCTION

Reviewing the course of evolution from single-celled lives to human society, it might be surmised that machines are a continuation of lives, in the same way, man's fighting against faults of machinery is an extension of man's fighting against diseases. Since Watt's invention of steam engine in 1781 and its widespread use in industrialization in around 1800, only some 200 years has passed. Up to now, Men fight against machine faults mainly by "curing" them, i.e., by repairing them after shutting-down. On the other hand, the diseases have been with human for more than 3 million years, but the history of real medical activity is merely about 10 thousands years. Nevertheless, human race is not vanquished or eliminated by diseases. The answer lies in self-healing mechanism and ability of life. Could a machine's fault be controlled and eliminated automatically during operation? Could fault be "healed", like disease of humans and animals? Could there be a parallel drawn between fault-fighting and disease-fighting? Could healing approach of machine, in addition to curing method, be invented and developed? Those are important questions that worth further consideration. [1]

Modern process equipment is becoming bigger, faster, more automatic and intelligent. It is especially true with those high-speed turbines, pumps, compressors, centrifuges and other major machines, which are widely used in petrochemical, electrical, metallurgical, including non-ferrous metallurgical and other process industries, and closely bonded with process to form a big system. Faults of such machines may cause serious accident and huge economic loss. Beginning in 1960s, the international technological cycle has developed condition monitoring and diagnosis technology, putting Predictive Maintenance and Intelligent Maintenance into practices among industrial enterprises. And the widespread use of emergency shutdown (ESD) system has contributed a lot to ensure safety of plants. But, fault-caused shutdown is not only a source of economic loss, but also a source of new faults.

As indicated by engineering practices, except for small proportional of abrupt incidents, most faults come into being and develop gradually. If detected early, most big faults can be avoided given that proper measures are taken. One major cause of current problem is the lack of foresight to check erroneous condition at the very beginning. Traditionally, from the designing and manufacturing stages of machines to their running or operating stage, there are very few, if any, considerations about the gradual deterioration of faults in those machines, thus the chance to control the faults is often missed and failure of the machines becomes inevitable. Another cause of such situation is that the machines are often not well-integrated with monitoring and control system, and lack of intelligence.

Emerging and developing of the Cybernetics has deepened the understanding about oneness of hylic world. The Cybernetics discloses the similarity and synergetic behaviors between organic life activities and inorganic machine operations, in the aspects of informatics, Cybernetics, and Systematics, and thus, breaks the boundaries between lives and machines. [2] Between the control of disease and that of fault, there are similarities too; therefore, the principles of medicine science can be adapted to the study of diagnosis, prediction and prevention of fault. The history of medicine science is more than 10 thousands years, while the fault diagnosis began only some 40 years ago in 1960s. The theories and precious experiences of medicine practices can be expected to guide the engineering practice of fault diagnosis and prevention.

Under the guidance of the Systematics breaking the old specialty barrier, transplanting the idea of "self-healing" therapeutic method from medicinal science, integrating the technologies of condition monitoring and diagnosis, artificial intelligence, active control, fault tolerant control, embedded technology, etc., in this paper the fault self-recovery regulation (FSR) technology of machine is discussed with the prevention and self-healing of faults as the goal. The SFR technology will provide machine with fault self-recovery capability, with which fault-caused shutdown could be reduced significantly. This paper mainly focuses on the theory of fault self-recovery and its engineering applications on machines and plant systems.

2 THE THEORY OF EQUIPMENT'S FAULT SELF-RECOVERY

Equipment is a materialization of human intelligence and an extension of human function. All equipments are designed to work orderly and steadily under certain design condition range. However, due to internal change and/or outer disturbance during operation, the equipment's actual working condition can deviate from its design condition range, consequently, making the equipment enter fault or abnormal situation. Fault self-recovery regulation is a method of retaining or restoring the equipment's working condition within its original design condition range using the technologies of intelligent diagnosis and prediction and active control during operation so as to ensure steady and orderly running of the equipment.

Information can reveal the change of a structural system, its inputs and outputs and their interrelations. When there is an abnormal change of the interrelations and inerreactions among machine's innner sub-systems, or an abnormal change of the interrelations and inerreactions between these sub-systems and their mass inputs/outputs, energy inputs/outputs and environments, i.e. when the machine deviates from orderly condition and enters a pre-fault state, information can be detected and processed realtimely to indicates fault syptoms, then diagnosis and prediction can be made.

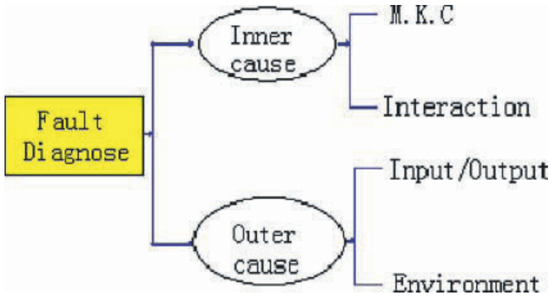

Fig. 1 Fault diagnosis both in inner and outer causes

2.1 Diagnoses and Prediction of Equipment's Faults

Following the idea of the Systematics, the pattern of fault origination and development can be studied. As shown in Fig.1, in the study, both information and relations should be taken into account, and both inner causes (i.e. change of mass, rigidity, damp etc. and their inner-reciprocity) and outer causes (input/output of mass and energy, and the influence of environment) should be considered. This will make possible early detection and diagnosis of initial cause of the fault of complex equipment system. Besides, by investigating the cause of a fault, the condition which may cause a fault can be predicted. In time domain and space domain, the evolution from failure analysis to initial cause tracking and to prediction of fault-causing condition is shown in Fig.2.

Diagnosis means the study of a complex equipment system, it's input/output of mass and energy and its interaction with environment. Through analyses of the monitoring information, the interactions and interrelations can be studied, and the rule of fault creation, development and prevention can be found, and the initial cause can be tracked through the use of fault causal chain.

Prediction has two meanings: to predict the developing trend of current fault; and to study the conditions that might lead to fault. It would be necessary to process and analyze diverse fault symptoms, to extract feature parameters, to evaluate the concordance of mass and energy input/output, to check the abnormal change of discharged material, to calculate and analyze the non-linear relation between the state of equipment system and the state parameters, so that the causes of a fault, especially the preconditions and features of a fault can be detected and a rational prediction can be made when the fault is at the beginning state.

2.2 The Theory of Fault Self-Recovery

The definition of fault self-recovery regulation: By real-time monitoring and analyzing the possibly fault-causing conditions and early fault symptoms during operation of an equipment system, through diagnosis and prediction, intelligent decision making and active control, the preconditions of a fault can be eliminated, or the fault can be automatically terminated at its beginning stage, or the possible fault can be found and intercepted, and then eliminated even before it really forms. [3]

In the modeling process of fault self-recovery system, the promptness and correctness of system response has to be studied. Since the target system is a complex system with a considerable amount of information, it is very important to extract useful information from large amount of information and to take proper measures timely, so as to fulfill self-recovery regulation. The system analysis method of the system engineering theory might be used to extract and analyze systemic information and to build an intelligent expert knowledge database to provide useful control strategy to assist intelligent decision-making.

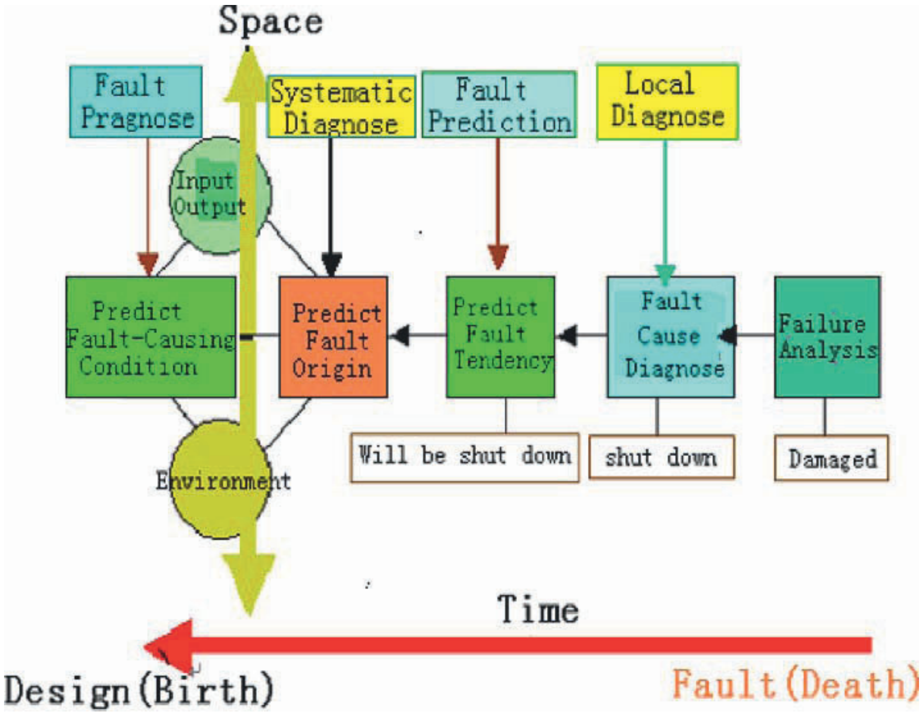

Fig.2 The evolution from failure analysis to fault-causing condition predict

The control system that aims at fault control and elimination, i.e., a fault self-recovery system comprises of real-time monitoring unit, comparison and judgment unit, diagnosis and prediction unit, intelligent decision-making unit, inter-transmitting link and execution unit. [4] The general style of fault self-recovery system is shown in Figure 3.

To build a fault self-recovery mechanism through the use of active control for the purpose of fault prevention and elimination, the major forms of fault self-recovery include:

1) The main idea of FSR is to change the working condition and state parameters. It can be done through following methods:

Compensation of disturbance. Activate a counter-reaction to prevent the creation and development of fault.

Removal of disturbance. Eliminate the fault-causing disturbance to eliminate a fault.

Deviation adjustment. Eliminate the fault-causing condition to prevent fault from happening and developing.

Hybrid approach. A combination of the above.

2) Sometimes, it might be possible to change allowable working range through dynamic regulation. The working range can be a dot, line of a multi-dimensioned region.

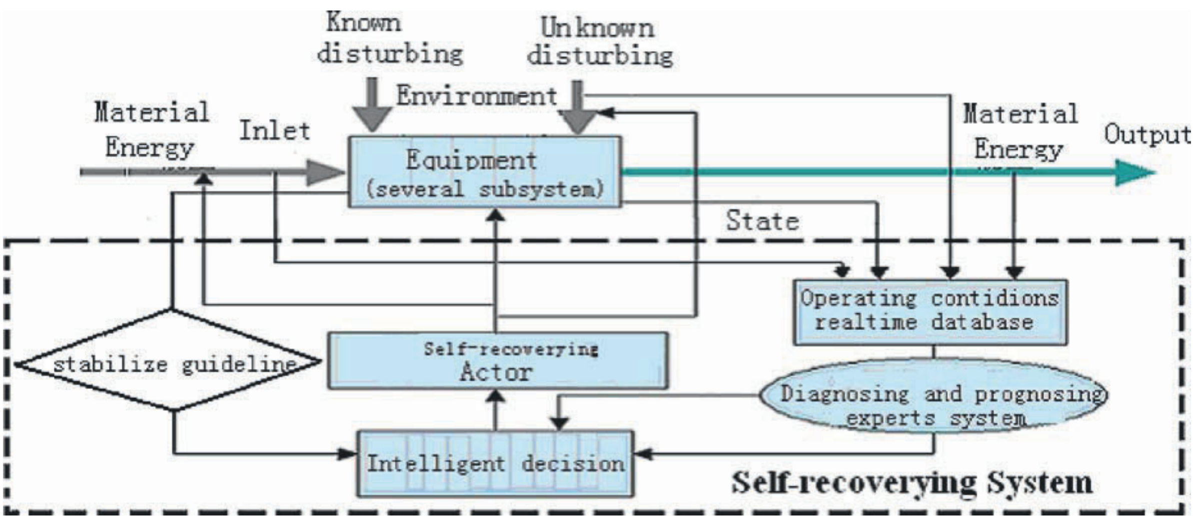

Fig.3 Model of fault self-recovering

3 ENGINEERING APPLICATIONS OF FAULT SELF-RECOVERY REGULATION OF EQUIPMENT

Above mentioned study can provide scientific basis and core technology for the development of industrial fault self-recovery regulation (FSR) system. Once a fault self-recovery regulation (FSR) system is installed before emergency shutdown(ESD) system, which is widely used in process industry, the automatic emergency shutdown cause by interlink device can be greatly reduced without necessarily having to sacrifice safety. And based on it, a new generation of equipment~~s~~, which is capable of self-healing, can be produced, changing or reducing the traditional maintenance works which mainly rely human intervene. In Fig. 4 it is illustrated how a FSR system bridges the gaps among state monitoring, diagnosis, maintenance of machine and process and process control, thus to build process machines integrated with diagnosis, supervisory and control system, consequently to achieve fault auto-maintenance, i.e., self-recovery function.

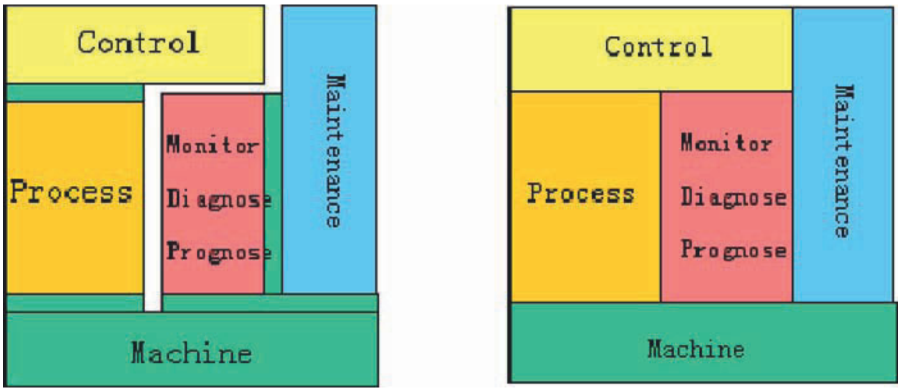

Fig. 4 Integration of process, machine, control and maintenance

Typical example applications of fault self-recovery in centrifugal compressor include:

Automatic balance of rotor: Automatic balancing system for high-speed rotor can be applied to single rotor, including vertical rotors and cantilever rotors, and multi-rotor systems (Form (a) of fault self-recovery: compensation of disturbance);

Active magnetic bearing: Diagnosis and self-recovery regulation using active magnetic bearing to deal with excess vibration (Form (d) of fault self-recovery: hybrid approach) ;

Injection of de-coking water: Under some situation, de-mineral water can be injected into the case of centrifugal compressor to reduce temperature thus to prevent coking on the rotor blades (Form (c) of fault self-recovery: adjustment to deviation);

De-coking through oil flush: washing the coke away from the blades of rotor by injecting oil into the case of centrifugal compressor (From (b) of fault self-recovery: removal of disturbance);

Adjustment of lube oil temperature for vibration control: By Adjusting pressure and temperature of lube oil, the stiffness and damp of bearing oil film can be changed to suppress vibration, such as 1/2 frequency (or low frequency) unstable vibration, to realize fault self-recovery (Form (c) of fault self-recovery: adjustment to deviation);

Anti-surge system: Through automatic reflux of feed, surge due to low suction flow can be prevented. (Form (c) of fault self-recovery: deviation adjustment);

Axial displacement self-recovery regulation: For high-speed turbo machine, through self-recovery regulation of axial displacement and adjustment of oil pressure to thrust bearing to prevent thrust bearing damage.(Form (c) of fault self-recovery: deviation adjustment);

Condition-based dry gas seal flushing: By monitoring whether the gas film carries liquid, and if so, blowing in some clean gas, the seal damage caused by loss of gas film stability can be avoided (Form (b) of fault self-recovery: removal of disturbance).

The following is a brief introduction to rotor auto-balance and axial displacement self-recovery regulation technology.

3.1 Auto-balancer

A large portion of faults in a rotating machine comes from rotor imbalance. This is especially true with the imbalance produced during operation due to coking, dirt forming or bending of rotor caused by thermal expansion. Such an imbalance can cause very severe vibration problem. Manual dynamic balancing is traditionally used to deal with such faults. If an online automatic balancing system is used, the imbalance of rotor or shaft can be automatically eliminated, and the fault can be recovered without having to shutdown the machine. The structure of auto-balancer for high-speed rotating machine is shown in Fig. 5. Self-recovery controller analyses oscillation signal from sensors and decides if the vibration is caused by rotor imbalance. If so, it calculates the magnitude and phase of the imbalance and sends a command to stationary ring to adjust the mass distribution of rotating ring to produce a counter-poise to original imbalance, thus to reduce vibration. The balancing heads often used in engineering are magnetic and hydraulic types. [5]

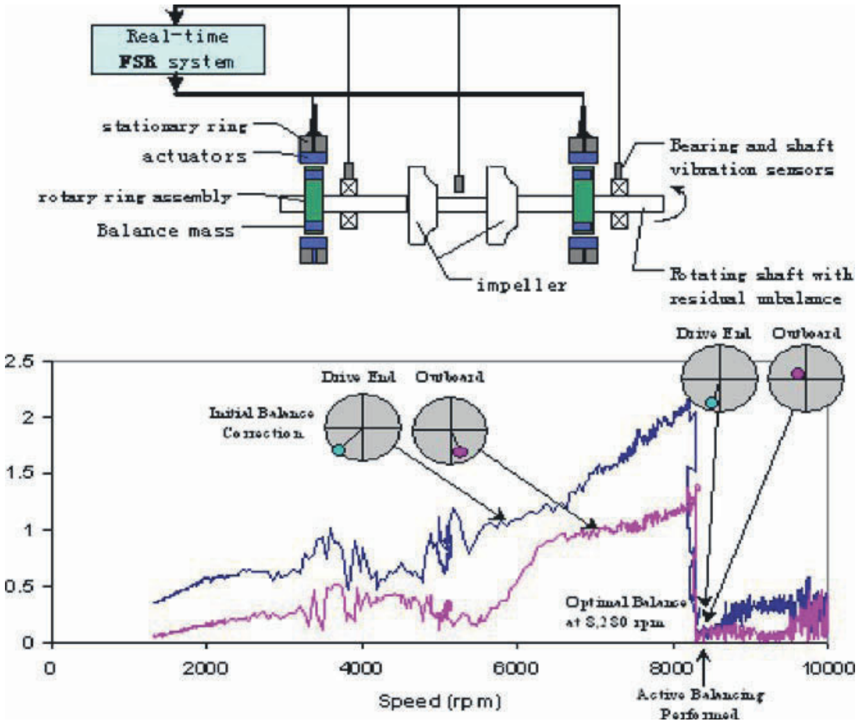

Fig.5 Principle of Auto-balancer

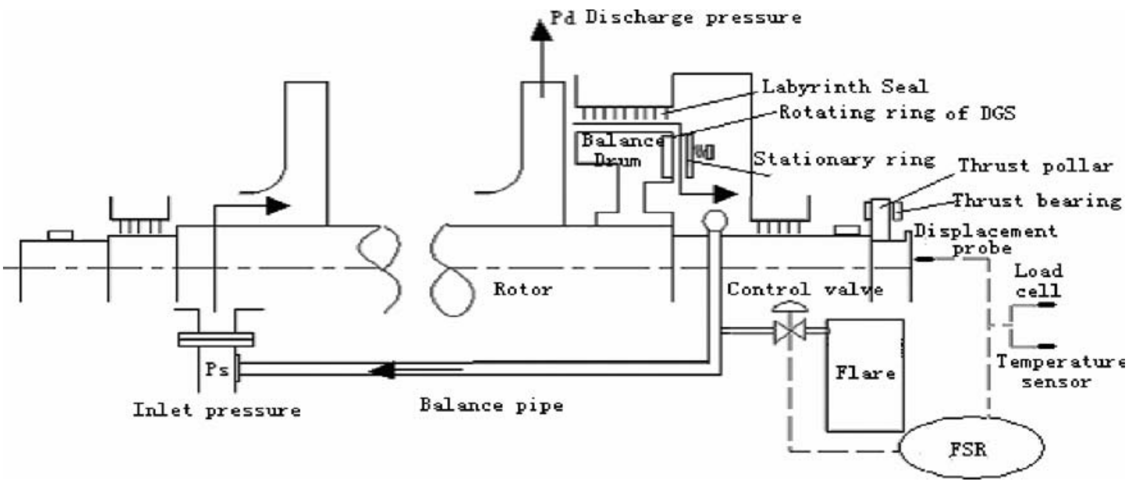
3.2 Fault self-recovery regulation of axial displacement

During the operation of rotary fluid machines (i.e. pumps, fans, centrifugal compressors), the interaction between rotor and fluid may produce an dynamic axial force. Often, most of such force is balanced by a pressure-difference type balancing drum, which reduces a large proportion of the dynamic axial force to reduce a load of thrust bearing. In abnormal situation machine must be shutdown by ESD system to prevent trust bearing damage from exceeding the thrust bearing's load.



Now under development a new kind of axial thrust balancing device with fault self-recovery regulation of axial displacement comprises a thrust detecting unit, a controller and a fluid flow rate adjusting unit to form a close control loop. The thrust detecting unit directly or indirectly measures the change of axial force applied to the thrust bearing, then the controller accordingly controls the flow rate adjusting unit to change the pressure difference between the balancing drum's two sides, in order to automatically adjust the bearing thrust load, therefore to prevent the thrust bearing damage from exceeding the thrust bearing's load, and in the same time to avoid unplanned trip and shutdown. Fig.6 and 7 illustrates the principle of fault self-recovery regulation of axial displacement on a high-speed turbine machine.

Since centrifugal compressors are often key equipments in petrochemical, metallurgical, and other process industries, and often there is no spare compressor. By adding a FSR system before ESD, the unplanned shutdown can be reduced without sacrifice safety. That is of obvious economical benefit.

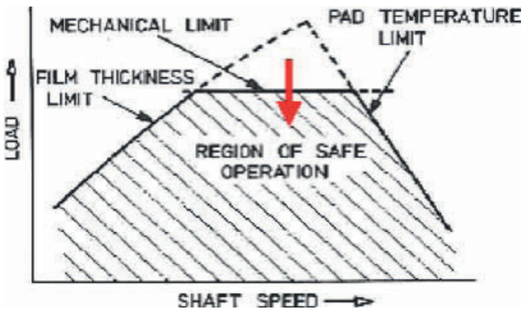


Fig.7 Safe operation region of thrust bearing

4 SELF-RECOVERY MECHANISM BASED INTELLIGENT MAINTENANCE SYSTEMS FOR MACHINE GROUP

The idea of fault self-recovery can be extended to cover the whole complex system of pump/machine group, including human, i.e., a man-machine-process-environment system. Gathering the knowledge of experts group and unitizing the power of computers, an operable intelligent platform that solves the problems of the man-machine-process-environment system can be implemented, and reliability centered intelligent maintenance system (RCIMS) can be built. See figure 8 and 9.

A networked reliability centered intelligent maintenance system (RCIMS) bases on monitoring and diagnosis system. It structures user, maintenance plan management, spare part management and maintenance groups to form a self-organizing (Self-healing) mechanism. An engineering demonstration of networked RCIMS has been built using system engineering approach to manage the moving equipments of Liaoyang petro-chemical plant, China National Petroleum Co. see Fig 10.

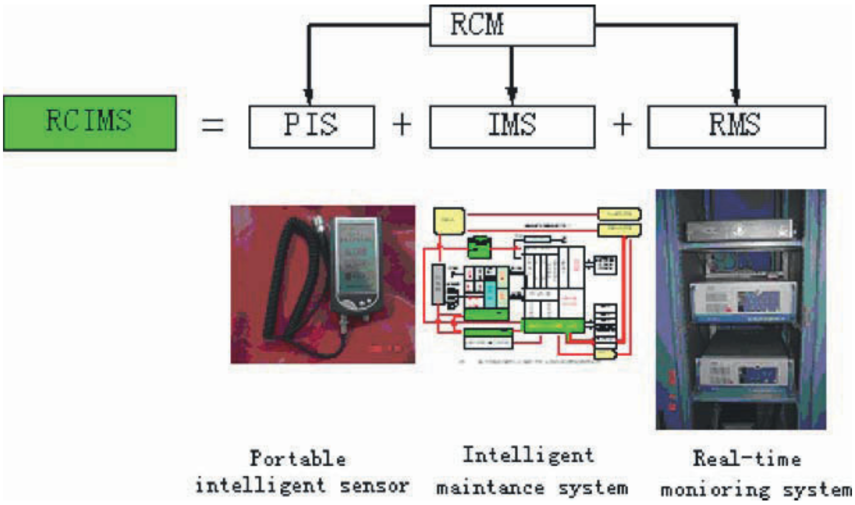

Fig.8 Reliability centered networking intelligent maintenance system

5 FAULT SELF-RECOVERY REGULATION OF ABNORMAL SITUATION IN PROCESS PRODUCTION UNIT

The idea of FSR can be used to prevent a man-machine-process-environment complex system from entering an abnormal situation. Such a system can be called an ASSR system (Abnormal Situation Self-recovery Regulation). Abnormal situation means an abnormal state of a plant that comes into being when severe disturbance exceeding design limit, which cannot be properly handled by control system. As some investigations stated, in the U.S. alone, the accidents stem from abnormal situation cost the petrol-chemical industry up to 20 billion dollars yearly. The ratio between the direct loss and the indirect loss of accidents is about 1:10. The loss caused by abnormal situation accounts for about 3-8% of the total cost.

The timely identification, diagnosis, assessment and adjustment conducted by a FSR system can enable a plant to restore normal situation or re-enter a safe state. The general technical strategy and solution is the all-rounded and all time-cycled monitoring of abnormal situation, with the focus mainly on the study of abnormal situation detection, prediction and its self-recovery regulation.

Detection and prediction: investigation in the cause of abnormal situation and in prediction of conditions that leads to abnormal situation.

Self-recovery regulation: Study concerning how to prevent, control or eliminate the inner change or outer disturbance of a system during operation, so as to prevent the system from exceeding design limit and entering abnormal situation.

For dangerous and critical operation, an automatic device or programmed control device, interlock device or linkage device should be provided to prevent disoperation.

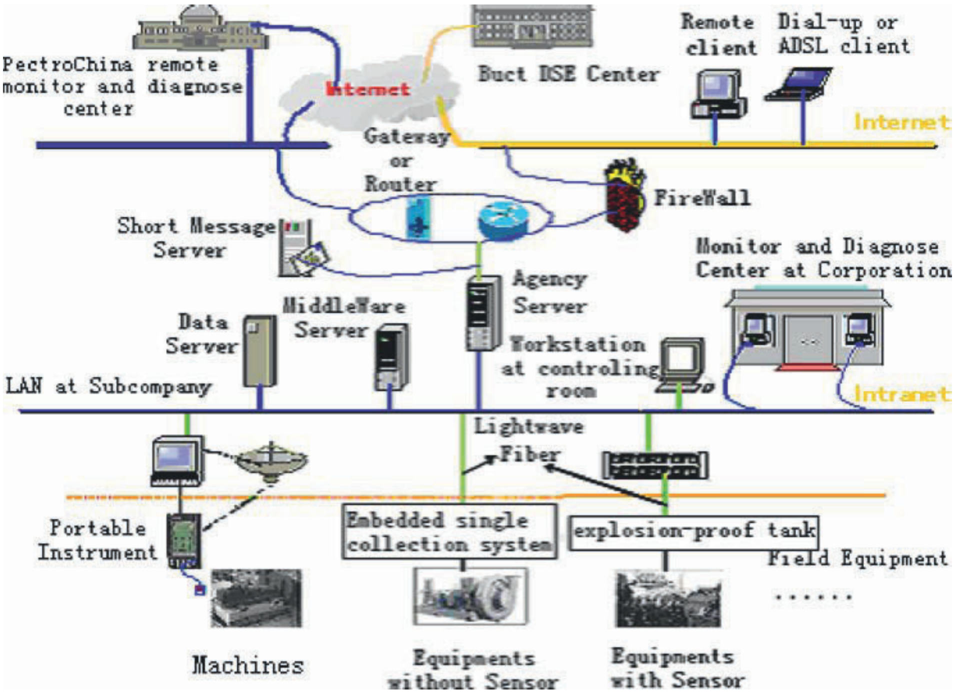

Fig.9 Network topology of reliability centered networking intelligent maintenance system

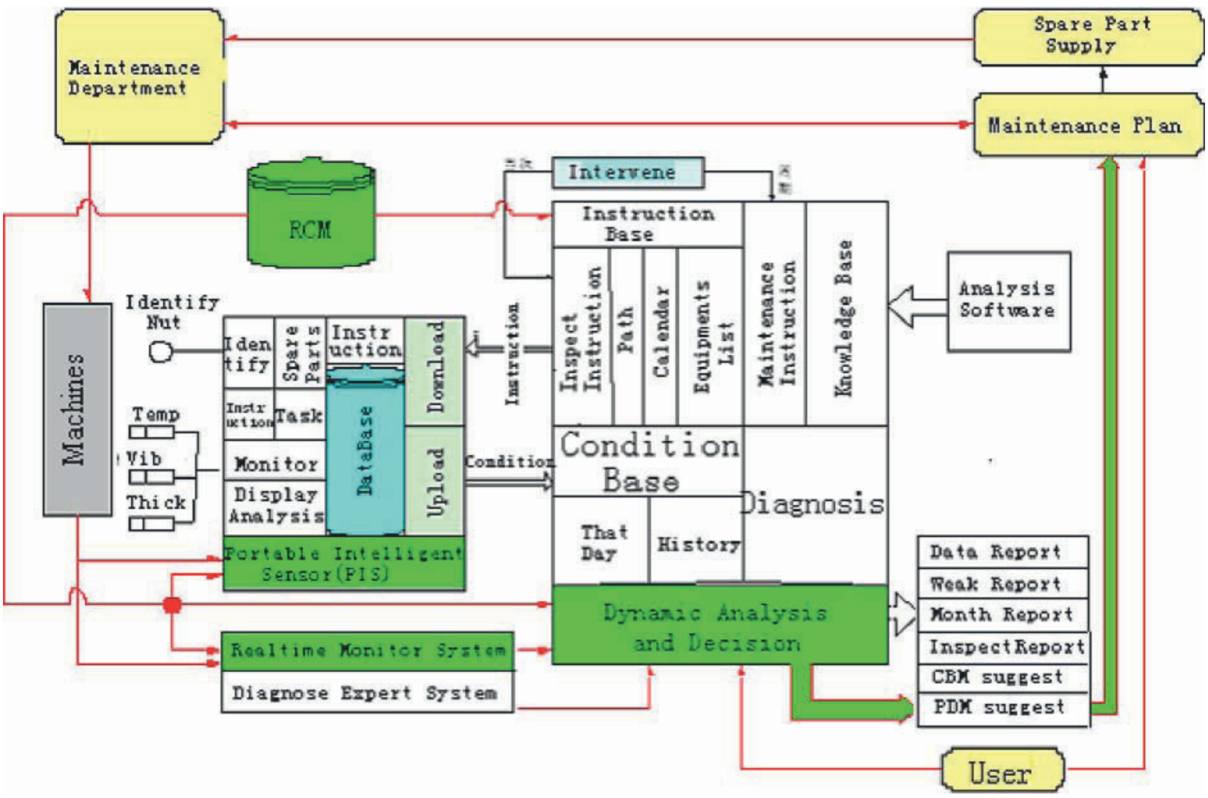

Fig10 FSR based and reliability centered networking intelligent maintenance system

6 INFORMATIONALIZED INTELLIGENT SAFETY ENSURING SYSTEM FOR PROCESS PRODUCTION UNIT

The principle of fault self-recovery and its engineering application in equipment, pump/machine groups and abnormal situation of complex process plants can effectively prevent and eliminate various kinds of faults in all time level, and thus can greatly boost safety and reliability of the process industry operations as shown in Fig. 9. [6] Following seven reductions (7 Rs) can be achieved:

1) Reduction of faults and accidents

2) Reduction of production loss due to shutdown

3) Reduction of "surplus inspection"

4) Reduction of "surplus maintenance"

5) Reduction of pollutant discharge

6) Reduction of spare part inventory

7) Reduction of equipment's dependence upon human.

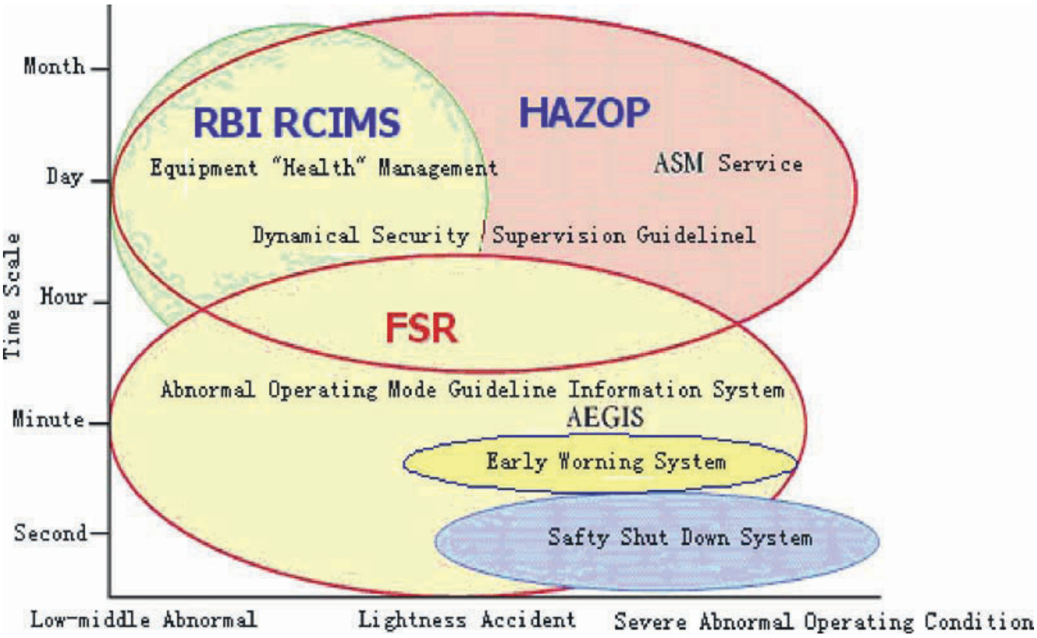

Fig.11 Principle of abnormal situation monitor and control with FSR

The FSR based design can shift the responsibility of maintenance duty from users to the manufacturers of equipment, and self-repair can shift the responsibility of remanufacture to operation which can prolong the safe operation period of equipment as shown Fig. 12.

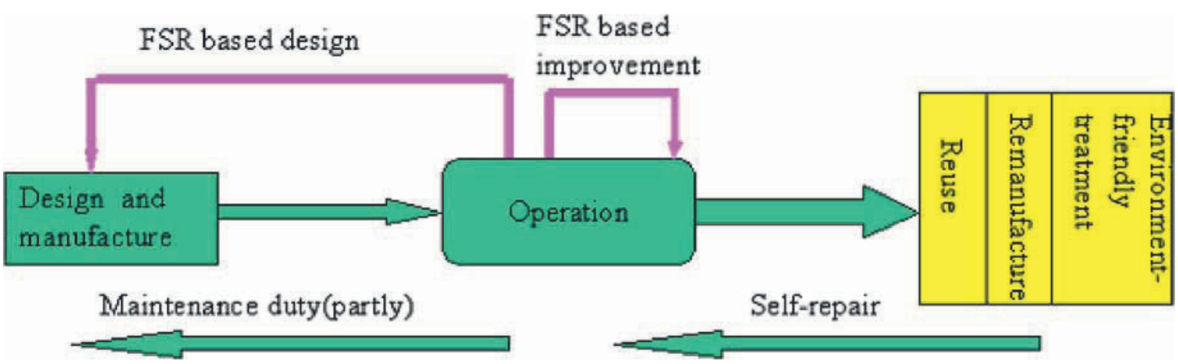

Fig.12 FSR based design can shift the responsibility of maintenance duty from users to the manufacturers

7 CONCLUSION

The fittest will survive in natural selection. From the viewpoint of scientific development, human should not only in harmony with nature, but also in harmony with their creation. The FSR can make engineers' dream come true. It will make the future equipments and production units more adapted to human demands, more harmonic with human. FSR is an advanced multidisciplinary technology, and is system engineering involving multiple personnel groups of different specialties; it opens a new horizon for Independent Innovation and has a great development potential in the future.

1) In the future, FSR can reduce the machines dependence upon human and liberate human from much of mental labors.
2) FSR can bring fighting against faults to the earlier designing stage and shift the duty of maintenance from user to the designer and manufacture;
3) FSR is an engineering method that can reduce disaster and boost productivity through fault prevention and reduction of maintenance, is very important to the long-cycle safe operation of process.
4) FSR provides a scientific base for the development of new generation equipments and process units that are maintenance free or require very little maintenance, to implement an environmental friendly and conservation-minded production process.

Abstract: Predictive maintenance (or prognostics) is critical to any engineering systems to avoid system breakdown, in particular, for complex systems. With the recent advances on pervasive computing, prognostics can be easily embedded in any devices and systems. When smart machines are networked and remotely monitored, and when their data is modeled and continually analyzed with sophisticated embedded systems, it is possible to go beyond mere "predictive maintenance" to intelligent "prognostics", the process of pinpointing exactly which components of a machine are likely to fail, and when and autonomously trigger service and order spare parts. This paper addresses the paradigm shift in modern maintenance systems from traditional "fail and fix" practices to "predict and prevent" methodology. Recent advances on prognostic technologies and tools are discussed. In addition, case studies are used to validate f these developed technologies and tools.

Key Words: diagnostics, prognostics, machine performance assessment, predictive maintenance

1 INTRODUCTION

For years, maintenance has been treated as a dirty, boring and ad hoc job. It's critical for productivity but isn't yet recognized as a key component of revenue generation. The simple question is often, "Why do we need to maintain things regularly?" The answer is, "To keep things as reliable as possible." But the real question is, "How much change or degradation has occurred since the last round of maintenance?" The answer is, "I don't know." Condition-based maintenance (CBM) deals with online data. Machine conditions are constantly monitored and their signatures evaluated. However, this is done at the machine level -- one machine at a time. It's a "fail-and-fix approach." Troubleshooting is the primary purpose. Today, CBM focuses on sensors and communications. All products and machines are networked by some means. It's hard to know, though, what to do with all this data. We need to turn data into information by using computational tools to process data locally. The maintenance world of tomorrow is an information world for feature-based monitoring. Information should represent a trend, not just a status. It should offer priorities, not just show "how much." If we do that, then our productivity can be focused on asset-level utilization, not just production rates.

Today, machine field services depend on sensor-driven management systems that provide alerts, alarms and indicators. The moment the alarm sounds, it's already too late to prevent the failure. Most factory downtime is caused by these unexpected situations. There is no alert provided that looks at degradation over time. If we can monitor degradation, then we can forecast upcoming situations and perform maintenance tasks when necessary (not too early or too late). Using these techniques, maintenance can be scheduled prior to failure. With the advent of modern computing and communication technologies, more products and machines are embedded with sensors and connected through tethered-and tether-free networks. In addition, with the seamlessly integrated network systems in today's global business environment, machines and factories are networked and information and decisions are synchronized, so any downtime in the system can jeopardize the entire enterprise productivity. On the another hand, constraints on security and communication bandwidth limitations require re-engineering to minimize or mitigate the risk of data exposure.

Intelligent maintenance systems (IMS) predict and forecast equipment performance so "near-zero breakdown" status is achievable. There are two reasons for failure: equipment performance and operator/human error. Near-zero downtime focuses on predictive techniques to minimize failures. It focuses on features of machine performance. Recently, many sophisticated sensors and computerized components have been developed, which are capable of collecting data carrying the degradation information of the machine's health status and performance. The problem is that most of this data has not been fully utilized in practical use. This is mainly because the available data are not rendered in a useable form. Therefore, advanced technologies are needed to process the data and extract the useful degradation information to be utilized in maintenance decision making in a more intelligent manner. Moreover, through the integrated life-cycle management, such degradation information can be used to make improvements in every aspect of product life-cycle. World-class companies already have taken a game-changing approach, implementing a new service business model to transform maintenance systems into smart service and asset management solutions. They reduce downtime and provide the ability to look ahead at the quality of products before they ship

by closely watching equipment performance and machine degradation. Rather than reactive maintenance — "fail-and-fix" — companies can indeed move to "predict-and-prevent" maintenance.
In this paper, we first review the state-of-the-art on maintenance technologies and introduce the concept of intelligent maintenance systems using product degradation information. Afterwards, the prognostic tools recently developed will be addressed, and several case studies are provided to demonstrate these tools in practical use. These real examples prove the effectiveness and potentials of these tools, as well as address needs in future research directions.

2 STATE-OF-THE-ART REVIEWS ON MAINTENANCE TECHNOLOGIES

2.1 Maintenance Technologies Overview

Looking back on the development history and forecasting the development tendency of maintenance technologies, the roadmap to excellence in maintenance can be illustrated as in figure 1.

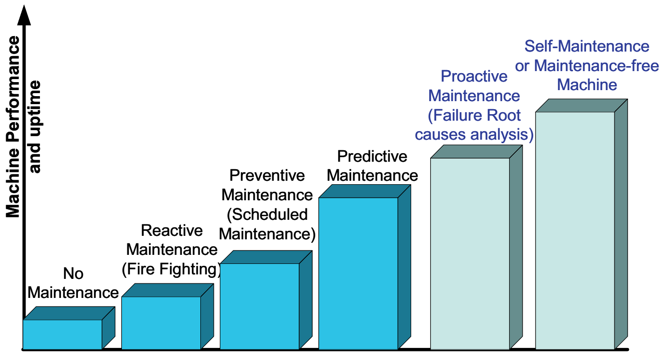

Figure 1. The development of maintenance technologies

2.1.1 No Maintenance

There are two kinds of situations in which no maintenance will occur.

- No way to fix it: the maintenance technique is not available for some special application, or the maintenance technique is not well developed at the early stage.
- Isn't worth it to fix it: some machines were designed to be used only once. Comparing with maintenance cost, it might be more cost-effective just to discard it.

Neither of the scenarios above is within the scope of the discussion here.

2.1.2 Reactive Maintenance

In plain English, the aim of reactive maintenance is just to "fix it after it's broken," since most of the time a machine brakes down without warning and it is urgent for the maintenance crew to put it back to work: this is also referred to as "fire fighting".

The reason that reactive maintenance happens is because some operations have developed through the years with very little attention given to the proper care of the machinery involved. Essentially, little to no maintenance is conducted and the machinery operates until a failure occurs. At this time, appropriate personnel are contacted to assess the situation and make the repairs as expeditiously as possible. In a situation where the damage to equipment is not a critical factor, as plenty of downtime is available, and the values of the assets are not a concern, the firefighting mode may prove to be an acceptable option. Of course, one must consider the additional cost of making repairs on an emergency basis since soliciting bids to obtain reasonable costs may not be applicable in these situations. Due to market competition and environmental/safety issues, the trend is toward appropriating an organized and efficient maintenance program as opposed to firefighting.

2.1.3 Preventive Maintenance

Preventive Maintenance (PM) is an equipment maintenance strategy based on replacing, overhauling or remanufacturing an item at a fixed interval, regardless of its condition at the time. Scheduled restoration tasks and scheduled discard tasks are both examples of Preventive Maintenance tasks.

2.1.4 Predictive Maintenance

Predictive Maintenance (PdM) is a right-on-time maintenance strategy. Predictive maintenance may be best described as a process which requires technologies and people skills, while combining and using all available diagnostic and performance data, maintenance histories, operator logs and design data to make timely decisions about maintenance requirements of major/critical equipment. It is the integration of various data, information and processes that leads to the success of a PdM program. It analyzes the trend of measured physical parameters against known engineering limits for the purpose of detecting, analyzing and correcting a problem before a failure occurs. A maintenance plan is made based on the prediction results derived from condition based monitoring. This can cost more up front than PM because of the additional monitoring hardware and software investing, manning, tooling, and education required to establish a Predictive Maintenance program. However, it offers increased equipment reliability and a sufficient advance in information to improve planning, thereby reducing unexpected downtime and operating costs.

2.1.5 Proactive Maintenance

Proactive Maintenance, in general terms, encompasses any tasks used to predict or prevent equipment failure. To be more specific, there are two working directions.

- Change the failure reactive to failure proactive by avoiding the underlying conditions that lead to machine faults and degradation. Proactive Maintenance focuses on analyzing the root cause, and not just the symptoms. It seeks to prevent or to fix the failure from the source after it identifies the root cause.
- Feed the maintenance information back to the design and operation department. Failure prevention should also be conducted in the design and operation department. The maintenance crew's job is not only to fix a machine or change parts, but they should also help by suggesting how to improve a machine's design and operation so that the failures are prevented proactively.

There is still some debate about the efficiency and failure response speed of proactive maintenance, but there is no doubt that there has been a lack of communication between maintenance and design

2.1.6 Self maintenance

Self-maintenance is a new design and system methodology. A self-maintaining machine can monitor and diagnose itself, and if any kind of failure or degradation happen, it can still maintain its functions for a while. A Self-maintaining machine doesn't belong in the conventional physical maintenance concept, but in the functional maintenance concept instead. Functional maintenance aims to recover the required function of a depredating machine by trading off functions, whereas traditional repair (physical maintenance) aims to recover the initial physical state by replacing faulty components, cleaning, etc. The way to fulfill the self-maintenance function is by adding intelligence to the machine, making it clever enough for functional maintenance. In other words, self-maintainability would be appended to an existing machine as an additional embedded reasoning system.

Another system approach to creating the self-maintaining ability is to add the self-service trigger function to a machine. The machine will then self-monitor, self-diagnose and self-trigger the service request with detailed and clear maintenance requirements. The maintenance task is still conducted by a maintenance crew, but the no gap integration of machine, maintenance schedule, dispatch system and inventory management system will minimize maintenance costs to the greatest extent and raise customer satisfaction to the highest level.

2.2 State- of-the-art review on Condition Based Maintenance (CBM)and Prognostics Technologies

Traditional reliability prediction is made based on failure time data; meanwhile, maintenance actions are initiated in terms of a reliability index. Usually such preventive maintenance schemes as block-replacement and age-replacement are time-based without considering the current health state of the product, thus are inefficient and less valuable for a customer whose individual asset is of the most concern.

The major role of degradation analysis is to investigate the evolution of physical characteristics or performance measures of a product leading to failure. A maintenance scheme, referred to as Condition Based Maintenance (CBM), is developed by considering current degradation and its evolution. CBM methods and practices have been continuously improved for the last decades. For example, a major manufacturer of elevators for high rising buildings continuously monitors the braking systems, and acceleration and deceleration of elevators globally to meet the high safety requirement. The main idea of CBM is to utilize the product degradation information extracted and identified from on-line sensing techniques to minimize the system downtime by balancing the risk of failure and achievable profits. The decision-making in CBM will focus on predictive maintenance. To do so, many diagnostic tools and methods have been developed with good successes. Sensor fusion techniques are also commonly engaged due to the inherent superiority in taking advantage of mutual information from multiple sensors (Roemer *et al*., 2001; Hansen *et al*., 1994; Reichard *et al*., 2000). For example, vibration signature analysis and oil analysis, because of their excellent capability of describing machine performance, have been successfully employed for prognostics for a long time (Kemerait, 1987; Wilson *et al*., 1999). In the mean time, alternative approaches in using time/stress, temperature, acoustic emissions (Goodenow *et al*., 2000), and ultrasonic are widely employed as well. However, major breakthrough has not been made in the development on prognostic since many methods were still based on traditional signal processing methods (Hardman *et al*., 2000).

In the recent technical literatures, a large variety of prognostic applications have been reported, and many of these were more application specific rather than generic. Some research activities about infrastructure of prognostics were also reported. From 1998 to 2000, the U.S. army logistics integration agency funded a project entitled, "Prognostics Framework" (Su *et al*., 1999). The project aimed to provide an overall architecture to manage the information provided by the individual prognostic techniques. This prognostics framework is generic and scalable, with open architecture and horizontal technology, which was intended to integrate with embedded diagnostics to provide a "total health management" capability.

Generally speaking, current prognostic approaches can be classified into three basic groups: *model-based prognostics*, *data driven prognostics*, and *hybrid prognostics*. An example of a characteristic *model-based prognostics* application includes collecting data from model-based simulations under normal and degraded conditions. Prognostic models are constructed based on different random load conditions, or modes. However, in the absence of a reliable or accurate system model, another approach to determine the remaining useful life is to monitor the trajectory of a developing fault and predict the amount of time until the developing fault reaches a predetermined level requiring action, which is the so called data driven prognostic method. An example of a hybrid method, which fuses the model-based information and sensor-based information and takes advantage of both model-driven and data-driven methods, was proposed by Hansen *et al*. (1994), by which a more reliable and accurate prognostic result can be generated.

Prognostic information obtained through intelligence embedded into the manufacturing process or equipment can also be used to improve the manufacturing and maintenance operations in order to increase process reliability and improve product quality. For instance, the ability to increase reliability of manufacturing facilities using the awareness of the deterioration levels of manufacturing equipment has been demonstrated through an example of improving robot reliability (Yamada and Takata, 2002). Moreover, a Life Cycle Unit (LCU) (Seliger *et al*., 2002) was proposed to collect usage information about key product components, enabling one to assess product reusability and facilitating reuse of products that have significant remaining useful life.

In spite of these progresses, many fundamental issues still remain:

1. Most of the developed prognostics approaches are application or equipment specific. A generic and scalable prognostic methodology or toolbox doesn't exist;
2. Currently, methods are generally focused on solving the failure prediction problem. Tools for system performance assessment and degradation prediction has not been well addressed;
3. Features used for prognostics need to be further developed;
4. Many developed prediction algorithms have been demonstrated in a laboratory environment without industrial validations.

To address these issues, a toolbox of algorithms for multi-sensor performance assessment and prediction, named Watchdog Agent™, has been developed at the Center for Intelligent Maintenance Systems (IMS) which is a multi-campus NSF Industry/University Cooperative Research Center between the University of Cincinnati and the University of Michigan. These tools enable one to quantitatively assess and predict performance degradation levels of key product components (Casoetto *et al*., 2003; Djurdjanovic *et al*., 2000; Lee, 1995; Lee, 1996), thus offering a possibility to physically realize a closed-loop product life cycle monitoring and management.

3 CURRENT DEGRADATION FEATURE EXTRACTION AND PREDICTIVE TOOLS

Watchdog Agent™ developed by the Center for IMS consists of embedded computational prognostic algorithms and a software toolbox for predicting degradation of devices and systems. The Watchdog Agent™ bases its degradation assessment on the readings from multiple sensors that measure critical properties of the process, or machinery that is being considered. It is expected that the degradation process will alter the sensor readings that are being fed into the Watchdog Agent™, and thus enable it to assess and quantify the degradation by quantitatively describing the corresponding change of sensor signatures. In addition, a model of the process or piece of equipment that is being considered, or available application specific knowledge can be used to aid the degradation process description, provided that such a model and/or such knowledge exist. The prognostic function of the watchdog is realized through trending and statistical modeling of the observed process performance signatures and/or model parameters. This allows one to predict the future behavior of these patterns and thus forecast the behavior of the process, or piece of machinery that is being considered.

In order to facilitate the use of Watchdog Agent™ in a wide variety of applications, with various requirements and limitations regarding the character of signals, available processing power, memory and storage capabilities, limited space, power consumption, personal user's preference etc, the performance assessment module of the Watchdog Agent™ has been realized in the form of a modular open architecture toolbox. The toolbox consists of different prognostics tools, including neural network based, time-series based, wavelet-based and hybrid joint time-frequency methods, etc., for predicting the degradation or performance loss on devices, process, and systems. Open architecture of the toolbox allows one to easily add new solutions to the performance assessment modules as well as to easily interchange different tools, depending on the application needs. The tools currently realizing the signal processing, feature extraction, sensor fusion and performance evaluation modules of the performance assessment Watchdog Agent™ functionality are summarized in Figure 2.

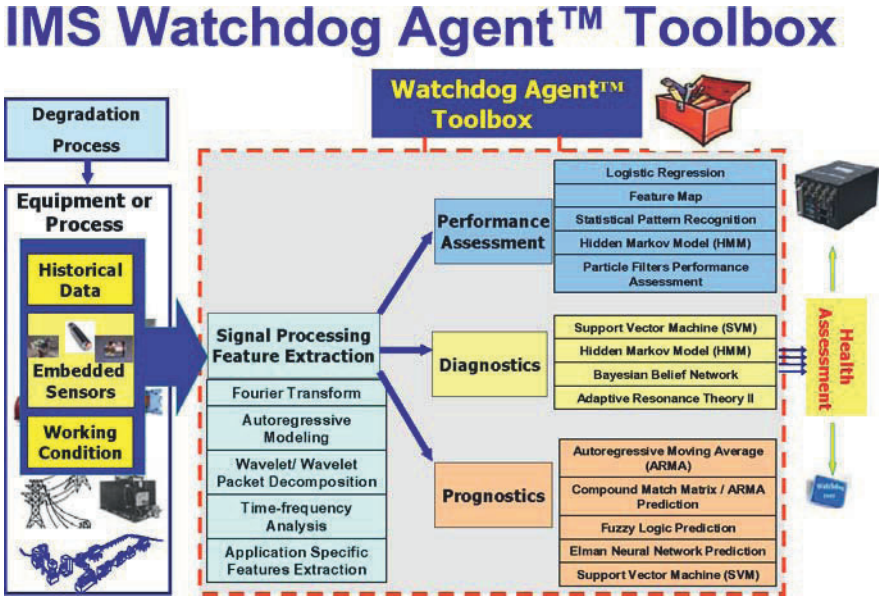

Figure 2. Watchdog Agent Prognostics Toolbox

Each of these modules is realized in several different ways to facilitate the use of Watchdog Agent™ in a wide variety of products and applications. Specifically, these modules are:

- **Sensory processing module** transforms sensor signals into domains that are the most informative of product's performance. Time-series analysis (Pandit and Wu, 1993) or frequency domain analysis (Marple, 1987) could be used to process stationary signals (signals with time invariant frequency content), while wavelet (Burrus, *et al*., 1998), or joint time-frequency analyses (Cohen, 1995; Djurdjanovic *et al*., 2002) could be used to describe non-stationary signals (signals with time-varying frequency content). Most real life signals, such as speech, music, machine tool vibration, acoustic emission etc are non-stationary signals, which place strong emphasis on the need for development and utilization of non-stationary signal analysis techniques, such as wavelets, or joint time-frequency analysis.

- **Feature extraction module** extracts features most relevant to describing the product's performance. Those features are extracted from the time domain into which sensory processing module transforms sensory signals, using expert knowledge about the application, or automatic feature selection methods such as roots of the autoregressive time-series model, or time-frequency moments and Singular Value Decomposition.

- **Decision-level sensor fusion** is based on separately assessing and predicting process performance from individual sensor readings and then merging these individual sensor inferences into a multi-sensor assessment and prediction through some averaging technique, or more complex functional transformation.

- **Performance evaluation module** evaluates the overlap between most recently observed signatures and those observed during normal product operation. This overlap is expressed through the so-called Confidence Value (CV), ranging between zero and one, with higher CVs signifying a high overlap, and hence performance closer to normal. In case data associated with some failure mode exist, most recent performance signatures obtained through the signal processing, feature extraction and sensor fusion modules can be matched also against signatures extracted from faulty behavior data. This matching allows the Watchdog Agent™ to recognize and forecast a specific faulty behavior, once a high match with the failure associated signatures is assessed for the current process signatures, or forecasted based on the current and past product's performance. Figure 3 illustrates this signature matching process for performance evaluation. The overlapped areas between the most recent behavior and the nominal behavior as well as the faulty one are continuously transformed into CV over time for evaluating the deviation of the recent behavior from the nominal and faulty ones.

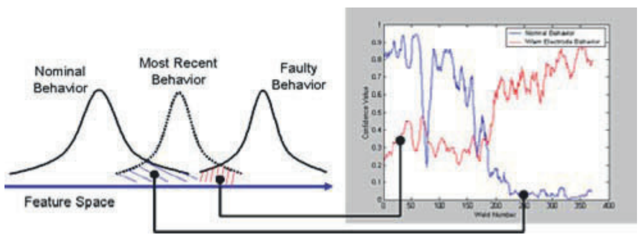

Figure 3. Performance Evaluation using Confidence Value (CV)

Realization of the performance evaluation module depends on the character of the application and extracted performance signatures. If significant application expert knowledge exists, simple but rapid performance assessment based on the feature-level fused multi-sensor information can be made using the relative number of activated cells in the neural network, or using the Logistic Regression approach. For products with open-control architecture, the match between the current and nominal control inputs and performance criteria can also be utilized to assess the product's performance. For more sophisticated applications with intricate and complicated signals and performance signatures, statistical pattern recognition methods, or Feature Map based approach can be employed. Over time, as new failure modes occur, performance signatures related to each specific failure mode can be collected and used to teach the Watchdog Agent to recognize and diagnose that failure mode in the future. Thus, the Watchdog Agent™ is envisioned as an intelligent device that utilizes its experience and human supervisory inputs over time to builds its own expandable and adjustable world model. Even though the performance CV already bares significant prognostic information about the remaining product's useful life, additional prognostic information can be extracted by capturing the dynamics of the product's behavior and utilizing it to extrapolate and predict the product's behavior over time. Currently, Autoregressive Moving-Average (ARMA) modeling and Match Matrix methods are used to forecast the performance behavior.

Furthermore, a system methodology and platform has been developed that enables transformation of product data into more useful formats for remote and telematics applications. The integrated IMS Infotronics platform (Figure 4) has been developed to allow scalability and reconfigurability for many research activities. This platform provides a baseline system for researchers and industry members to develop next-generation intelligent product service systems.

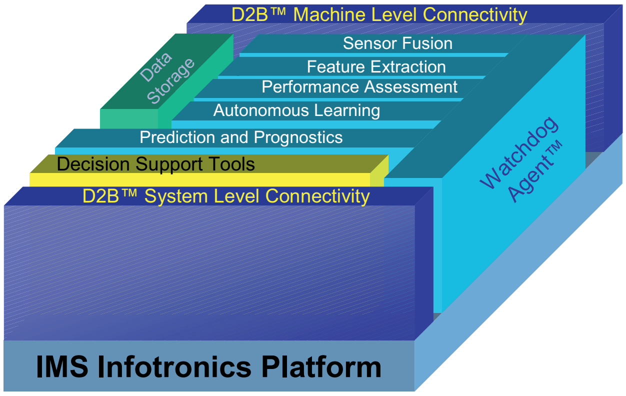

Figure 4. Integrated IMS Infotronics Platform

3.1 Watchdog Agent® Platform Development

3.1.1 Flowchart of developing Watchdog Agent® system

Figure 5 shows the four steps of developing the Watchdog Agent® system for a specific application. Step 1, find out the conditions and needs. Step 2, select the right tool, build and evaluate it. Step 3, Build a prototype system and test it in a real application environment and analyze the results. If the results are not acceptable, then go back to the previous steps. If it's acceptable, go to step 4, build the finalized system and deploy it.

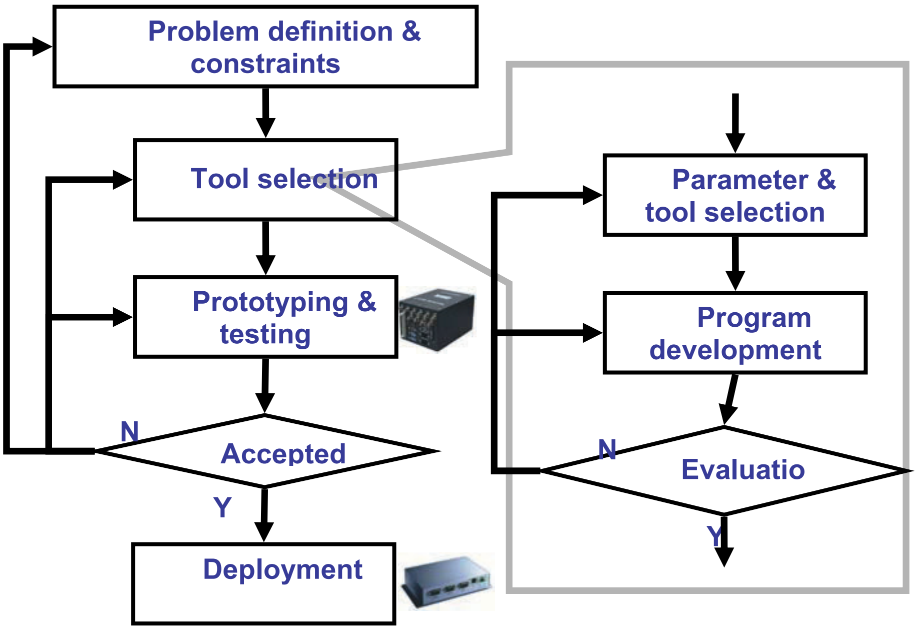

Figure 5. Flowchart of developing Watchdog Agent® system

3.1.2 System Architecture

The Watchdog Agent® system includes embedded computer hardware, an embedded operating system, embedded software and remote client software. The embedded software is comprised of three modules: the Watchdog Agent® tools, the database and the web server. Sensor signals, such as vibration, temperature, pressure, etc, are acquired by the system and processed by the Watchdog Agent tools. Then useful information, such as health information, is saved to the database and published to the internet through an embedded web server. A remote computer may be a remote monitoring workstation, or a maintenance server. The client software we developed runs on a remote computer and gets the useful information via the Internet in order to conduct further analysis.

3.1.3 Hardware Requirements

Hardware requirements depend on the application and the tools we select. For example; an analog input, a digital input, an Ethernet input or a serial input. The tools will be selected based on the computation capacity needs, such as CPU speed, amount of memory and storage. The working environment will decide the storage type, temperature range, etc.

3.1.4 Prototype Hardware Development

Figure 6. Prototype hardware

The prototype hardware is based on PC104 architecture. It has a powerful VIA Eden 400MHz CPU and 128MB memory. It can embed complex algorithms into the hardware. It has sixteen high speed analog input channels to deal with highly dynamic signals. It also has various peripherals that can acquire non-analog sensor signals such as RS-232/485/432, Parallel and USB. PC104 architecture enables the hardware to be easily expanded to multi-board system, which includes multiple CPUs and large amount input channels. The prototype uses a Compact Flash card for storage, so it can be placed on top of machine tools and is suitable for withstanding vibrations in a working environment.

Hardware specification:

- PC104 architecture
- VIA Eden 400 CPU, 128MB RAM
- DAQ features
    - 16-channel, 16 bit 100KHz analog input
    - 4-channel analog output
    - 24 DI/DO, 2 counter/timers
- Dual network interface
- RS-232, USB x 2, VGA
- Spindle-free storage (no HDD)
- Fanless design
- Extended temperature range

3.1.5 Commercially Available Hardware

As an option, we also are evaluating commercially available hardware such as Advantech and National Instruments (NI).

a) Advantech UNO-2160

b) NI-CompactRIO reconfigurable embedded system

Figure 7. UNO-2160 for Watchdog Agent Applications

Figure 8. NI-CompactRIO for Watchdog Agent Applications

3.1.6 Software Development

The software consists of two parts: embedded side software and remote side software, as shown in Figure 9. The embedded side software is the software running on the embedded hardware which consists of the communication module, command analysis module, task module, algorithm module, function module and DAQ module. The communication module is responsible for communicating with the remote side via TCP/IP protocol. The command analysis module is used to analyze different commands coming from the remote side. The task module includes a multi-thread schedule and the management. Algorithm module contains specific watchdog agent tools. The function module has several auxiliary functions such as channel configuration, security configuration, email list and so on. The DAQ module performs A/D conversion using either interrupt or software trigger to get data from different sensors.

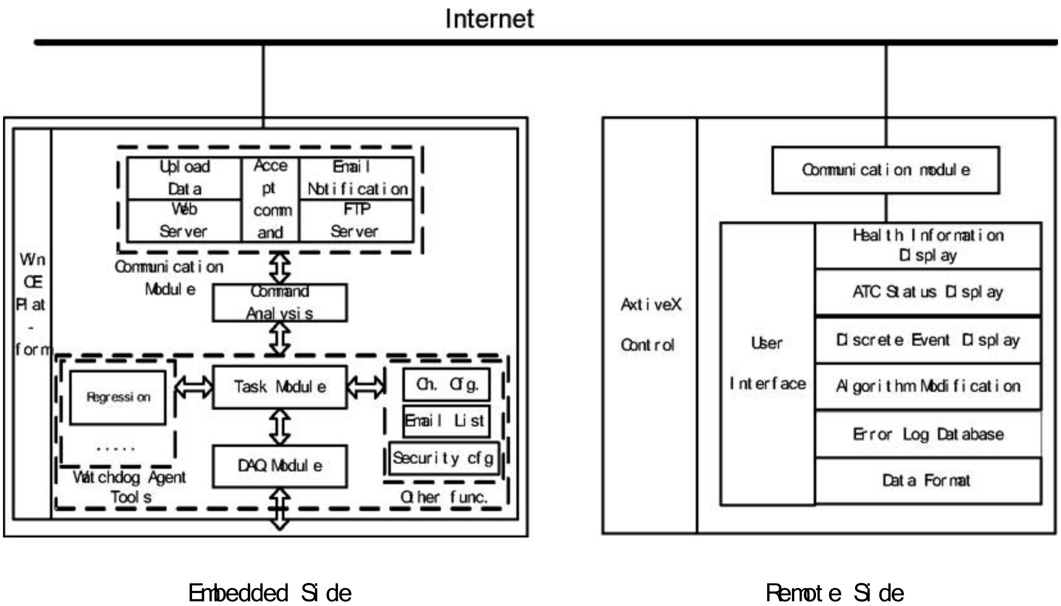

Figure 9 Software structure

The remote side software is the software running on the remote computers. It is implemented by ActiveX control technology and could be used as a component of the Internet Explorer Browser. The remote side software is mainly composed of a communication module and a user interface module. The communication module is used for communicating with the embedded site via TCP/IP protocol. The user interface has a health information display, ATC status display, and a discrete event display, algorithm module, error log database and data format.

4 CASE STUDIES

Several Watchdog Agent™ tools for on-line performance assessment and prediction have already been implemented as standalone applications in a number of industrial and service facilities. Listed below are several examples to illustrate the developed tools.

4.1 Example 1: Prognostics of an AS/RS Materials Handling Systems

A time-frequency based method (Cohen, 1995) has also been implemented for performance assessment of a gearbox in an AS/RS material handling system shown in Figure 11. Four vibration sensor readings have been fused to autonomously and on-line evaluate its performance. The vibration signals were processed into joint time-frequency energy distributions (Cohen, 1995) and a set of time-shift invariant time-frequency moments (Zalubas, *et al*., 1996; Djurdjanovic *et al*. 2000; Tacer and Loughlin, 1996) was extracted. Since those moments asymptotically follow a Gaussian distribution (Zalubas, *et al*., 1996), statistical reasoning was utilized to evaluate the overlap between signatures describing the normal process behavior (used for training) and those describing the most recent process behavior. Figure 12 shows a screenshot of the software application housing this time-frequency based Watchdog Agent used for performance assessment of a material handling system. The CV was generated by fusing multiple signal features for performance assessment.

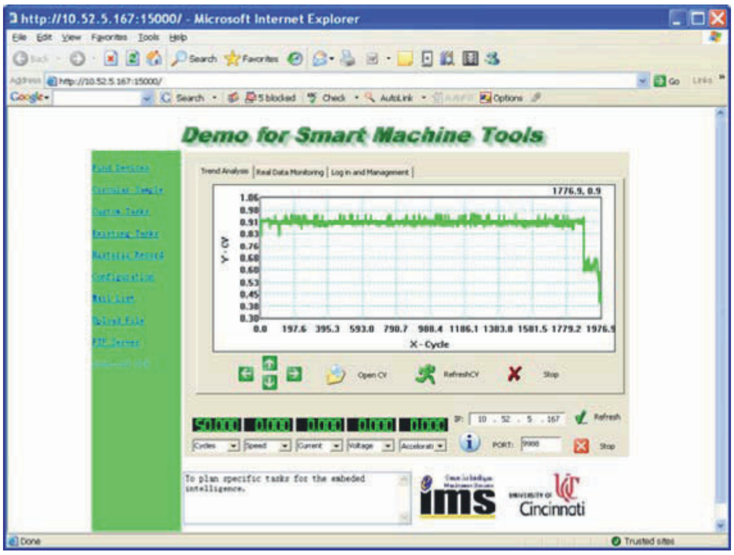

Figure 10. Remote client software

Figure 11. Material Handling System for Mail Staging

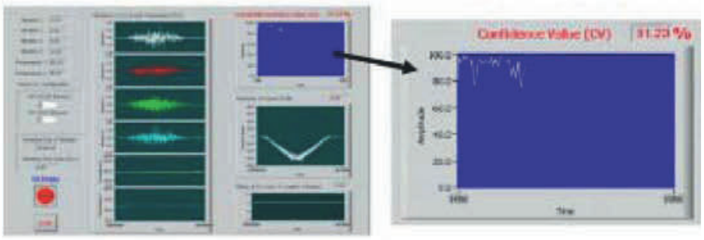

Figure 12. Screenshot of the Time-frequency based Watchdog Agent Assessing Performance of the Materials Handling System Shown in Figure 5

4.2 Example 2: Roller Bearing Prognostics Testbed

Most bearing diagnostics research involves studying the defective bearings recovered from the field, where the bearings exhibit mature faults, or from simulated or "seeded" damage. Experiments using defective bearings have less capability to discover natural defect propagation in the early stages. In order to truly reflect the real defect propagation processes, bearing run-to-failure tests were performed under normal load conditions on a specially designed test rig sponsored by Rexnord Technical Service.

The bearing test rig hosts four test bearings on one shaft. Shaft rotation speed was kept constant at 2000rpm. A radial load of 6000lbs is added to the shaft and bearing by a spring mechanism. A magnetic plug installed in the oil feedback pipe collects debris from the oil as evidence of bearing degradation. The test stops when the accumulated debris adhered to the magnetic plug exceeds a certain level.

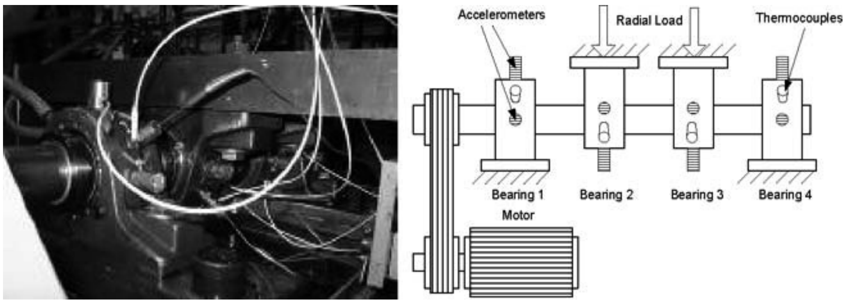

Figure 13. Bearing Test Rig

Four double row bearings were installed on one shaft as shown in Figure 13. High sensitivity accelerometer was installed on each bearing housing. Four thermocouples were attached to the outer race of each bearing to record bearing temperature for monitoring the lubrication purposes. Several sets of tests ending with various failure modes were carried out. The time domain feature shows that most of the bearing fatigue time is consumed during the period of material accumulative damage, while the period of crack propagation and development is relatively short. This means that if the traditional threshold-based condition monitoring approach is used, the response time available for the maintenance crew to respond prior to catastrophic failure after a defect is detected in such bearings is very short. A prognostic approach that can detect the defect at the early stage is demanded so that enough buffer time is available for maintenance and logistical scheduling.

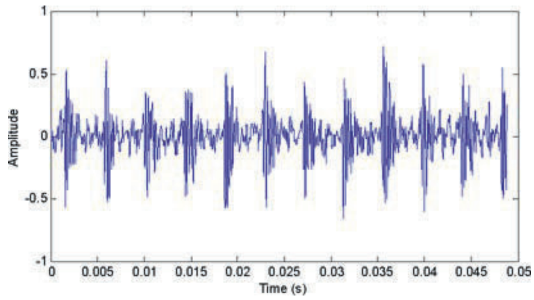

Figure 14. The Vibration Signal Waveform of a Faulty Bearing

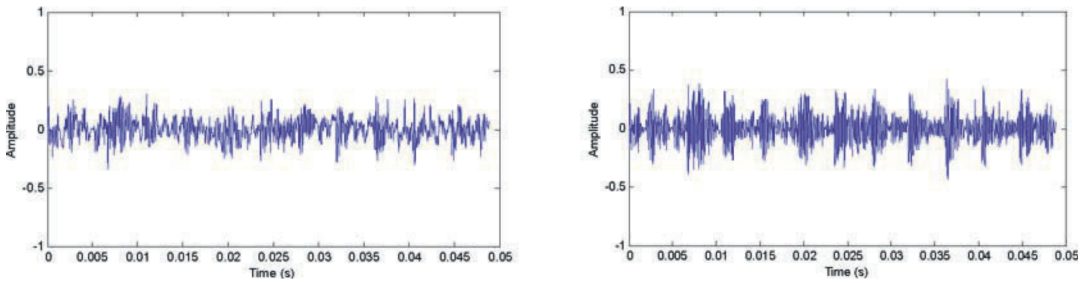
Figure 14 presents the vibration waveform collected from bearing 4 at the last stage of the bearing test. The signal exhibits strong impulse periodicity because of the impacts generated by a mature outer race defect. However, when examining the historical data and observing the vibration signal three days before the bearing failed, there is no sign of periodic impulse as shown in Figure 15(a). The periodic impulse feature is totally masked by the noise.



(a) **(b)**

Figure 15. The Vibration Waveform with Early Stage Defect (a) Raw Signal (b) De-noised Signal using the Wavelet Filter

An adaptive wavelet filter is designed to de-noise the raw signal and enhance the degradation detectability. The adaptive wavelet filter is yielded in two steps. At first, the optimal wavelet shape factor is found by the minimal entropy method. Then optimal scale is identified by maximizing the signal periodicity. Applying the designed wavelet filter to the noisy raw signal, the de-noised signal can be obtained as shown in Figure 15(b). The periodic impulse feature is clearly discovered, which is strong evidence of bearing outer race degradation. The wavelet filter-based de-noising method successfully enhanced the signal feature and provided potent proof for prognostic decision-making.

4.3 Example 3: Bearing Risk of Failure and Remaining Useful Life Prediction

An important issue in prognostic technology is to estimate the risk of failure and the remaining useful life of a component given the component age and its past and current operating conditions. In numerous cases, failures are attributed to many correlated degradation processes, which could be reflected by multiple degradation features extracted from sensor signals. These features are the major information regarding the health of the component under monitoring; however, the failure boundary is hard to define using these features. In reality, the same feature vector could be attributed to totally different combinations of the underlying degradation processes and their severity levels. In other words, the failure boundary is gray by monitoring the degradation features. There is only a probabilistic relationship between the component failure and the certain level of degradation features. A typical example can be found during bearing operation. Two bearings of the same type could fail at the different levels of RMS and Kurtosis of vibration signal. To capture the probabilistic relationship between the multiple degradation features and the component failure as well as predict the risk of failure and the remaining useful life, IMS has developed a Proportional Hazards (PH) approach (Liao *et al*. 2005) based on the PH model proposed by Cox (1972). The PH model involving multiple degradation features is given by:

$$\lambda(t;\underline{Z}) = \lambda_0(t)\exp(\underline{\beta}'\underline{Z})$$

where $\lambda(t;\underline{Z})$ is the hazard rate of the component given the current age t and degradation feature vector $\underline{Z}$; $\lambda_0(t)$ is called the baseline hazard rate function; $\underline{\beta}$ is the model parameter vector. This formulation relates the working age and multiple degradation feature to the hazard rate of the component. To estimate the parameters, maximum likelihood approach could be utilized using offline data including the degradation features over time of many components and their failure times. Afterwards, the established model can be used for predicting the risk of failure of the component by plugging in the working age and the degradation features extracted from the on-line sensor signals. In addition, the remaining useful life $L(t_{current})$ given the current working age and the history of degradation features can be estimated by:

$$L(t_{current}) \approx \int_{t_{current}}^{\infty} \exp\left(-\int_{t_{current}}^{\tau} \lambda(v;\underline{\hat{z}}(v))\, dv\right) d\tau$$

where $\underline{\hat{z}}(v)$ is the predicted feature vector.

Consider the vibration data obtained from the test rig in Example 2. To facilitate on-line implementation, root-mean-square (RMS) and Kurtosis are calculated and used as degradation feature. Figure 10 shows the predicted hazard rate over time based on these degradation features. This quantity can be utilized to trigger maintenance when the risk level crosses a predetermined threshold level. Table 1 provides the remaining useful life predictions given the current bearing age and the feature observations. The predictions are in accordance with the actual life of the studied bearing (32.5278 days) with minor prediction errors when the degradation progresses.

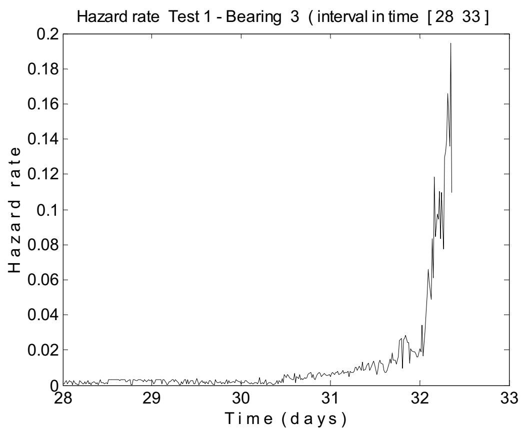


Figure 16. Hazard Rate Prediction of Bearing 3 in Test 1

Table 1. Estimates of Expected Remaining Useful Life – Test 1, Bearing 3

Time *	26	29	31
Estimated expected remaining useful life*	3.5549	3.3965	1.5295
True remaining useful life *	6.5278	3.5278	1.5278
Error *	2.9729	0.1313	0.0017

* in days

5 CONCLUSIONS AND FUTURE RESEARCH

Watchdog Agent™ is a tool for multi-sensor assessment and prediction of machine or process performance. This tool can be utilized to realize predictive Condition-Based Maintenance as well as identification of components with significant remaining useful life. A wide variety of Watchdog Agent™ realizations have been devised to address applications of different nature and different levels of complexity and criticality. Innovative sensory processing and autonomous feature extraction methods are developed to facilitate the plug-and-play approach in which Watchdog Agent™ can be set and ran without any need for expert knowledge or intervention. Watchdog Agents™ have been successfully implemented in industrial testbeds.

ASSET MANAGEMENT – AN INSURANCE PERSPECTIVE

Ian Barnard

Senior Risk Management Engineer - American International Group

Abstract: The global insurance industry is vitally interested in the Asset Management systems that are implemented at industrial sites. While these systems are usually implemented to protect and manage plant and equipment, often the impact of these systems on the corporate financial model are overlooked. The type and effectiveness of the asset management system can affect the companies viability in terms of insurance cover and hence capital raising and risk profiling. This paper discusses the operation of the insurance market and the impact that asset management systems have on both the insurer and the insured.

Key Words: insurance, plant, asset management systems

1 BACKGROUND

The insurance industry is a global business centred in New York, London, Zurich and the Bahamas. Worldwide, insurance premiums in 2004 exceeded $3 trillion. In the United States, which accounts for about 34 percent of the world's insurance business, premiums total in excess of $1 trillion. The insurance industry is generally viewed as three distinct segments, property / casualty, life and health. The property / casualty part of the industry provides insurance for cars, homes and businesses. The term "casualty" dates back to the time before the 1950s when property/casualty insurers were two distinct kinds of insurance companies, with casualty or liability insurers covering losses that resulted from casualties and property insurers covering damage to or loss of property.

Property/casualty insurance can be broken down into two major categories: commercial lines or types of insurance and personal lines. Personal lines, as the term suggests, includes coverage for individuals –- car and homeowners insurance. Commercial lines, which accounts for more than half of U.S. property / casualty insurance industry premiums, includes the many kinds of insurance products designed for businesses.

Commercial insurance performs a critical role in the world economy. Without it, the economy could not function. Insurers essentially protect the economic system from failure by assuming the risks inherent in the production of goods and services. This transfer of risk frees insured companies from the potentially paralysing fear that an accident or mistake could cause large losses or even financial ruin. As a consequence, the Insurance industry's interest in asset management systems is very real and very focused.

Managing risk requires an in depth knowledge of the systems and processes utilised by a large variety of businesses. The North American Industrial Classification System identifies some 1,170 different industries according to the processes used to produce goods or services. In the United States, there are some seven million business establishments, each of which employs one or more of these processes and each of which buys some kind of insurance.

AIG and all comparable insurance companies collect plant and system root cause failure analysis data, including type faults which may occur in established and new plant and equipment. This data is used as reference material for this paper.

2 THE WAY THE INDUSTRY WORKS

2.1 Capacity

Each insurance company has a finite level of risk (financial reserves) that can be allocated to a given project or industrial complex. This risk is termed Capacity, and the magnitude of the capacity varies with the size of the company in terms of its financial reserves, and the risk profile that the insurer currently has on its books. Companies vary their capacity in proportion to the level of risk already on their books in a given industry sector or geographical region. In order to secure the full insurance cover required by large businesses, insurance risk is spread over a number of insurance companies.

Every policy has a lead insurer, who will negotiate terms and conditions with the insured or their agents (Brokers). The lead insurer takes the first and highest probability risks for the site, and allocates a certain capacity to that risk, at a certain premium.

Other companies are then invited to participate in the risk, and their involvement will be initiated if / when the losses for an event exceed a predetermined level. In this way, the insurance book is filled for a give client.

The globalisation of the insurance industry can be grasped by examining a typical (simplified) portfolio of insurance providers for a major industrial asset.

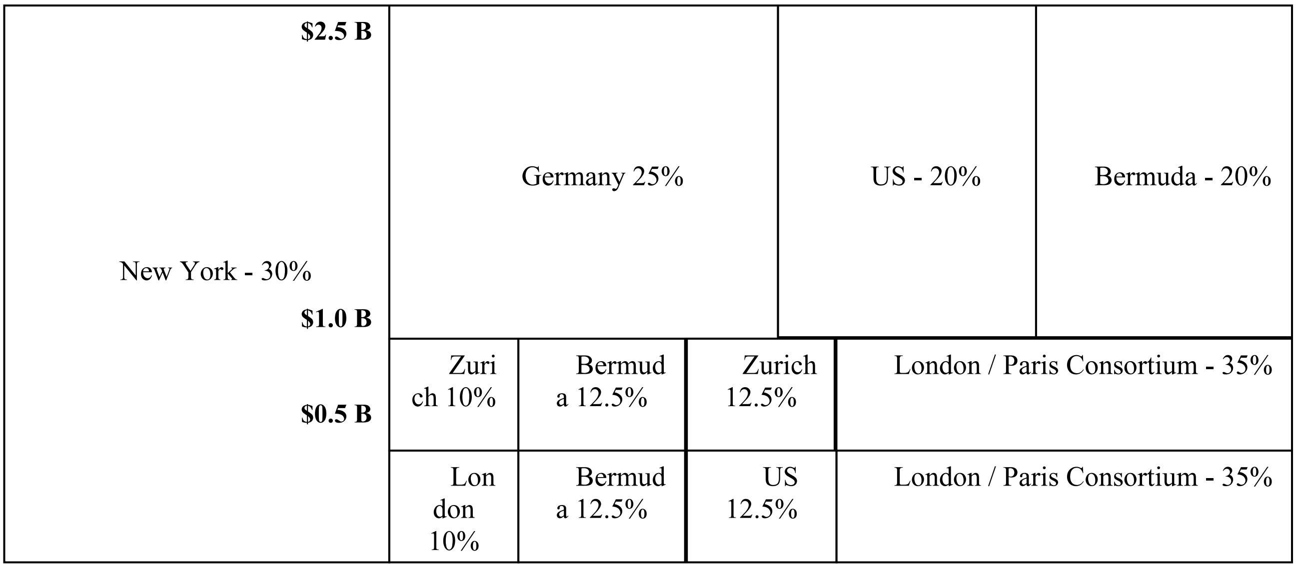

Figure 1: Typical Insurance Placement Map

The diagram depicts the levels of insurance cover and the companies that offer that cover. The Y axis depicts the total level of cover for the industrial plant, which in this case is $2.5B. The X axis is complied from companies who agree to cover certain percentages of the risk up to defined limits. In this example, a consortium of companies will provide cover to this risk up to the first $500 M. A different consortium of companies will provide cover for the second $500M, taking the combined cover to $1B. Likewise, the final $1.5B cover will be provided by a third and different set of companies. Each company will charge a premium based on their level of exposure, and where they are placed in that cover, be it the first, second, third or more tier. Obviously, the companies in the first tier of cover are exposed to the greatest risk, and so the price for this tier is higher than for subsequent tiers. The first New York company, who is providing cover over the whole risk, is the lead insurer. However, this company will also offset its exposure by utilising the services of one or more Reinsurance companies, effectively “buying” more capacity and divesting some of its risk to third parties. Other members of each tier may also utilise reinsurance.

The point of this diagram is that there are a large number of decision makers involved in determining not only the cost of insurance to a particular project, but also deciding on their involvement or otherwise in the risk. This means that, for a large asset, there are many people and organisations that need to be convinced of the soundness of the insured’s Asset Management strategies. Unless all parties are satisfied with the risk, the facility will not be insured.

2.2 Typical Plant Policy Structure

Insurance for a large industrial plant is generally structured so that relatively minor losses are born solely by the company which owns the plant. The typical structure for a power generation facility, for example, is that only losses above $5M are claimable, and interruptions to business of less than 45 days are not insurable. This fact alone has a significant impact on the way insurance companies view asset management systems. In general, from a loss viewpoint, asset management systems which protect small and / or low impact systems are not on the Insurance radar.

Premiums will generally run at between 1% and 2% of the insurable loss in first world politically stable economies. For a typical large power generation facility with a capacity of 2000 MW, the premium will be somewhere between $2M and $4M.

2.3 Loss Probabilities

Loss probabilities for a risk are calculated based on the likelihood of certain events. Following are the standard loss definitions with examples for a power station.

NLE: Normal Loss Expectancy

This type of loss is based on a normal event that has a reasonably high likelihood of occurring in a plant. While the event will affect production, the scenario is reasonably common and in general is not covered by insurance given that the policy deductible (excess) will exceed the cost of rectification.

Plant	Boiler	Turbine
Event	Mild Furnace Explosion	Steam turbine incident
Property Damage	$250,000	$2.7M
Business Interruption	5 days	30 days
BI (% Prod. Effected)	25%	25%
$BI	$250,000	$1.5M
TOTAL ($)	$500,000	$4.2M

PML: Probably Maximum Loss

This type of event is not expected to occur under normal condition, but experience shows that it has a finite probability of eventuating over the life time of the asset. The losses associated with this type of event are large, and rhe values are calculated assuming that all installed protection and asset management systems function as designed to limit the impact of the event.

EVENT	Low boiler water	Fire resulting in loss of rotor
Property Damage	$25M	$36M
Business Interruption	180 days	365 days
BI (% Prod. Effected)	25%	25%
$BI	$9M	$18M
TOTAL ($)	$34M	$54

EML – Expected Maximum Loss

This is the loss that can be expected to occur under the worst possible conditions for a plant and where the protection systems designed to minimise the loss fail completely. The loss is limited only by passive protection such as plant spacing. This is the largest of the possible losses, and the values associated with this type of loss are greatly affected by inherent risk mitigation such as building and processes separation etc.

EVENT	Boiler explosion	Catastrophic fire
Property Damage	$160M	$85M
Business Interruption	30 months	30 Months
BI (% Prod. Effected)	25%	25%
BI	$45M	$45M
TOTAL ($)	$205M	$130M

Despite the significant level of research and technical analysis that is applied to determine the risk for a given project, often the decision by a particular insurance company to be involved (and effectively investing in) a project is not fully quantifiable. Insurance professionals are in the main financial specialists, and are not engineers. Traditionally, they were concerned with questions of political and market stability, natural perils such as flood and earthquake, facility fire protection and a host of other risks to a project or site. While the actual numbers generated statistically to evaluate a risk profile are important to a decision, there is a certain amount of qualitative analysis that occurs, and this is best described by intangibles such as the experience of an underwriter in a particular risk field. Not only do the numbers for a risk have to be right, but the “feel” of the risk has to be right.

In recent years, the profile of the commercial and industrial insurance industry has developed to include risks far removed from the traditional insurance cover.

3 INSURANCE TYPES

There are almost as many types of insurance as there are insurance companies. By type of insurance we mean the types of risks covered. As stated previously, the types of insurance can be divided into Personal and Commercial. For our purposes, we will concentrate on the insurance that is concerned with commercial business assets.

3.1 Property Insurance

Traditionally, insurance cover was primarily related to the destruction of a facility or assets by either fire or natural disaster. This type of insurance is known in the industry as Property cover, and as the name suggests it relates principally to the replacement value of real property. Impacts here include political, geological, fire, explosion and other major issues that can destroy of severely damage the physical plant as a whole. The insurance industry is well versed in analysing and assessing the risks related to these issues, and various statistical tools are used to quantify the risks from these aspects of an operation.

3.2 Boiler and Machinery Insurance (BM)

This type of insurance, despite the name, relates to the risk of plant being destroyed or rendered inoperable from any source. In effect, it is Reliability Insurance for the plant, and takes into account aspects such as premature failure of major systems, the destruction of plant from fire, design defects and a myriad of other causes. It is interesting to note that stupidity is insurable, laziness is not. By this we mean that damage due to honest mistakes by operators or maintainers will be covered by the policy. Damage resulting from poor maintenance and inspection practices, plant over load, operation outside design parameters and a number of other inferior practices are not covered by these policies.

3.3 Business Interruption Insurance (BI)

BI Insurance covers the loss of profit risk to a project or site from an interruption to the supply chain. It is possible for this type of insurance risk to exceed the risk from all other sources. For example, the destruction of a compressor in a petrochemical plant from a catastrophic rotor failure may require a complete compressor replacement costing approximately $1M. However, if the compressor is a purpose built machine, with a replacement time of say 6 months, the loss of profit to the organisation may exceed the cost of replacement by orders of magnitude. Business interruption insurance has a critical interest in the quality of the asset management systems applied to a process.

BI insurance does not include damage related to wear and tear, or plant and equipment that is not maintained and inspected to industry standard. This aspect has connotations for asset management systems designers, as the term “industry standard” has no global reference, and varies from industry to industry and country to country.

4 RISK RATINGS

Asset management system design and implementation has a crucial impact on both Boiler and Machinery and Business Interruption insurance. Insurance companies assess the standard of asset management applied to a particular site, and decide not only on the cost of such cover, but on the provision of such cover based on engineering reports compiled on the project.

Engineering reports are produced by qualified and experienced engineers who visit and review a site or project, and inspect the systems in place at the site to minimise risk. The systems review includes human and technical systems, and looks at both the design of systems and the level of effective implementation of the system. At AIG and in other major insurance companies, plants are categorised and rated as Excellent, Good, Fair and Poor risks based on a quantitative and qualitative assessment of the risk management systems implemented at the site. The headings used to evaluate the risks for an engineering study are:

Location, Plant Layout, Fuel Storage and Handling, <u>Process Control</u>, <u>Reliability</u>, <u>Maintenance</u>, <u>Inspection</u>, Operation, Fire Protection, <u>Risk Management</u>. The underlined topics are critically dependant on asset management technologies.

As an example, below is a sample of grading standards for the Process Control element in a power station as determined by AIG. Grade 0 is excellent, Grades 1 and 2 are Good, Grade 3 is Fair, Grade 4 is Poor.

Process control	**Grading**
Control rooms & systems:	Grade 0: Process control DCS separate from critical ESD and trip systems, hard wired or Triple Modular Redundancy system, input voting system. Grade 1: As above, but DCS and ESD are linked and dependent. Grade 2: Manually actuated automatic shut down of process unit, with satisfactory level of auto shut down of unit packages such as rotating equipment. Grade 3: Mix of old and new systems but not integrated. Unmanned stations. Grade 4: Local controls only
Boiler	Grade 0: fully automatic combustion controls on all burners. Alarms interlocks. Drum level trips, 2 out of 3 voting system, separate level indication in control room (CCTV). Double isolation valve on gas or oil feed. Grade 1: some manual controls on non critical processes Grade 2: strict purge sequence, drum level trip, burner management system Grade 3: no burner management system Grade 4: no burner management system, no combustion control, manual light up
Turbine	Grade 0 : Double overspeed protection system, remote condition monitoring, on-line protection facility. Fully automated governor control with stress control (ST). On line gas analysis for GT Grade 1 : On line vibration measurement with trips and trending Grade 2 : On line vibration and eccentricity with trips. Single overspeed protection system. Grade 3 : On line vibration and eccentricity without trips. Grade 4 : No condition monitoring system (ST).
Generator	Grade 0: generator core monitoring, on line partial discharge monitoring, phase and balance protection, reverse power protection Grade 1: As above but no online PD Grade 2: See best practice page 23 (minimum practice). Grade 3:

Figure 1: Excellence Grades for Power Station Process Control Element

From these ratings, an overall risk management profile and rating is developed.

Facilities placed in the Excellent category have no trouble obtaining insurance cover, and will have the lowest premiums and the least stringent policy conditions. These companies will have significant bargaining power in the insurance market and may even be able to dictate their own terms to the global insurance market.

Industrial sites placed in the Good category will obtain insurance on terms that reflect the lower rating. Premiums are likely to be higher and insurance companies may impose restrictions and riders that limit the level of cover. In many cases, additional risk management and asset protection systems will be specified by insurance companies before cover is applicable. In some cases, these additional systems can cost millions of dollars.

Facilities in the Fair and Poor categories will find insurance difficult to obtain, and this will effect the viability of the operation as a whole. Banks will not finance companies who cannot obtain insurance. If insurance companies are at all interested in being involved in the facility, a whole range of management systems may be mandated prior to cover being negotiated, and the premiums for the insurance will reflect the poor risk profile.

5 PLANT FAILURES

From an asset management perspective, it is necessary to understand the root cause of plant failure in order establish effective condition monitoring and asset management strategies. AIG and other organisations have conducted considerable research into the reasons for plant failure. Not surprisingly, many plant failure studies into mechanical and electrical equipment failures reveal similar system failure root causes, which are indicated in the following graphics.

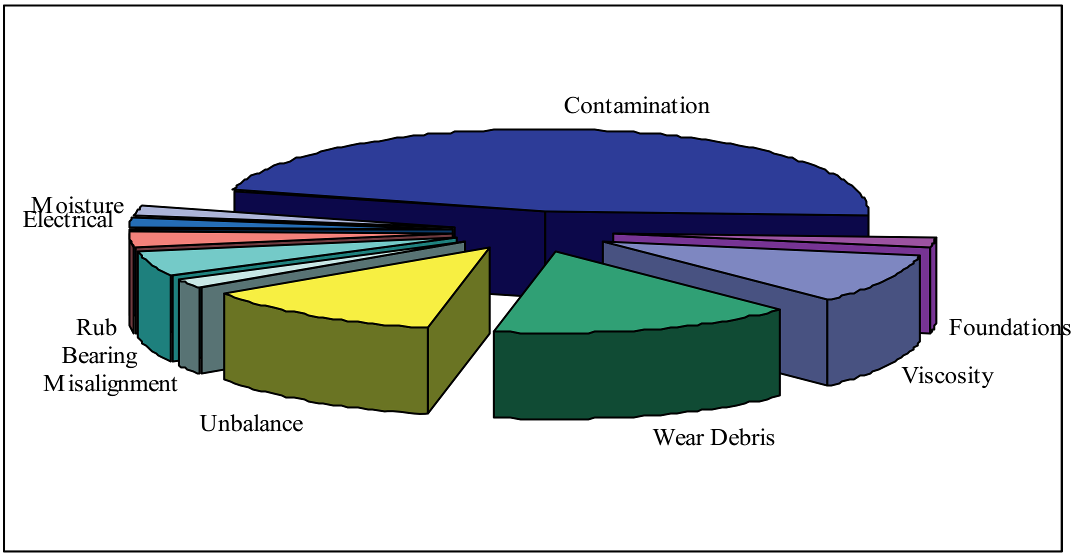

Figure 2: Primary Causes of Mechanical Equipment Failure

This data has been taken from a number of industries of varying ages and capacity factors. In general, the data indicates that human intervention in the machine in the form of lubrication quality and contamination control is the primary factor in the longevity of mechanical plant. The data also indicates that lubrication analysis is the prime control method of determining mechanical plant condition, particularly in rotating mechanical plant.

The following graphic depicts the systems within electrical plant that have been the principle failure cause for that plant. It is interesting to note that mechanical systems within electrical plant are the prime failure areas. The obvious connotation from this data is that the complete suite of both mechanical and electrical testing and condition determination regimes must be applied to all plant types. The complimentary nature of the condition assessment techniques requires that the systems used to record and report on plant condition need to be fully integrated, and contain data, analysis and prognosis from disparate CM tools to give a complete description of the plant condition.

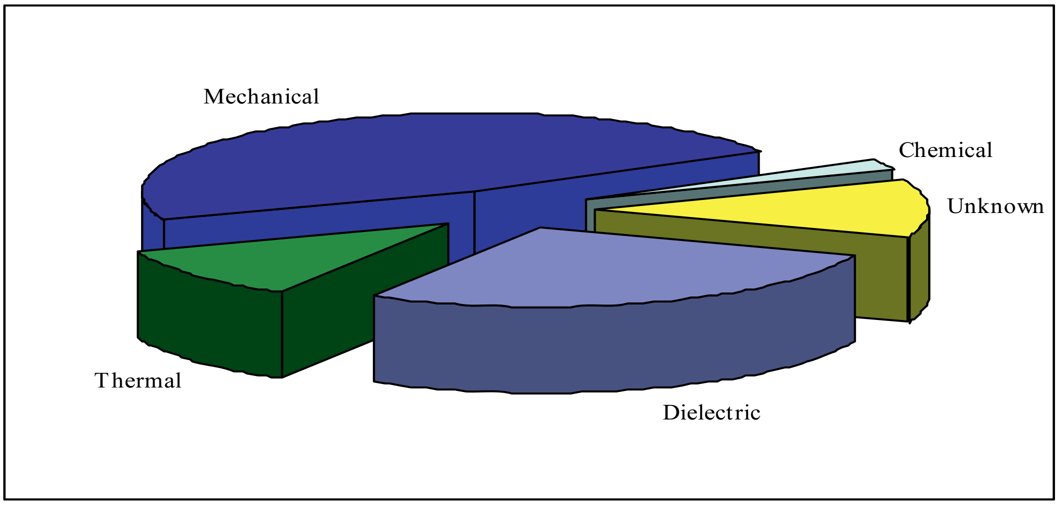

Figure 3: Primary Causes of Electrical Plant Failure

With these failure modes in mind, to obtain an excellent rating from insurers the asset management and condition monitoring technologies that are required for a utility include:

Mechanical:
- Online vibration spectral analysis of main plant including turbines, generators, feed pumps.
- Online vibration measurement and trips on auxiliary plant.
- Spectro chemical and Microscopic wear debris analysis of all main lube oil systems.
- Infra red thermography of all main plant including turbine casings, boilers, auxiliary plant bearings.
- Eddy current testing of condensers
- Time of flight ultrasonics (TOFD)
- Eddy current & remote field testing (EC & RFT)
- Remote visual inspection (RVI)
- Replication
- Bore oxide ultrasonics
- Mini creep testing
- X Ray analysis

Electrical:
- Dissolved gas analysis (DGA)
- Dissolved moisture
- Oil quality (acid, interfacial tension, dielectric strength, dielectric dissipation factor)
- Particle count
- Dissolved metals and sulphur
- Furans
- Dielectric loss angle
- Insulation resistance
- Dielectric dissipation factor
- Insulation recovery voltage
- Partial discharge
- Time reflectometry
- Radio frequency emission
- Transfer function

Risk Assessment Tools
- HAZOPS - Hazard & Operability Studies
- QRA - Quantitative Risk Assessment
- WRAC - Workplace Risk Assessment and Control
- RCM-RA - Reliability Centred Maintenance Risk Assessment

It should be carefully noted however that the existence of these systems at a site is NOT the determining factor for a risk management engineer. The critical aspect is how these systems are utilised in the asset management planning cycle. All of the above systems require analysis and prognosis development by humans, and of crucial importance to the insurance industry are the qualifications and experience of the people conducting the testing and performing the analysis.

6 IMPACTS FOR ASSET MANAGEMENT SYSTEM DESIGN

The insurance industry is both a friend and foe to the designers and researchers involved with asset management systems.

Firstly, the scale of the asset management systems from an insurance perspective is company and / or plant wide. The levels of insurance deductible (excess) imposed means that companies effectively self insure for the first $5M, and cover their own business profit losses for the first 45 days . Asset management systems which protect plant with an impact less than these figure are generally not important to the insurance industry. It should be noted however that risks which are placed in the Excellent and Good ranges by the insurance Risk Consultant as a result of superior asset management systems can often effectively negotiate the deductible and BI exclusion period..

Secondly, to obtain Business Interruption insurance for example, insurance policies mandate that an insured company follows a number of guidelines, including adherence to the equipment manufacturers operations and maintenance schedules and compliance with industry normal practice for the asset. This has the effect of greatly limiting the scope for innovation to be applied in asset management techniques and methodologies from an insurance premium reduction perspective.

On the other hand, the insurance companies also mandate that traditional asset management and condition monitoring methods be applied. For example, the application of thermography, oil and vibration analysis, dissolved gas analysis, partial discharge testing, the full suite of non destructive metallurgical techniques and a host of others are all required by business interruption insurance providers to protect the assets.

The message here is that's its is necessary to utilise proven CM techniques to manage assets, but don't rely on anything too innovative and unproven.

Risk management engineers are usually assigned to a client for the duration of the insurance relationship. These people are the front line of the technical interface between the insurance portfolio developed for the client and the asset management processes implemented by the client. They are in a position to suggest additional asset management technologies that would benefit the clients business and reduce the risk of breakdown and business interruption.

The point here is that a direct link between emerging asset management technologies and the potential market for those technologies exists through the insurance chain. This link has been largely unutilised by the asset management community. If asset management researchers and technology developers wish to get their work acknowledged and into the market, the insurance industry in general and the risk management consultant in particular can be a valuable ally, provided that the technology has demonstrable advantages to both the insured and insurer.

While it is not possible to quantify the effect that the installation of a particular technology at a site will have on an insurance premiums, it is possible to move a risk from a Fair or Poor risk rating to a Good or Excellent rating, with a consequential improvement in the companies insurance profile. In some cases, the implementation of additional risk management systems will determine the viability of the whole project.

7 HUMAN ELEMENT OF ASSET MANAGEMENT

All those who work in the Asset Management field know of examples where effective asset management technologies have been implemented only to fail in the field due to a lack of integration with existing systems and processes. The assessment by insurers of asset management systems does not rely on the presence of installed technology, or the levels of capital investment by a company in asset management technologies. The assessment of the asset management standard of a plant is based solely on how the technologies are utilised to reduce the risk of plant failure.

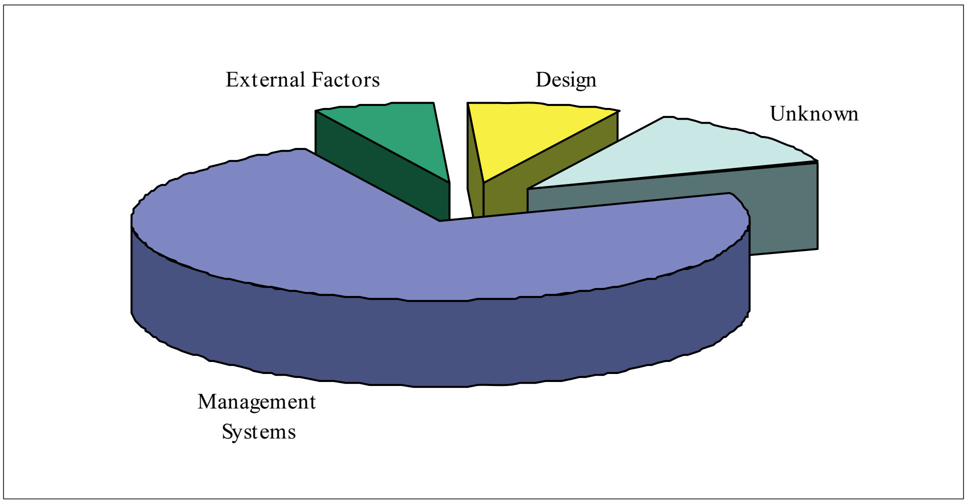

Figure 4: Upper Level Systems Failure Analysis

The following graph depicts the major causes (from a systems failure viewpoint) of insurance losses experienced in the US in the power industry in 2005. While all these losses can be analysed to identify the aspects of the mechanical and electrical systems that failed, the losses have been further analysed to determine if a failure in asset management systems contributed to the level of loss incurred.

In this graph, Management Systems denotes all types of risk management systems, including HAZOP studies, plant inspections, condition monitoring systems and routine plant inspections. External factors include incidents that occurred outside the plant over which the plant management had no control.

The data indicates that approximately 75% of losses resulted from a failure to implement or sustain targeted and robust plant asset management systems.

The data was further analysed to ascertain the most appropriate loss prevention strategy that could have been implemented to reduce that particular risk of failure in the plant.

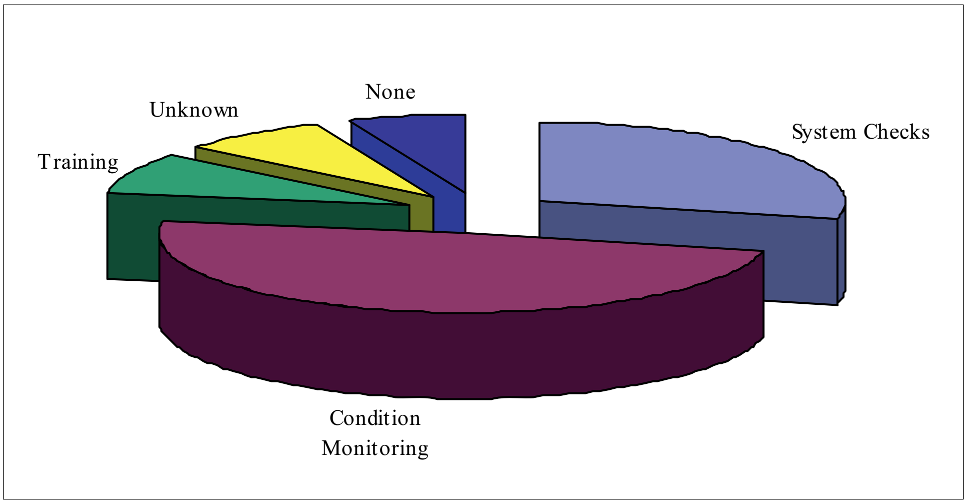

Figure 5 : Possible Loss Prevention Strategies

This data indicates that approximately 50% of the loss values could have been avoided or reduced if the appropriate plant condition monitoring systems had been implemented. A further 30% of the losses could have been favourably impacted by the application of simple plant inspection regimes. It is interesting to note that 6% of the losses incurred could not have been mitigated using technologies available today, and in a further 8% the system failure at the root of the loss is unknown.

This data, plus large amounts of anecdotal evidence, suggests that it is not the development of additional asset management technologies that will have the greatest impact the levels of losses in this industry. Rather, it is the development of systems which are fully integrated into the plant operations and maintenance process that will reduce the levels of plant downtime. This is not to say that the development of new techniques in plant condition monitoring are not important or required. Many companies and industries are in dire need of specialist testing techniques to enable product improvement and to increase reliability. However, Insurance companies are primarily interested in systems that deliver real reliability and availability returns on a plant wide basis.

8 CONCLUSIONS

The information presented above includes some salient points for Asset Management system designers:

- Rightly or wrongly, the insurance industry has considerable influence on the types of asset management systems implemented in a commercial enterprise. This fact can be used to advantage by asset management system developers.
- Insurance underwriters rely almost completely on the information supplied by relatively few risk management engineers to determine the adequacy of the asset management systems installed at a facility.
- In the main, the insurance industry does not financially support the development of asset management technologies. The industry is principally geared towards the implementation of those technologies and systems which are proven to improve the reliability of plant and equipment.

- While it seems incongruous with the previous point, the insurance industry is vitally interested in technologies which reduce the risk of business interruption to plant and processes.

- Insurance company Risk Management Engineers may be a valuable aid in implementing innovative asset management and plant condition monitoring technologies.

Abstract: Ensuring optimal performance of assets in capital-intensive industry sectors is crucial towards sustained growth in terms of returns on investment (ROI). The primary challenge is to achieve optimal utilization of the assets over their productive lifecycle and identify the need and timing for replacement and/or enhancement. Such decisions are not trivial and can affect the ROI considerably. Operational and planning decisions related to the assets need to be based on the concept of Total Cost of Ownership (TCO) if they have to be economically optimal. The technical challenges posed are in terms of selection of a mix of techniques and methods for extracting useful information/knowledge from raw operational data, its use to construct predictive models for asset performance, and use of the models to achieve continuous optimization of asset performance with TCO consideration. It requires a model based approach to achieve asset performance over multiple lifecycles. Technology enablers are also a crucial element in achieving the maturity of asset management processes and practices in the organization. The paper discusses an EAM maturity model and its technological requirements that would help organizations to achieve sustained asset performance based on TCO.

Key Words: Enterprise Asset Management (EAM), Total Cost of Ownership (TCO), Optimization, Asset Performance, Model Based Approach, Process Maturity

1 INTRODUCTION

Enterprise Asset Management (EAM) is traditionally defined as the organized and systematic tracking of an organization's physical assets such as its plant, equipment and facilities. The machinery used to manufacture the products has to be reliable, the electricity must flow, the computers must remain on line, and the delivery trucks must be operational. If just one of these assets breaks down unexpectedly, the operations may be interrupted and this can impact organization’s bottom line. In its earlier avatar of Maintenance Management, the thought revolved primarily around Maintenance, Repair, and Operations (MRO). This was limited to fixing any sort of equipment should it get out of order or broken (repair) as well as performing the routine actions which keep it in working order (maintenance) or prevent trouble from arising (preventive maintenance). Preventive Maintenance focused on the activities required to continuously monitor health of the equipment and plan timely maintenance ensuring its availability as per the organizational requirement. The approach and underlying thought process sufficed to support the typical organizational thought process of doing business with high levels of profitability and operational efficiency. The MRO philosophy is sufficient from the perspective of driving operational efficiencies and deriving appropriate benefits out of that to optimize the profitability on ongoing basis.

One of the reports by the National Institute of Standards and Technology (NIST GCR 04-867) estimates that the U. S. Capital Facilities Industry loses over $15.8 billion annually due to inefficient exchange and management of design and engineering information. This is a glimpse of the size of benefits that can be achieved through systematic asset management [3].

This paper aims a discussion on holistic approach to Enterprise Asset Management from all the important dimensions of incorporated into the asset’s product lifecycle. The thrust of this discussion is to understand the effect of these dimensions on EAM and handling of various trade-offs that impact the long-term planning of assets. The discussion will also touch upon the asset strategy dimensions required to achieve optimal asset performance with respect to TCO. The Total Cost of Ownership is a combined effect of all these dimensions over a period of time under consideration. The challenge is to achieve optimal assert performance based on the total cost of ownership derived using these dimensions. An important aspect of this discussion is the leverage of advancements in the technology which is a combination of computing infrastructure, instrumentation or enterprise sensory networks, and state-of-the-art methods in intelligent and knowledge based approaches. Our overall objective is to emphasize the need for use of a combination of these advancements to add value from EAM system solution's perspective.

The paper is organized as follows. Section 2 discusses the typical asset strategy levels in an enterprise and the concept of total cost of ownership. A discussion on dimensions of asset performance and prime drivers of strategic asset related decisions is covered in section 3. The need for model based approach to asset management maturity and movement of information/decisions across levels of the maturity is discussed in section 4. Role of technology in intelligent asset management solutions is emphasized in section 5. Ultimately, section 6 summarizes the key message of the discussion.

2 ASSET STRATEGY LEVELS

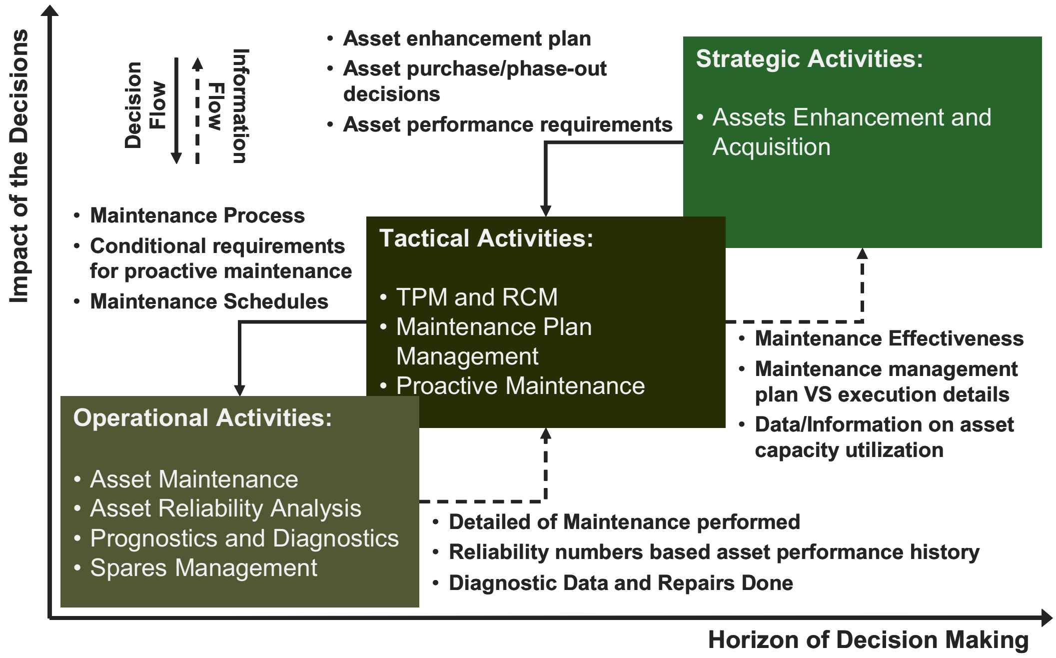

Figure 1: Asset Management Strategy Levels

Enterprise asset strategy is a combination of decisions that are at multiple levels and varying time horizons of decision making. Figure 1 shows broad categorization of the asset management activities and decisions into three levels of an enterprise.

Operational: These are a set of functions necessary to keep the asset(s) up and running to the enterprise need. Operational level aims at providing the bare minimum intelligence required to bring together all the ingredients of the maintenance function along with the diagnostic ability required in case of failures or breakdowns.

Tactical: Functions in this layer are proactive than reactive and aim at making the asset maintenance in line with overall planning. Monitoring of assets and planning of their maintenance triggered by conditions is managed by this layer. The overall process of operational asset management is driven from the tactical layer.

Strategic: The strategic layer does long-term asset planning from TCO perspective. This layer is the key in choosing amongst a number of asset acquisition options available based on the most optimal total cost of ownership. Decisions at this level are long-term and high impact as they involve capture of total ownership cost over entire asset lifecycle. The other two layers primarily work towards complying with the performance expectations set by this layer while making strategic asset related decisions for a long time horizon.

2.1 Operational

Operational layer of asset management concentrates on fulfilment of tasks related to maintenance activities of different types, capture of data/information, and analysis towards understanding the asset behaviour better. Use of the knowledge acquired at this level is brought in use by levels above it.

Asset Maintenance: Involves preventive (frequency or run-hour based), corrective (event based), and management of maintenance work force.

Reliability Analysis: Reliability of a system is defined as the trustworthiness to do what the system is expected or designed to do. At the system level the reliability can be characterized by a number of metrics such as POFOD (probability of failure on demand), ROCOF (rate of failure occurrence), MTTF (mean time to failure), and AVAIL (availability or uptime). Reliability of complex systems consisting of interconnected sub-systems needs a more comprehensive consideration owing to the individual nature of the sub-systems, behaviour of these sub-systems when interconnected with each other, effects due to propagation of faults/failures through interconnections, and effects of sub-system level interaction on higher level systems. While the systems (or complex equipments) are hierarchical by their design, this alone may not be sufficient to capture the effects of reliability of individual sub-systems on the higher-level complex system. Functional dependencies in addition to hierarchical dependencies need a careful consideration for creating sound models for equipment reliability.

Prognostics and Diagnostics: Up-keeping of assets and their health is an important aspect of operational asset performance. Being able to detect and predict forthcoming failures in the assets is a much required capability that asset management solutions need to possess to make the long term asset planning a well-informed exercise. Three primary levels of diagnostics are detection of abnormal conditions, prediction of abnormal conditions, and fault diagnosis to gain better understanding of the dependencies of these conditions. Prognostics are a proactive form of diagnostics where it is equally important to trace back to the root cause while predicting.

Spares Management: The demand for spares is triggered by periodic spare replacement as well as corrective spare replacement triggered by breakdowns. While the planning of the spares requirement is done by the tactical layer above the operational one, the key measure at this layer is making the right spare available whenever required by a maintenance task.

2.2 Tactical

The tactical layer uses the knowledge and understanding built at the operational layer to manage the operations effectively. The prime objective of this layer is to ensure that the asset management plans are in place and the operational layer indeed adheres to them.

Maintenance Plan Management: Involves a number of functions related to management of different types of maintenance activities. Creation of maintenance schedules and ensuring the availability of required resources to fulfil them is the key function here.

Proactive Maintenance (Condition or Prediction based): Monitoring of the assets and performing maintenance based on the current condition is the function also covered at the tactical layer. The idea is to avoid any major breakdowns or failures in the future and take preventive actions well in advance.

Reliability Centered Maintenance (RCM): Reliability Centered Maintenance (RCM) is a best practice approach for identifying and implementing the most effective maintenance program for any group of assets. Asset functionality is the primary focus and RCM provides a way to select the maintenance strategy that best balances maintenance costs against losses to the organization when functionality is impaired.

Total Productive Maintenance (TPM): Predictability of asset uptime and availability is an important factor in ensuring productivity of the assets. TPM works towards prevention of deterioration and not towards repairing machines/assets reactively. Key measure of TPM is Overall Equipment Availability (OEE).

Collaborative Management: The tactical layer also tries to connect with the related functions in the enterprise, such as, production, materials planning, and operations. Effort is to bring in the collaboration so as to achieve best possible utilization of the asset.

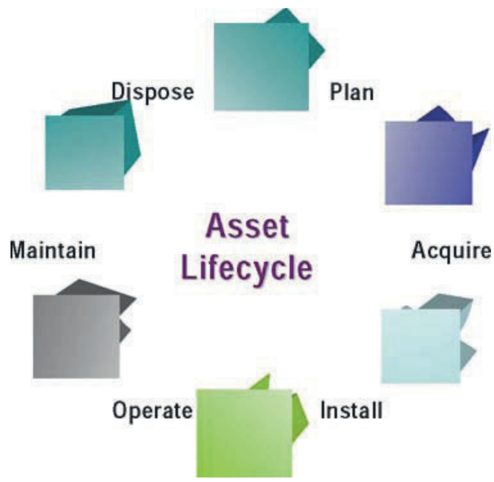

Figure 2: Typical Asset Lifecycle

2.3 Strategic

Asset management at strategic levels deals with long term planning decisions such as asset acquisition, asset phase out, and setting asset performance requirements for planning and operational layers of asset management.

Figure 2 depicts the typical asset lifecycle at strategic level of asset management. The asset lifecycle begins with asset planning and acquisition. After successful installation of the assets in operations the lifecycle continues with the operations and maintenance of these assets till it reaches the phase out stage. Primary purpose of asset lifecycle management is to maintain or increase the asset values through a series of these lifecycles. Significant decisions at the strategic level are that of acquisition of new assets or major enhancements to existing assets. The very decision between these two at any given point is also a trade-off at the strategic level of asset management. Asset operated in an optimal manner provides value and is an important aspect of asset management but that does not comply with the concept of asset optimization based on TCO. Optimization of TCO essentially involves continuous monitoring of profits and loss of each of these asset lifecycle phases and focus on asset optimization across the lifecycles [2].

2.4 Total Cost of Ownership (TCO)

Total cost of ownership (TCO) is a financial estimate of direct and indirect costs related to purchase and operation of assets over their lifecycle. TCO should ideally incorporate not only the cost of purchase but all aspects in the further use and maintenance of the equipment, device, or system under consideration. It includes the costs of training support personnel and the users of the system, costs associated with failure or outage (planned and unplanned), diminished performance incidents (waiting time), costs of security breaches (in loss of reputation and recovery costs), costs of disaster preparedness and recovery, floor space, electricity, development expenses, testing infrastructure and expenses, quality assurance, incremental growth, decommissioning, and more case specific aspects.

Many organizations fail to understand and calculate TCO and instead rely on TCA (Total Cost of Acquisition) in making new asset acquisition decisions. Also, in some cases, purchasers may not bear all of the TCO-related costs directly even though their parent organizations always do (i.e. "cost shifting"). TCO can and often does vary dramatically against TCA, although TCO is far more relevant in determining the viability of any capital asset investment. TCO also directly relates to total costs across all projects and processes and, thus, organization’s profitability.

3 ASSET PERFORMANCE ENHANCEMENT

Measurement is a key to performance enhancement. An ability to understand the current maturity and performance level of the asset management process is an essential element in being able to drive continuous performance optimization. A model based approach to drive EAM helps in defining the objectives as well as the drivers leading to those objectives.

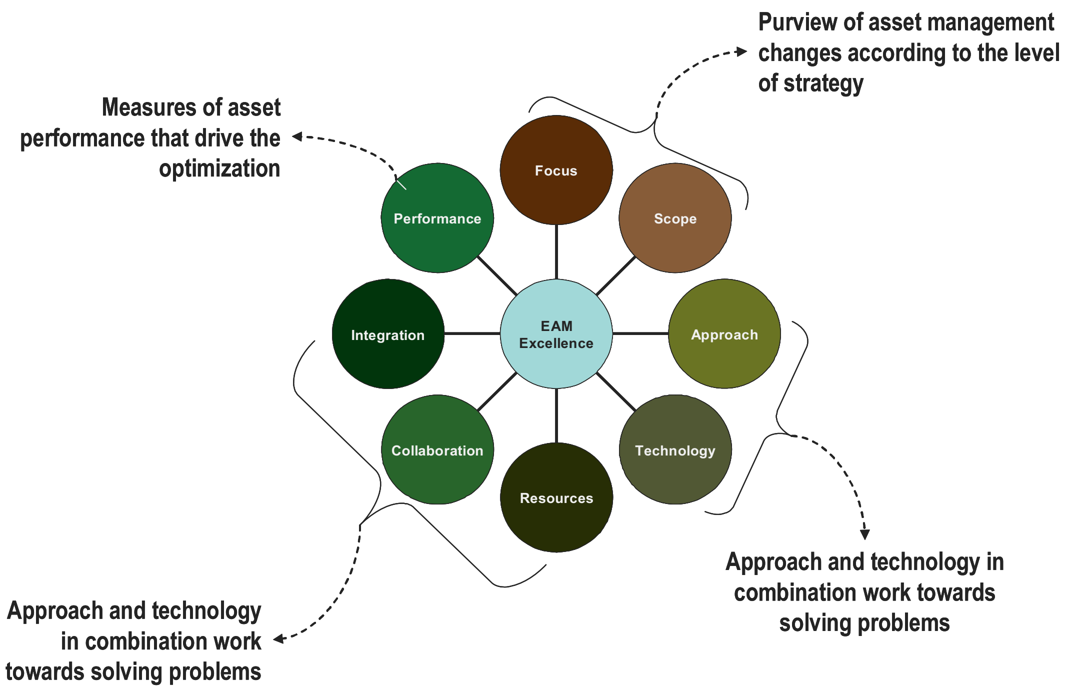

Figure 3: EAM Excellence Model Dimensions

Figure 3 shows important dimensions of the EAM excellence model (based on ARC Multi-Attribute Model of Asset Management) [3] that can be described as:

Focus: An asset can be defined as a single equipment of a large collection of equipments. Coverage of the focus dimension changes based on the level of asset management one is looking at.

Scope: Is defined based on the level whether it is operational, planning, or strategic.

Approach and Technology: Approach and technology is selected based on the focus and scope of asset management activity. This can range from well-defined processes for maintenance activity all the way to intelligent methods or formal optimization based techniques at strategic levels.

Integration, Collaboration, and Resources: These are tightly related to each other as the integration enhances the collaboration between different resources that are part of the asset management world. Information Technology based solutions with use of appropriate approach and technology can achieve this effectively.

Performance: Measurement of asset management effectiveness through well-defined Key Performance Indicators (KPI) at different levels of asset management functions.

Over 65 percent of manufacturing investments are in production facilities that directly affect revenue generation [3].

3.1 Objective Drilldown

Asset performance is defined by a number of top level objectives that need to be drilled down to requirements and activities that fulfil them. This drilldown is essential to achieve the objectives as well as facilitate the decision involving capital investments.

Figure 4 is an example of a typical drilldown from a top level objective such as "Ensuring Asset productivity". Immediate dependencies in ensuring asset productivity are asset utilization, reduction of operating costs, and prolonging of productive asset life. They further drill down into their dependencies finally leading to the set of activities and processes that need to be in the place to fulfil the objective. As can be see clearly from Figure 4 there are a number of conflicting dependencies in the hierarchy. Replacement of non-productive parts conflicts with the aim of keeping the operational costs low or the need for regular overhauling conflicts with ensuring close to 100% available time. The challenge is to weigh these actions on the basis actual cost and select the most optimal balance that would achieve the top level objective.

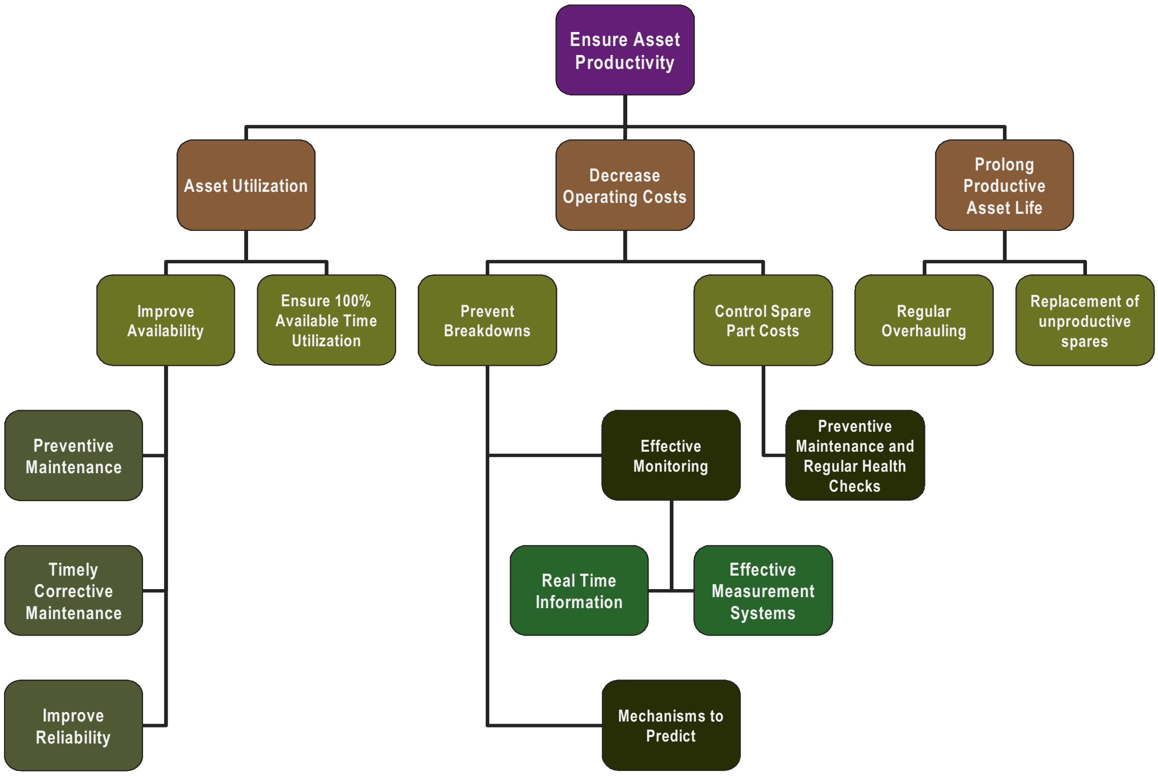

Figure 4: Typical Objective Drilldown

3.2 Capital Determinants in Strategic Decisions

Capital determinants of asset strategy are part of maintain, dispose, and plan phases of typical asset lifecycle shown in **Error! Reference source not found.**. The key understanding required is the point at which the organization should stop maintaining the existing assets and move towards acquiring enhanced newer ones by disposing the existing ones. This decision involves a number of drivers such as capital investment required to acquire new assets, operating costs of existing assets, operating costs of the assets being newly acquired, impact on productivity, reliability and residual life of the existing assets, and a number of qualitative factors, all of them leading to the strategic objective of the expectation of return on investment on the new assets. The key drivers listed above can be described in detail as:

Capital investment on new assets: Investment of capital required to acquire new assets is a major consideration in asset acquisition decisions. The investment amount in combination with the time required to return on the investment forms an important element of the go or no-go decision. Investment amount comprises of mainly the cost of assets, cost of space required to house the assets, cost of training, and skill enhancement required.

Expected operating (O&M) cost of new assets: It is not only the capital investment required but also the expected operating and maintenance cost of the new assets that adds to the consideration for new asset acquisition. Build-up of the operating costs over the initial investments in combination with the qualitative factors can have significant impact on the decisions. The operating cost changes over time and needs to be considered over entire lifecycle of the new asset.

Operating (O&M) cost of existing assets: Operating and maintenance cost of existing asset over its remaining life is also a consideration in acquisition decisions. As the assets get old the cost of maintenance and operations starts ramping up. While, this sounds trivial but its combination with the capital investment for new assets, O&M cost of new assets, and impact on productivity coupled with a number of qualitative factors is not so straightforward.

Impact on productivity: Comparison in terms of impact on productivity with induction of newly acquired assets. It is trivial that the productivity has to go up in case of new asset acquisition but the order of improvement is what matters. Productivity incorporates a number of factors such as time for maintenance, typical waiting time, percentage availability, and inherent productivity of the asset when it is running.

Reliability and residual life of existing assets: O&M costs and productivity do not remain attractive towards end of asset life. The residual life and the expected behaviour of the asset reliability over residual lifetime is important and links very closely with the overall effectiveness of the asset in terms of its availability and productivity.

Qualitative factors: A number of qualitative factors also form part of this decision making process. Aspects such as changes required in the skills of people to use the new assets, change in number of people required, current productivity agreements with worker unions, and environmental factors. Although mostly qualitative, these factors have a significant impact on the decision to acquire new assets. A number of qualitative factors may get added based on specific situations such as geography, maintenance and service support possible, maturity of new technology, etc.

A combination these costs and factors give an estimate of what can be called as the expected return on investment towards new assets. A comprehensive model for comparison of new assets with existing ones helps in supporting such decisions with analytical backup. The optimization problem becomes straightforward in case of extreme situations where the existing assets are highly unreliable or at the fag end of their productive life. It is not only a decision on whether to go for new assets or not but also decide on the most optimal time to go for them. Given the projections on various cost factors an organization needs to simulate a number of decision options in terms of exact time of transition to new assets and find out the expected time of return on investment.

Another important consideration at such juncture is the choice between buying the new assets and adopting a service oriented model for use of the assets. The service model is prominent in civil aviation industry where the cost of assets is prohibitively high both on acquisition and O&M front.

The approach to this decision needs to be model based given the need for continuation with a similar TCO based approach post acquisition. This aspect of asset lifecycle is discussed in the following section.

4 REAL-TIME INFORMATION BASED ASSET PERFORMANCE ENHANCEMENT

While the decisions about new asset acquisition are made based on TCO it is equally important to continue the use of this model throughout its lifecycle till its disposal and replacement by newer asset. The idea is to subject the TCO based model to real time asset performance information during its lifecycle and use the feedback to make changes/improvements to asset management practices within the organization. The TCO based model would essentially generate the actual TCO on real-time that can be compared with the projected TCO at the time of new asset acquisition to trigger these changes.

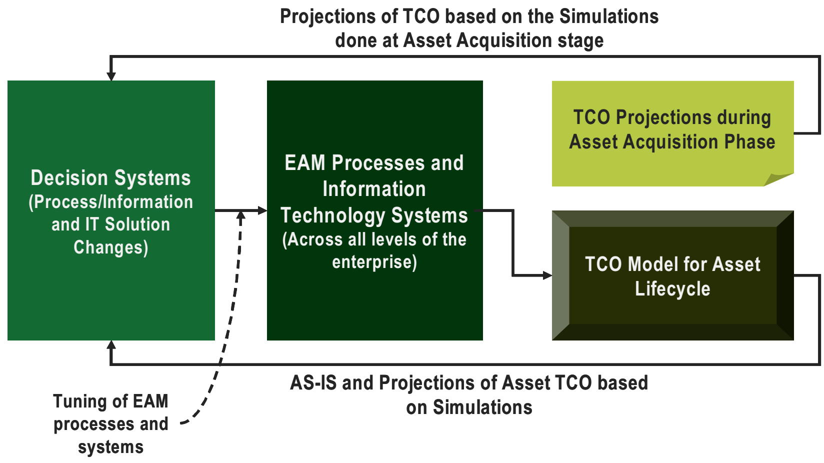

Figure 5: Feedback Based Asset Performance Enhancement

The changes to asset management processes and systems have to be drilled down the layers of the enterprise all the way to the operational layer. The decision systems to bring about these changes are also spread across the layers of the enterprise. The EAM maturity model discussed in the following section talks about the levels that an enterprise can strive to graduate across in the process of driving asset management using the TCO model.

4.1 EAM Maturity Model

Asset management is essentially a layered function that spans across definite acts of corrective maintenance all the way to strategic decisions leading to acquisition of new assets. The maturity of EAM in an organization is a chain of levels leading to topmost layer of achieving optimization on TCO basis.

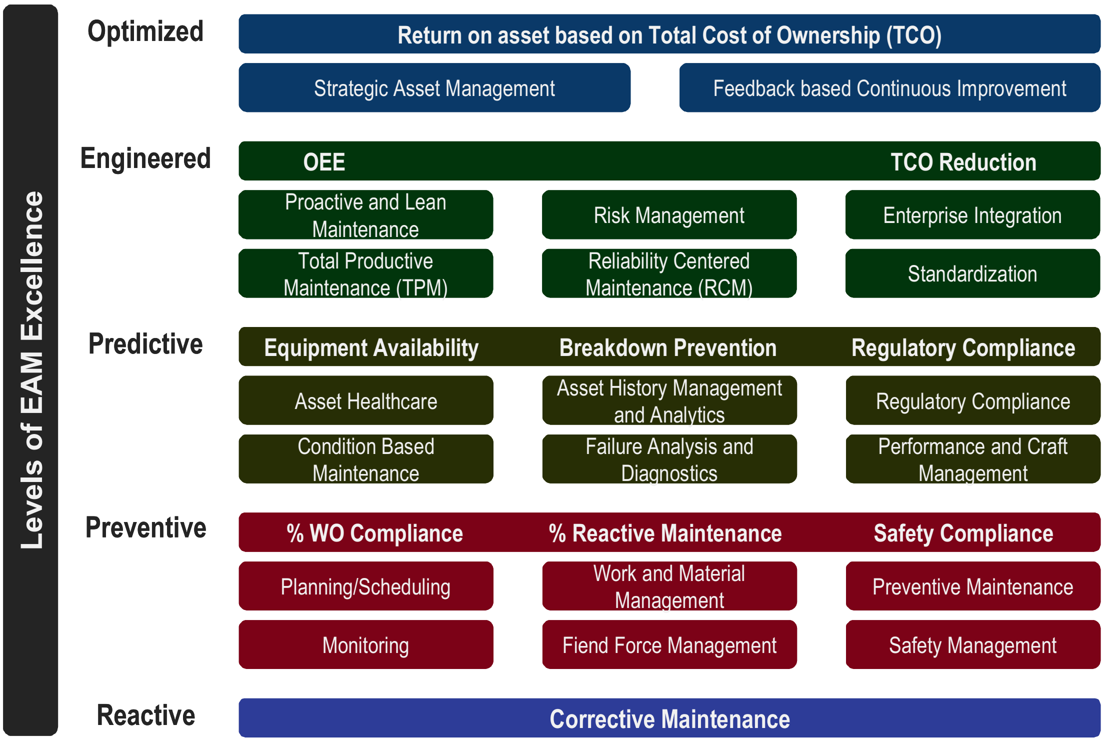

Figure 6: EAM Excellence Maturity Model

The levels of asset management maturity can be thematically described as:

Reactive: This level focuses on getting back to normal from a breakdown or failure situation at the earliest. Maturity at this level essentially means standardization of repair processes and procedures.

Preventive: Measures required in avoiding a breakdown or a failure is the prime objective of this level. Monitoring and preventive maintenance are the prime drivers to achieve the maturity required. Key performance measures for this level are defined around compliance to preventive maintenance plan, degree of reduction achievable in reactive maintenance, and compliance to safety related measures. The outcome should be to avoid an event that would result in loss of asset availability or major expenses towards recovery of the assets from breakdown.

Predictive: This is a knowledge oriented level of asset management. Use of past experience in combination with monitored data is the key to achieve predictability. The prime objective is to build knowledge using history and use it to enable the lower level of preventive asset management to avoid breakdown situations. Another important function this level does is that of continuous learning using the feedback from the lower layers. Key performance measures for this layer are defined around availability of equipment/asset achieved, number of breakdown situations prevented, and compliance to regulatory norms. Ability to learn, create knowledge, and use it for effective asset management at lower levels is the theme of predictive level of maturity.

Engineered: Complete view of total cost of asset ownership and integration across different functions of the enterprise is the theme of this layer. Total Productive Maintenance (TPM) and Reliability centred Maintenance (RCM) to achieve the near optimal asset management function over a time horizon is the desired key achievement of this layer. Overall Equipment Effectiveness (OEE) is the underlying objective to drive the activities at this layer of maturity. It also serves as a build-up for the higher layer of ensuring optimization of asset management over multiple lifecycles.

Optimized: The highest layer of asset management maturity where the key is to achieve asset optimality over multiple lifecycles. Being able to have a long term view of asset performance is the primary requirement of this layer. As discussed before the optimization of TCO involves continuous monitoring of profits and loss of asset lifecycle phases and their use in arriving at optimal decisions. Another aspect is to continuously monitor the costs and gains as the assets progress in their lifecycle to enable a feedback controlled mechanism into asset management. Performance optimization of real-life situations cannot be achieved without feedback and this crucial ability is required at the optimized layer.

The EAM maturity model [5] layers map to the dimensions shown in Figure 3 as given in Table 1.

Table 1: Maturity Mapping to Model Dimensions

Dimensions	**Asset Management Maturity Level**				
	Reactive	Preventive	Predictive	Engineered	Optimized
Focus	Machine	Machine	System	Process	Enterprise
Scope	Fault Correction	Reliability	Performance Improvement	Functionally Improvement	Enhancements and New Acquisitions
Approach	Corrective	Preventive	Predictive	Engineering	TCO Optimization
Technology	NONE	Usage Monitoring	Health Monitoring	Online Health Monitoring and Decisions	Model based optimization and self-diagnostics
Resource	Plant	Plant	Business	Enterprise	Asset Lifecycle
Collaboration	Maintenance Work Force	Planning and Scheduling	Diagnostic Knowledge	Decision Support through defined goals	Decision Support through well defined responsibility
Integration	Spares Management	Procurement	Production Management	Enterprise	Supply Chains
Performance	Service Efficiency	Asset Availability	Asset Performance	OEE	Return on Assets (ROA)

4.2 Information Feedback

The maturity model is not complete without a well defined information and decision flow across the maturity layers. The model maturity layers essentially translate into processes or IT based systems to automate the processes at every level. The flow of information upwards into the maturity layers enables decision making to strategically drive the layers below.

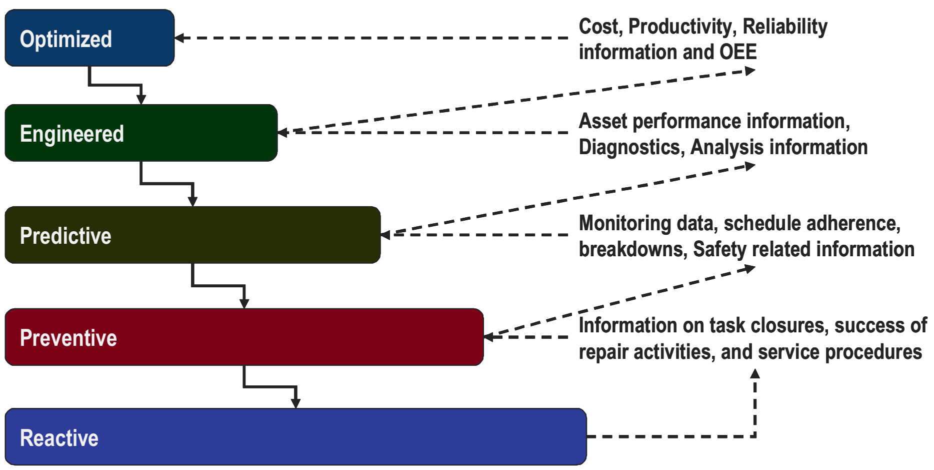

Figure 7: Information Feedback up the Maturity Layers

Technology plays an important role in establishing the connectivity between the systems and processes at each level of maturity. While the maturity model is conceptual the EAM systems has to be a combination of applications working at various levels to achieve the asset management maturity. The role of technology is to enable measurements, integration, and facilitate decision making through use of advanced algorithms and methods in optimization. Next sections discusses how recent the advances in technology have made this possible is covered in the next section.

5 ROLE OF TECHNOLOGY IN INTELLIGENT ASSET MANAGEMENT

Evolution of advanced technology in recent years had contributed positively to deployment of intelligent decision-making solutions in industry. Asset management is not an exception and continues to use the technological enhancements to its advantage. Three significant dimensions of technological advancements are:

Computing: Speed of computing has considerably increased over past decade and that has led to more widespread use of high speed computing in applications as never before. The increase in computing speed is also coupled with reduction in cost and size enabling use of powerful computers in applications closer to manufacturing layers of an enterprise. The standard PC environment is now capable of running heavy number and data crunching applications in short times leading to use of intelligent decision making algorithms more commonly.

Instrumentation and Sensing: Availability of information is the key to effective decision making process. Development of technology to realize sensory networks that provide complete information about the assets on real-time is possible because of availability of advanced instrumentation that can span across an enterprise. With monitoring going real-time it is possible to combine the real-time information with high computing power as enablers for use of advanced methods in decision support.

Advanced Algorithms: Learning from data and use of intelligent algorithms to arrive at real-time decisions can be achieved by using advanced algorithms given the technological advanced mentioned above. It is possible to use formal methods in multi-objective optimization to arrive at decisions that are based on TCO. Such problems can be large scale and complex by nature but availability of high-speed computing infrastructure and real-time sensory information makes it possible to tackle them in finite time.

5.1 Technology Investments

Setting up information movement and decision support mechanisms across the layers of asset management systems of the enterprise necessitates investment towards a variety of enabling technologies. The enablers can be classified into the following:

Sensory Mechanisms: Online measurements are the key to process improvement. Measurement of operational parameters of the assets are required for condition based maintenance, assessing asset reliability, asset health management, diagnostics, knowledge capture for intelligent maintenance, and number of other decision making mechanisms in the higher levels. Sensory mechanisms are either hardware or software based. Software based methods are necessary in the situations where the operating parameter has to be estimated rather than measured. The need is to create a network of sensors that capture complete snapshot of operating condition of the assets at any given time.

Instrumentation and Historian Systems: While the measurements are used online for condition monitoring, a greater use is in capture of knowledge and analysis to facilitate decision making at higher levels. Instrumentation systems to connect the sensory mechanisms to the higher layers and historian systems to maintain history of the asset operations are required at this level. Availability of operating data of the assets over their lifecycle is the key to asset performance analysis.

Knowledge Capture Mechanisms: The operational data is a goldmine for learning more above asset behaviour and organization need to invest towards acquiring knowledge extraction algorithms that do this job. The knowledge capture is along the application such as condition based maintenance, reliability analysis, root cause analysis, prediction mechanisms, and residual life analysis. A number of methodologies such as data mining, text mining, learning algorithms (e.g. ANNs), statistical analysis, correlation analysis, and case based learning are available for knowledge capture. The key is to form an effective combination of these methods to facilitate capture of knowledge in the form that is usable by higher layers of asset management function.

Maintenance Management Systems: Commonly known as Computerized Maintenance Management Systems (CMMS) that take care of the operational maintenance requirement for the organization. Majority of the operational functions at the reactive, preventive, and predictive layer are handled by CMMS.

Optimization Tools: Formal methods in optimization are essential for trade-off analysis along a number of cost dimensions in decision making. As discussed in section 3.2, these trade-offs are almost never obvious and need a comprehensive mathematical model along with optimization algorithms to solve it using real cost data.

Decision Support Systems: Results of optimization can never deliver the final conclusion at the strategic levels. Optimization serves as a tool to compare number of options available and reduce them to finitely many to facilitate quick decision making. A number of qualitative factors then play an important role in strategic decision making. This has been discussed before in section 3.2.

Apart from these investments, a significant investment may be required on the infrastructure front. Computing and networking hardware are primary components of infrastructural investment. Their discussion is out of scope in this context.

6 SUMMARY

This discussion is aimed at three important messages related to effective asset management. First is the significance of Total Cost of Ownership (TCO) and its use in not only in acquiring the assets but also in running the assets in an optimal manner. Second is the importance of model based approach to achieving the maturity of asset management function in an enterprise and third is the need of advanced technology in achieving the information movement and decision support mechanisms required in place to achieve the maturity of asset management along five levels of the maturity model discussed. The success of strategic asset management decisions is a combination of asset management process maturity, information feedback, and use of the feedback for ongoing decisions across multiple lifecycles of the assets.

AN AUDITING PROCESS TO IMPROVE ASSET MANAGEMENT PERFORMANCE

Visser, JK [a] and Mollentze, JJ [a]

[a] *Department of Engineering and Technology Management, University of Pretoria, South Africa.*

Abstract: An organisation's maturity in asset management practices and processes can be determined through the application of an asset management audit. The main objective of this study was to develop and validate an asset management auditing methodology. This methodology includes the development of a program for asset management improvement and the application of business process re-engineering (BPR) as a tool to realise the improvement opportunities identified through the audit. The application of an asset management audit, according to the developed methodology, can create a "roadmap" to Asset Management improvement. By optimising the asset management practices and processes, a positive contribution can be made to the profitability of any business enterprise.

Key Words: Asset management, performance, audit process,

1 BACKGROUND ON ASSET MANAGEMENT

Asset management (AM) as a concept evolved from maintenance management to provide a more holistic approach to managing the total life of a physical asset. Asset management in organisations has become the focal point to improve and optimise the contribution of a physical asset to the overall success and profitability of the organisation. In order to achieve optimum return on investment from a physical asset and maximise its contribution to the revenue or success of an organisation, the organisation needs to grow its maturity in asset management. This means that, taking into consideration the stages in an asset's life cycle, maturity levels have to be defined. An assessment is needed to map the level of maturity of the organisation's current practices and processes. Kaizer [1] states that management audits provide a framework for organisations to systematically review, analyse and recommend improvements in performance. Its purpose is also to ensure that management is carrying out its mission, meeting its goals and objectives, following proper procedures and managing resources effectively and efficiently.

2 AUDITING ASSET MANAGEMENT

Traditional maintenance management audits are conducted through interviewing key role players in the organisation with a standard list of questions, performing walk-abouts and studying some requested documents and key measures. The results of such audits are then given in the form of a score with areas of concern highlighted. Coetzee [2] says that measurement, as part of the maintenance cycle, consists of regular (typically annual) maintenance audits and a maintenance performance measurement process (typically performed monthly). The objective of the audit is to determine how well the processes succeed in achieving the results envisaged by management in setting up the maintenance policies and procedures.

2.1 Research Objectives

Many definitions for asset management have been formulated. A consolidation of the different views and opinions was needed to provide an acceptable definition for asset management. Furthermore, the framework for asset management has yet to be fully developed. Various organisations and agencies have developed frameworks which are not fully comprehensive and do not take into consideration all issues in the concept of asset management. Within the elements of such a model or framework, the basic business processes needed have not been formally identified with their desired attributes. A methodology to conduct asset management audits needs to be formulated in order to map the current performance or maturity of an organisation. Included in this methodology should be the improvement process at completion of such an audit.

The main objective of the study was to develop and validate an asset management auditing process or methodology. This has not been addressed in the literature yet. Other objectives, supporting the main objective, were the development of:

- A clear definition of asset management.
- A comprehensive, all-inclusive framework for asset management.
- Business processes associated with each element of the framework.
- An asset management improvement strategy and program.

3 LITERATURE REVIEW

3.1 Background

A literature survey was done on asset management definitions and frameworks as well as on asset and maintenance auditing methodologies. A few of the important literature sources are mentioned briefly in this paper. A detailed discussion of the literature is given by Mollentze [3].

3.2 Definition of Asset Management

Campbell [4] states that maintenance is one of the steps (or phases) in a nine-step asset management process. This process is initiated with an 'asset strategy' phase during which the question is answered on why the asset is required by the business enterprise. The process is concluded when the asset is terminated or 'phased out'.

Clarke [5] states that physical asset management involves the management, co-ordination and execution of all the business activities and processes required through the physical asset's life-cycle, from identification of the business need for a physical asset, through the acquisition, operation, maintenance and eventual disposal.

According to Woodhouse [6], asset management is the set of processes, tools, performance measures and shared understanding that glues the individual improvements or activities, related to assets, together. Woodhouse [6] defines physical asset management as *'The set of disciplines, methods, procedures and tools to optimize the whole life business impact of costs, performance and risk exposures (associated with the availability, efficiency, quality, longevity and regulatory/safety/environmental compliance) of the company's physical assets'.*

Asset Capability Management (ACM) consultants [7] state that maintenance must be defined and managed as a process. Processes need to be established in order to effectively manage maintenance activity and overall asset life cycle management.

Peterson [8] says that strategic asset management involves managing the capital investment towards a long-term program of increasing the return on assets. Peterson [8] defines asset management as *'A global management process through which we consistently make and execute the highest value decisions about the use and care of our assets.'*

3.3 Asset Management Frameworks or Models

Campbell [4] explains that before an organisation embarks on an improvement plan it should assess the strengths and weaknesses of the present system. The diagnostic must be a clear roadmap of the next steps to achieve their vision and should be comprehensive and cover strategic, procedural, technical, administrative and cultural issues. Campbell [4] proposed ten major areas that should be included in an asset management framework.

The New South Wales Government [9] formulated a basic framework for the development of an asset strategy. This framework, illustrated in figure 1, considers each characteristic as a "gate" through which assets are analysed.

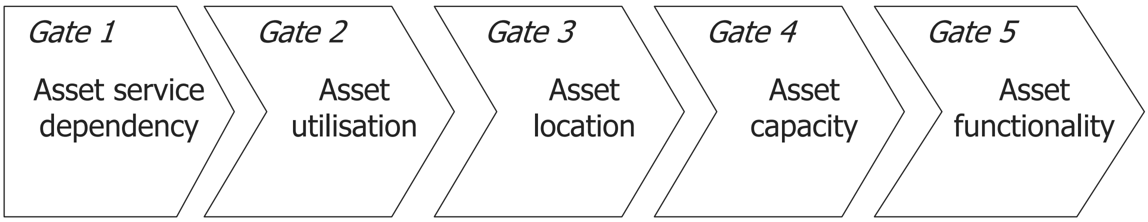

Figure 1. NSW Government framework for development of an asset strategy [8]

Woodhouse [6] views asset management as a set of integrated processes that comprise mainly resource control, work control, cost control and change control.

3.4 Auditing Methodologies

Kaizer [1] defined a seven-phase auditing methodology for maintenance management. These phases are:

- Establish priorities and schedule the audit
- Define and organize the audit
- Form the audit team
- Perform the audit
- Prepare the report

- Define management action
- Final follow-up of results

Hoberg and Rudnick [10] also defined a number of steps for an assessment/audit. Aspects like defining the scope of the audit, planning the activities, forming the team, training of team members and documenting the outcomes of the audit are mentioned.

4 THEORETICAL FRAMEWORK FOR ASSET MANAGEMENT

4.1 Definition of Asset Management

Asset Management is defined in this paper as 'The management of physical assets through its acquisition, operation, maintenance and disposal life cycle phases in order to optimise life cycle costs and maximise contribution to the profitability or success of an organisation'.

4.2 Asset Management Framework

According to the definition of Asset Management given above, the new high-level framework will include the four phases of the asset's life cycle. This gives a holistic scope for the concept of asset management and clearly shows that maintenance management is only one of the elements of asset management. A high-level framework for asset management, based on the four life-cycle phases, is illustrated in figure 2.

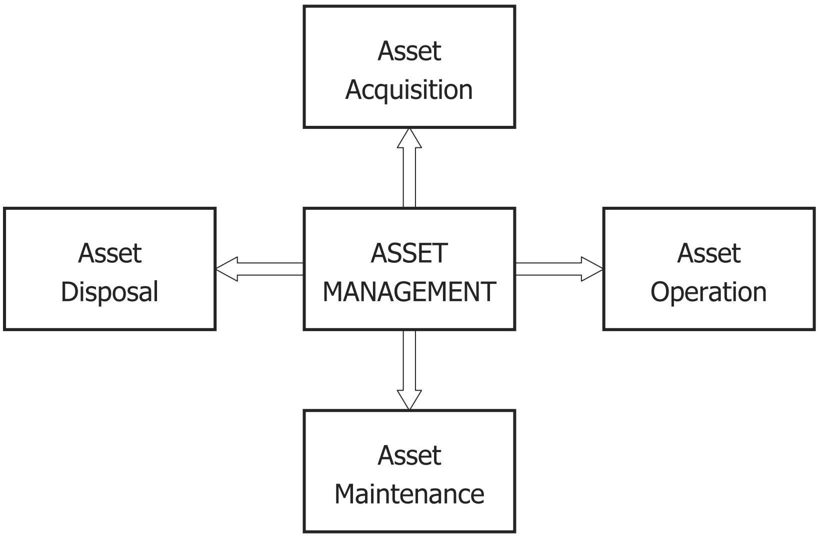

Figure 2. High level framework for Asset Management

The elements of each of the four life cycle phases of an asset are mentioned below. The characteristics of each of these elements are discussed in detail by Mollentze [3].

4.2.1 Asset Acquisition

The *'Asset Acquisition'* phase of a physical asset's life can be divided into four elements namely:

- Asset requirements analysis
- Asset design/procurement
- Asset life cycle analysis
- Asset installation and commissioning

4.2.2 Asset Operation and Maintenance

The *'Operation'* and *'Maintenance'* phases indicated in figure 2 are grouped together since they occur in the same time period. The '*Asset Operation and Maintenance'* phase comprises fifteen sub-phases or elements.

- Strategy development
- Maintenance tactics
- Work management
- Human resources
- Performance measurement
- Continuous improvement
- Financial management
- Materials management
- Systems and information
- Change management
- Outsourcing
- Safety, health, environment and risk (SHER)
- Control and automation
- Operating procedures
- Technology management

4.2.3 Asset Disposal

The final phase in the life cycle of an asset, i.e. '*Asset Disposal*', comprises the following 4 elements that represent the business processes that must be managed.

- Asset decommissioning
- Asset divesting
- Asset retrospect
- Safety, Health, Environment and Risk (SHER)

4.3 Proposed Asset Management Auditing Methodology

A number of auditing methodologies were mentioned in section 2.4. A more comprehensive methodology that includes the concept of Business Process Engineering was formulated and is shown in figure 3. As part of the audit methodology, business processes are identified, mapped and assessed according to the developed framework for Asset Management. The proposed methodology is applicable to a large plant or site and should be scaled down for smaller or sites. A brief description of each phase or element of the proposed methodology is given below. A more detailed discussion is provided by Mollentze [3].

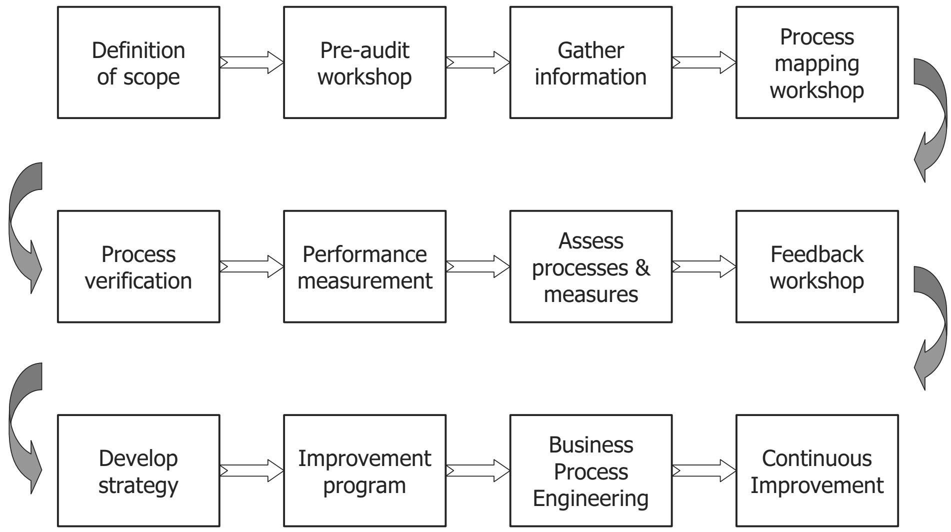

Figure 3. Proposed asset management auditing methodology

Sponsor/Management Definition of Scope

Management or the identified sponsor defines the scope of the audit together with the auditor. The framework, as discussed earlier, consists of elements and a decision has to be made whether certain of these elements will be excluded or not.

Pre-Audit Workshop

Before the audit is conducted a pre-audit workshop is conducted with the key role-players from the section. It is important to include representatives from all affected departments in the organisation, particularly operations and maintenance.

Information Gathering

According to the selected scope, information on the relevant elements is gathered. This information includes the current processes in each element in the form of policies or procedures as well as the supporting systems and tools.

Process Mapping Workshop

This step is different from the ordinary run-of-the-mill audits. After the information has been gathered and the auditor identifies that there are certain processes that he could not be supplied with (because it has never been documented), he should facilitate a short workshop to map the outstanding processes. It may also be found that the required process does not exist.

Process Verification

This can be compared to the physical audit of "traditional" audits. The auditor will visit the section and question certain key personnel on the execution of the processes in the workplace. One may find that a business process has been documented in the form of a procedure, governing the execution thereof, but that in the day-to-day situation in the workplace it is executed differently from what is prescribed.

Performance Measurement

Organisations and even sections within organisations have different ways of calculating the same measurement. The different elements of the audit framework should have a least one or two measures assigned to it to enable comparison to benchmarks.

Assessment of Processes and Measures

After the auditor has gathered all the information required he will be able to assess and appraise the organisation's level of maturity in each of the elements. A guideline for assessing the business process maturity is shown in table 1.

Table 1

Five levels of maturity for business processes in asset management

Level 1	Level 2	Level 3	Level 4	Level 5
The business process (BP) does not exist	Business process exists, not documented, no training in BP's, not been improved in previous few years	Business process exists, is documented and communicated in form of policy or procedure, readily available and understandable. Some revisions done in previous year.	Business Process training is performed, roles and responsibilities of individuals according to it. Systems support 80% of BP's.	Business Process has been modelled with ongoing BP Improvement initiative. Integrated across functional and departmental boundaries. All elements in AM covered by BP's.

Examples of some KPI's and benchmarks that can be used are shown in table 2.

Table 2

Five levels of maturity for performance measures in Asset Management

Element	Metric	Level 1	Level 2	Level 3	Level 4	Level 5
Maintenance Tactics	Planned vs. Unplanned maintenance hours ratio	40:60	50:50	60:40	70:30	80:20
Materials Management	Stores value vs. Equipment replacement value	4,0%	3,5%	3,0%	2,5%	2,0%
Financial Management	Maintenance cost vs. Equipment replacement value	8,0%	6,5%	5,0%	3,5%	2,0%
Work Management	Labour utilisation (Wrench time)	45%	50%	55%	60%	65%

According to the findings of the auditor, the maturity of performance and practices of the organisation can be mapped on these matrices. This allows for scoring and determining the average level of maturity in each element and asset management as a whole.

Feedback Workshop

The feedback workshop should include all the key personnel that were involved in the audit as well as a representative from different levels and departments. A full report can also be distributed during this session.

Strategy Development

When developing the asset management strategy, representation from all key stakeholders is imperative. This is important to ensure that the necessary support and buy-in is gained from the people that are going to make it work. Opportunities for improvement have been identified by the audit and according to this, the strategy will be developed. Aspects to be addressed in this step are the development of a vision, mission, key objectives and key performance indicators (KPI's).

Improvement Program

The gaps have been identified, targets have been set and the *Program for Asset Management Improvement* (PAMI) has to be developed. This program will contain the plans to close the gaps and achieve the targets. PAMI is a living program that details all the necessary actions, resources and timelines that can take the organisation to the desired future state. PAMI needs to be communicated and displayed to all stakeholders so that current and future actions can be visible to all concerned.

Business Process Engineering (BPE/BPR)

Tritter [11] postulates that the entire organisation can be seen as a set of processes. Various tools and methodologies are available in industry to perform Business Process Re-/Engineering. Examples include the *Business Process Re-design* of Malhotra [12], *Control Self-assessments* by Tritter [11] and *Process Reengineering Life Cycle* by Grover [13], to name a few. The organisation will have to review the methodologies available to perform Business Process Re-engineering and adopt what is most suited for the organisation.

Continuous Improvement

The Asset Management audit is not a once off exercise. It is advisable to perform follow up audits to assess the implementation of the improvement actions as well as the effectiveness thereof. As you apply the audit process and compare trends with past audits, you gain increasing knowledge about the dynamics of your organisation.

5 VALIDATION METHODOLOGY

The validation of the asset management framework and audit methodology was done by means of a practical application as well as a survey distributed to different representatives from a wide range of organisations.

5.1 Data Collection

5.1.1 Practical Application

The auditing methodology as discussed in section 3.3 of this paper was applied on the Final Recovery Plant at the Jwaneng Diamond Mine in Botswana. The first step was to determine the scope of the audit. Members of the management team at the plant decided, due to several reasons, to limit the scope to only eight elements of the asset management framework as discussed in section 3.2.

5.1.2 Survey

A questionnaire was drawn up to test the asset management framework and audit methodology in the field. The questionnaire comprised five statements and respondents were requested to indicate whether they (i) fully agreed, (ii) partially agreed or (iii) disagreed. The questionnaire was distributed within the De Beers group of companies in Southern Africa and addressed to persons directly involved in the field of asset management.

5.2 Data Analysis

5.2.1 Survey

The results of the survey are summarised in table 3 below.

Table 3

Summary of responses to the questionnaire

Question	Agree (%)	Partially agree (%)	Disagree (%)	Some comments of respondents
The definition for Asset Management as quoted in 3.1 of the article describes the concept of physical Asset Management clearly, considering the whole life cycle of assets	100	0	0	Operation and maintenance are two different processes but they occur in the same time frame in the life cycle of physical assets.
The elements of the developed framework, for Asset Management, address most of the possible elements/business processes within a typical organization as described in 3.2	57	43	0	Would prefer to see a fifth dimension, that of operational readiness, an asset taken through from being acquired to operational phase.
The framework is simplistic and easy to understand (down to Supervisor level)	57	43	0	A study of the concepts involved will have to be carried out to fully understand their meaning and the language could be simplified.
The asset management audit methodology described in paragraph 3.3 is practical and could easily be applied to your organisation	43	57	0	Asset Management should have a strong business orientation and, whatever framework is used, should support Business Value Add within an Asset Life-cycle context.
The application of the asset management audit methodology should have the potential to positively affect the profitability or success of an organisation	86	14	0	Auditing is a management tool addressing the need for assurance, much more than it is a strategy implementation vehicle. It cannot circumvent investment in people etc. but admittedly enhance the success of these investments by assuring basics are and stay in place.

The results from the survey indicate that the new auditing methodology is accepted and supported, as well as the framework and elements identified as the scope of Asset Management. Some of the comments can be used to update the audit methodology. Most of the partial agreements could not be validated as it seemed that the respondent either did not understand, or misinterpreted, the information provided before the survey was done. The biggest concern highlighted by participants was that the audit might be too holistic, but it is made clear that the first step of the audit is to determine and/or narrow down the scope. Obviously, when this step is performed the environment where the audit will take place must be taken into consideration and this will ensure that the scope of the audit is then applicable for the specific application and is not too broad.

5.2.2 Practical Application

The auditing methodology described in this paper was applied successfully at the Red Area, Jwaneng Mine and the stakeholders of the Red Area supported the new auditing methodology and were willing to use it on a regular basis. The results from the audit were regarded as accurate and supported their subjective evaluation of the asset management function.

6 CONCLUSIONS AND RECOMMENDATIONS

The main objective of this research, i.e. to formulate a comprehensive framework for asset management, and to develop and validate an auditing methodology, was achieved. Aspects of the Business Process Re-engineering methodology were included in the audit methodology.

The proposed audit methodology can be applied in virtually any business enterprise. It was tested practically at a section of the Jwaneng diamond mine in Botswana and the results were satisfactory for the mine management. Several opportunities were identified within the predetermined scope of the audit at the site that otherwise may not have been identified. The Program for Asset Management Improvement will contribute to improving the performance of the production assets.

A contribution was also made to the theory of asset management through the development of a comprehensive framework for asset management. The framework and elements of the framework contribute to the theory of asset management by defining the various issues that should be addressed through asset management during the life cycle of a physical asset.

Abstract: Maintenance management is a complex partnership between the people directly or indirectly involved in maintenance, the processes and strategies to direct the people's actions, the physical assets being maintained, and the Computerised Maintenance Management Systems - the main link between the "people", the "processes and strategies", and the "asset". Although the maintenance literature contains many recipes for success, anecdotal evidence suggests that maintenance management is often ineffective. Despite advances in instrumentation, computer capabilities, integrated asset management software, and the involvement of reliability engineers and maintenance managers, unexpected and costly equipment failures still occur – sometimes with adverse effects on people and the environment. Literature on systematic research to support or contradict the anecdotal evidence is, however, hard to find. This paper introduces a research project which aims to identify and analyse various influences on maintenance management. The research (using contemporary social sciences investigation methods) is conducted by experienced engineers, and is part of a larger project on the nature of engineering work. The paper also provides a literature overview aimed at providing an insight into the major aspects leading to successes or failures in the field of maintenance management.

Key Words: SAP™ PM, Plant Maintenance, Computerised Maintenance Management System

1 INTRODUCTION AND INITIAL PROBLEM STATEMENT

Maintenance is a huge industry. On a global scale, Thomas [[1]] estimated maintenance cost at 9% of an estimated world Gross Domestic Product (GDP) of 45,000 billion AUD. Not only is maintenance on global scale huge, but individual companies also experience maintenance costs as substantial. Hägerby and Johansson [[2]] reported that the total cost of maintenance for the companies reviewed by them, is as high as 40% of company turnover.

The size of the maintenance industry resulted in the abundant supply of software, instrumentation, analysis techniques and specialists to support the maintenance industry. Landmark books have been published in the last decade that contain "recipes" to optimise companies' maintenance systems and procedures. Examples of techniques widely used by companies in projects aimed at optimising their maintenance costs include Reliability Centred Maintenance (RCM) [[4]], root cause failure analysis [[5]] and preventive and predictive maintenance (PM) [[6]]. Furthermore, our understanding of functional failures of equipment and how these present themselves in an operational environment has improved dramatically; and we now have generic preventive maintenance tasks and typical maintenance intervals that can be used as a main source when developing preventive maintenance programs. There have been dramatic advances in computer capabilities in the last decade; and instrumentation that monitors the condition of equipment has also become better and cheaper. The larger companies have maintenance engineers to address the operational day-to-day maintenance issues, and reliability engineers to address long term maintenance strategies.

Despite all of this, anecdotal evidence suggests that maintenance management still has huge unsolved issues, and that improvements in the last decade have not been as beneficial as one would expect. Unexpected and costly failures are still experienced - sometimes with far reaching consequences and ramifications. An example of such a recent event linked to maintenance was a burst main water pipe next to a freeway in Perth, Western Australia. An estimated 12 megalitres of water flooded the neighbouring areas in a short period, resulting in the hasty evacuation of business premises and private homes. Vehicles were stuck on the highway and major roads for several hours, ambulances could not transfer patients to hospitals, parents could not pick up their kids from school, taxis could not get rid of their passengers and people missed their flights.

Very little systematic research could be found on whether the anecdotal evidence about the efficiency and effectiveness of maintenance is true or merely the perceptions of a small group of individuals. If the perception that maintenance still has huge issues is shared by a larger group of people in the maintenance field, no clear reasons for this have as yet been identified. The research literature found on maintenance management mainly focuses on technical issues and advanced analysis techniques. The literature is also predominantly prescriptive. Many writers have contributed suggestions and techniques for effective maintenance programs, but these are either based on their own experiences or are aimed at promoting a specific product.

2 RESEARCH PROJECT AIM

This paper introduces a research project aimed at beginning to identify common issues experienced in the field of maintenance management, and how these issues are being (or have been) addressed by the companies participating in the research project. The research, using contemporary social sciences investigation methods, is conducted by experienced engineers and is part of a larger research project at the University of Western Australia into the nature of engineering work [[3]].

Because of the uncertainty on where the real issues are, it was decided to develop a list of possible explanations for the problems experienced in maintenance management. This list is based on information extracted from various articles, past experience of members on the research team, and from discussions with various people involved in different aspects of maintenance. Section 4 of this paper provides more details on this potential list of issues (referred to as "possible hypotheses" in the remainder of the paper).

The project will be undertaken in two phases, with the main aim of the first phase to gather real data on what people in maintenance roles experience as current issues in maintenance management. This data will be analysed, and the initial list of very broad potential hypotheses adapted to only those that seem to contribute to the problems in maintenance management. The second phase will analyse in more detail only those common experiences that emerged during the fist phase.

The main source of data for both phases will be interviews with people from a wide range of maintenance roles. Where considered appropriate, data extracted from analysis of the interviews will be supplemented with "shadowing" (i.e. following) of some people, interrogation of the Computerised Maintenance Management System (CMMS) and a review of relevant company documentation. As a minimum, it is planned to interview maintenance engineers, reliability engineers, maintenance technicians and operators. If time allows and if more information is required, inspectors, purchase buyers and accountants will also be interviewed. All interviews will be analysed using well-established qualitative analysis techniques. These techniques provide guidelines on the development of the questionnaires, as well as the coding and interpretation of the data.

3 DEFINITION OF MAINTENANCE MANAGEMENT

In the context of this research project ***maintenance management*** is defined as the preserving of the ability of an asset to safely and economically produce something through structured management of the following elements throughout the life cycle of the asset:

- The asset - the physical items requiring maintenance (e.g. plant equipment, fleets and buildings).
- People – the individuals in the organisational structure involved directly or indirectly with maintenance. Some people are very visible in the maintenance work flow process (such as asset managers, maintenance engineers, maintenance supervisors, maintenance technicians and plant operators) while others are less visible, but not less important, in the maintenance work flow process (e.g. reliability engineers, inspectors, accountants, purchase buyers, and CMMS Administrators).
- Processes and Strategies – defined as the maintenance-related business processes, maintenance strategies implemented to optimise maintenance cost, maintenance engineering and analyses techniques.
- Computerised Maintenance Management Systems (CMMS) – the heart of each modern maintenance system, and the main link between the "people", "processes and strategies" and the "asset".

4 POSSIBLE HYPOTHESES TO BE ANALYSED IN FIRST PHASE OF PROJECT

The remainder of this section contains a list of possible hypotheses that might explain some of the problems experienced in maintenance management. These hypotheses address the following three of the four elements of maintenance management as defined in section 3:

- The people
- Processes and strategies
- The CMMS

The asset being maintained is not included in the scope of this research project.

4.1 Hypothesis 1 related to "People"

"Maintenance" has negative connotations and as a profession it has little social status

The following saying by an experienced consulting engineer was once overheard "People don't stand around the barbecue bragging to their friends that they had a meeting with their maintenance engineer. However, they like telling others about their accountants, lawyers and medical specialists". It seems that maintenance is not seen as a "sexy" job when compared with other professions, and even with engineering in general. Even the word "maintenance" seems to have negative connotations. When Palarchio [[7]] for example asked a group of managers from maintenance and production what comes to mind when the word "maintenance" is mentioned, and the most common responses he received were (i) high cost (ii) under utilised (iii) not highly valued (iv) bottom of the management group (v) non exploited opportunity for competitive advantage. All the responses were very negative in nature. According to Thomas [[1]], the feedback received by Palarchio mirrored his own experience as a maintenance consultant of 30 years. Following a series of interviews with people on what they do as engineers, Trevelyan [[3]] reported that "Maintenance is a major area of engineering in its own right and it was interesting that in our early interviews it hardly rated a mention".

The first phase of this research project will try to determine whether maintenance does have negative connotations. If so, the reasons for this will be investigated further in the second phase of the project. A possible explanation to investigate further could be that "maintenance" is seen as the culprit in major incidents. We know that some major accidents such as Chernobyl and Piper Alpha could be linked to in some way to maintenance and the procedures followed during maintenance. However, the general perception is often that "maintenance" – and not incorrect procedures during maintenance – caused the incidents. In Chernobyl for example, it was human errors made during preventive maintenance intervention that were the direct cause of the accident. On Piper Alpha, a series of procedural oversights and accidents led to the catastrophic destruction of the offshore gas platform and the death of people. The main oversight was not following the required procedures of informing the supervisors of the removal of a safety-critical component during a preventive maintenance action.

Another possibility to potentially investigate in the second phase of the project relates to the way in which accidents are covered by the news media. The public is sometimes subjected to repeated, visually impressive footage, supported by speculations on the cause of the accidents which are presented as facts. To the uninformed, "maintenance" can then become the easy explanation for the accident, instead of the errors made during maintenance.

4.2 Hypothesis 2 related to "People"

The strategic importance of maintenance is not fully appreciated in companies – especially not by strategic decision makers

The authors are aware of recent directives from top management of a large mining company to "*reduce maintenance cost by 30 million AUD over the next three years*". Numerous questions come to mind from such a directive: What would be considered as "maintenance costs savings"? Is maintenance cost seen in context by strategic decision makers? How sustainable will the cost reduction efforts be in the longer term? Is cost of "production loss due to failures" taken into account? Does top management fully appreciate the complex and interactive nature of maintenance?

Below are some thoughts on two of these questions.

"Is maintenance cost seen in context by strategic decision makers?" According to Hägerby and Johansson [[2]] the answer is "no"; and that the "true" cost of maintenance is neither fully understood nor presented in context in companies. Their results showed that for the seven Scandinavian companies reviewed, direct maintenance cost (e.g. cost of spares and labour) was overshadowed by the loss of production cost due to unavailability of the plant. The loss of production cost was up to 40% of company turnover, compared to the direct maintenance cost of approximately 8% of company turnover. Reducing direct maintenance cost in the short term might make some managers happy, but the potential effect could be an increase in failures in the longer term, with a resulting increase in production loss cost.

"Is maintenance well presented at board level or in top management?" According to Thomas [[1]] it might be true on paper that maintenance is presented on high levels in organisations, but in real life that is not true: "*Many organigrams show maintenance at the same level as production, marketing, finances, etc., but in my experience the reality is that maintenance is not part of "The Management Club*". According to O'Malley [[8]], understanding the importance of maintenance is not only a problem on higher management levels of organisations. Even the members in the maintenance team, such as reliability engineers, sometimes struggle to see the importance of maintenance - making it difficult for them to "sell" maintenance as a benefit to top management.

If maintenance is not well presented on the level where strategic decisions are made, and if the information provided to these strategic decision makers does not reflect the real benefits of maintenance, there is the risk that maintenance cost will be seen as an unnecessary expenditure - especially as it goes against human nature to spend time and money on something that has not happened (which is the basic principle of preventive maintenance). These decision makers might then put continuous and unrealistic pressure on the maintenance department to reduce the maintenance costs.

In the first phase of the research project, information will be gathered to determine how well maintenance is presented or understood by strategic decision makers. If there are indications that the maintenance is poorly presented, the second phase will try to determine the effects of the "poor" presentation of maintenance. Are there examples of where pressures on the maintenance team were considered "unrealistic", and if so has this pressure resulted in unsustainable cost cutting actions? Were the maintenance team members aware before implementing the actions that they were unsustainable?

4.3 Hypothesis 3 related to "People"

Maintenance management roles have a high turn-over, restricting the effectiveness of maintenance optimisation projects

Based on the authors' experience, people in maintenance management roles seem to stay in that specific role for approximately 2 years before moving on – either to a different role in the company, or to a different company. During consulting involvement over a period of six years, for example, the first author had to deal with three successive maintenance managers in one company. The different managers did not seem to fully appreciate previous maintenance optimisation efforts, and new strategies and changes were introduced by each, shortly after taking over the role. Besides duplication of efforts and costs, people affected by the changes also seemed to become "change-weary" and reluctant to embrace the changes.

Hayward [[9]] noted that most of the employees in the maintenance department of an American energy provider have been through some form of a change process between 1990 and 2000. They have been exposed to re-organisations, process re-engineering, competency modelling, continuous improvement, organisation development intervention and RCM. Few questioned the intent of these efforts, but many however questioned whether these changes were truly successful as no feedback was provided regarding the success rate.

The first phase of the research project will try to determine the turn-over of individuals in maintenance management roles, and how other people (e.g. the maintainers) experienced the changes in management. We also need to determine whether the turnover of maintenance managers differ from similar non-maintenance management levels. If is true that maintenance management roles have a high turnover, the second phase will gather more information on the effects of the high turn-over of managers. Were maintenance personnel for example subjected to continuous changes in approaches and strategies? Do these people show resistance towards new ideas because of this? Is there an underlying thought that a new idea will be replaced by another before long? Can evidence be found that organisations where maintenance managers stayed on for longer periods are more efficient and effective than other organisations where there had been a high turnover of maintenance managers?

4.4 Hypothesis 4 related to "People"

New maintenance managers and supervisors from different backgrounds experience different problems in their roles

The background of maintenance managers and supervisors seem to differ vastly. Some managers for example have engineering degrees while others have worked their way up through the ranks. No evidence could be found in literature that managers with different backgrounds have different approaches and success rates towards maintenance management. There was a hint, though, from Hägerby and Johansson [[2]] that some of the problems experienced by maintenance managers relate to their backgrounds. Some of the top performance workers in the maintenance field that were rewarded through internal promotions to maintenance supervisors and maintenance engineers, ended up managing their friends with whom they have worked for many years. The new managers experienced a lack of professional respect, and they struggled to "control" their workers. Thomas [[1]] is of the opinion that maintenance supervisors and team leaders lack management skills in general, and therefore are working at less than 60% of their potential. According to Orr [[10]] many technicians try the job of maintenance manager, but the pressures are such that few last.

In the first phase of the project, information will be gathered on the background of maintenance managers and supervisors. Managers will be asked how well they think their backgrounds prepared them for their new roles, and how well they were supported in their new roles. Finally they will be asked to comment on how they felt about their own performance – especially initially. If there are indications that managers from different backgrounds experience different problems, this will be investigated further in phase 2.

4.5 Hypothesis 5 related to "People"

Maintenance workforce is ageing, and there is no special preparation to transfer / extract the experience and knowledge from the older work force

According to Hayward [[9]], 40% of craft work force in the Department of Energy in USA will retire between 2002 and 2007, with the average age of the maintenance work force at the beginning of that period 50 yrs old. No statistics could be found on the average age of the maintenance work force in Australia, but anecdotal evidence suggests that this component of the work force in Australia is also ageing.

In the first phase of the project, the average age of the Australian maintenance work force will be determined. If there is evidence that the maintenance work force is ageing, the second phase will determine whether there is evidence of special preparations by companies to transfer the knowledge from an experienced work force to the younger people. One way of transferring this knowledge could be to get the older workforce to review and update all the job procedures attached to preventive maintenance tasks. These procedures often have mistakes, as highlighted by an engineer involved in the development of job procedures [[3]] "*To a certain extent, the engineer also relies on trained workers to detect and avoid mistakes or simple omissions in the instructions*". Another mechanism of transferring knowledge could be to provide inexperienced younger maintainers with experienced mentors for a period.

4.6 Hypothesis 6 related to "People"

Maintenance managers experience e-mail correspondence as excessive – especially in a corrective "fire-fighting" environment

One of the roles of the maintenance manager is normally to provide short term maintenance engineering support – especially where the repair of equipment is complex or non-standard, or where the correct functioning of the equipment is critical for the safe operation of the plant. Reliability engineers, on the other hand, are involved in the development and implementation of long term maintenance strategies.

From the authors' experience, the maintenance engineers are the first to suffer in a corrective "fire-fighting" maintenance environment - especially with a growing trend to communicate via elaborate e-mails. Between managing the technical aspects of high-priority and complex repairs, and processing hundreds of e-mails (of which a guesstimated 80% were sent to the maintenance manager "for information only") there seem to be little time left for the maintenance managers to reflect on the situation, and to introduce actions to move away from this corrective "fire-fighting" mode. Some maintenance managers expressed their reluctance to go on holiday or training courses, because they receive up to 250 e-mails *per day*! The effect of a holiday is quickly cancelled out by the daunting prospects of working through all those e-mails, which were not handled by the acting manager, during the manager's absence. In a study by Mintzberg [[11]] on what managers do, he noted that most managers that were required to read a lot of correspondence expressed a dislike for long memos, and that most long reports and correspondence were only scanned quickly. If maintenance managers also follow this approach of skimming through e-mails, important information could be missed or misunderstood, which can lead to dangerous or costly decisions.

In the initial phase of the project, it must be determined whether maintenance managers experience e-mail correspondence as excessive, and whether the capability to do their jobs is restricted by the amount of e-mail they have to deal with. If this is a valid hypothesis, the second phase of the project will determine (i) the quantity and typical length of e-mails received by maintenance managers; (ii) How much time the managers spend on processing e-mails; (iii) The percentage of e-mails sent to the managers "for information only", and how many e-mails require a reply from the manager; and (iv) Whether there is a link between the corrective maintenance and the amount of correspondence on the matter.

4.7 Hypothesis 1 related to "Processes and Strategies"

Tools and techniques used in maintenance optimisation projects do not always produce the expected results

The size of the maintenance industry resulted in the development of abundant tools and techniques to help the reliability and maintenance engineers in their efforts to optimise the maintenance. Technology in this field also changes extremely fast; and new terminology, tools and techniques are introduced continuously. Levitt [[6]] writes "*Every year some smart scientist, engineer, or maintenance professional comes up with one or two more techniques for predictive maintenance"*. On only one website (*http://www.plant-maintenance.com*) over 700 software packages managing some aspect of maintenance are advertised. There are no definite rules as to which tools and techniques are the best for a particular application, and a lot therefore relies on the experience (and biases) of reliability engineers, as it is expected of them to select the appropriate tools and techniques (O'Malley [[8]]) – a daunting task given all the choices, and easy to get it wrong.

Anecdotal evidence suggests that organisations are realising more and more that the tools and techniques used by them to optimise their maintenance do not always deliver what they expected. Leonard [[12]] speculates that many RCM initiatives in the industry failed because of the application of the cumbersome and inflexible RCM methodology in industrial contexts that differ widely from the aviation industry where the RCM technique was first applied. Feedback from individuals interviewed by Hägerby and Johansson [2] suggested that "first line maintenance" as a maintenance technique has been applied with limited success since the limited first line maintenance tasks expected from operators (such as lubrication) were not performed well. The majority of the maintenance people interviewed by Hägerby and Johansson [2] reported general dissatisfaction with the amount and type of maintenance done on their assets. Thomas [[1]] writes "*I cannot remember the number of times when visiting maintenance offices that I have seen expensive condition monitoring equipment gathering dust [……]. No doubt these were bought in good faith but they failed due to the lack of basic maintenance principles.*"

Information is required on (i) What techniques and/or tools are used by the reliability engineers to determine the "best" amount and type of maintenance (ii) On what did reliability engineers base their particular choices (iii) Is there evidence that these tools/techniques produce the expected results, and (iv) Are the facilitators that use the tools and/or techniques trained and experienced in using it.

4.8 Hypothesis 2 related to "Processes and Strategies"

Improper work flow processes and work order execution rules limit the effectiveness of maintenance optimisation projects

The maintenance work flow processes define the activities involved from identifying a requirement for maintenance to close-out of the work order or job card. The following are typical tasks that appear in maintenance work flow processes (i) create a request for maintenance work, (ii) review request for maintenance, (iii) determine the priority of the maintenance request and create a work order, (iv) scope the work, (v) approve the work order, (vi) execute the work, and (vi) capture maintenance history in the CMMS and close-out the work order/job card.

If the work flow process is to be used as the main communication tool between the various maintenance roles, the tasks listed above can be supported by additional information such as who should execute the task, and how should the task be done in the CMMS.

No researched evidence could yet be found on the importance of work flow processes in the management of maintenance, but the experience of the authors supports the value of a well-defined work flow process. One of the production plants where the work flow processes were updated by the first author reported a rise of 40% in the number of safety-critical preventive maintenance tasks completed in the agreed time. This dramatic increase was experienced only two months after introducing the new processes and re-training of the end-users on the changes and how to do their jobs in the CMMS. Hägerby and Johansson [[2]] noted that if the work flow and work prioritisation are not documented and enforced, people tend to do the interesting work orders first - leaving the boring work such as regular oil sampling for the next shift. This results in a backlog of "uninteresting", but essential maintenance work.

The first phase of the project will gather information to determine the value of work flow processes. Maintenance areas where the work flow processes are well defined and enforced will be compared with maintenance areas where the work flow processes are vague or not documented at all. Interrogating the CMMS as well as reviewing relevant documentation will be used to support and correlate the feedback from the interviewees. If the work flow processes do seem to play a substantial role in the effectiveness of maintenance optimisation projects, and if there is evidence that many maintenance departments underestimate the importance of work flow processes, the second phase will gather more detailed information.

4.9 Hypothesis 3 related to "Processes and Strategies"

The quality of the maintenance history data collected in the CMMS restricts useability of the data by reliability engineers

Yang & Strong [[14]] define data quality as *data fit for purpose,* and may be measured using key parameters that are important to the users of the data. What would be considered "poor data quality" to one user, might be seen as sufficient by another user. At the very least though, organisations would be expected to distinguish between the mandatory and optional information to be gathered in the CMMS.

From the authors' experience, many organisations are not serious about the quality of the maintenance history gathered in the CMMS. It is not clear to the maintainers (the main source of maintenance history) what information is mandatory to provide, data collected in the CMMS is not audited regularly, and feedback is not provided to the maintainers on how the data was used and what improvements resulted from the analyses of the data. Levitt [[6]] confirms this experience by reporting that "*Management has been wishy washy about requiring work orders and other maintenance record keeping to be accurate and complete*". An engineer interviewed by Trevelyan [[3]] remarked "*Often I find that we are collecting data but not using it effectively. Of course there are sometimes issues with the quality of the data and that needs to be taken into account before making too much use of it*".

The first phase of the project will determine (i) Whether information on the organisations' requirements with respect to maintenance data quality is readily available; (ii) Whether people are clear on what data fields in the CMMS need to be completed by whom, and when; (iii) Is there evidence that data is evaluated regularly to determine the accuracy and useability of the data? (iv) Is there evidence that the data is used by reliability engineers? and (v) Are the providers of the data informed on how the data is used?

4.10 Hypothesis 1 related to "CMMS"

CMMS implementations by people with limited understanding of maintenance and the organisation's business requirements result in CMMS considered ineffective and inefficient

Anecdotal evidence suggests that where "quasi-experts" (i.e. experts in the Computerised Maintenance Management Systems, but with little understanding of maintenance) were used to configure and later support the CMMS, people in the maintenance environment experience many frustrations in the day-to-day usage of the CMMS. Some individuals interviewed by Hägerby and Johansson [2] reported that "*The initial (PM) program was developed by people with little or no experience in operative maintenance. For this reason, unrealistic assumptions have been made, resulting in a PM program that contains* *several unnecessary or even totally inappropriate activities*". Mather [[15]] considers maintenance an area neither easily nor rapidly understood by those outside the discipline, and advises that only people with sufficient knowledge in both maintenance and the company's specific business requirements make critical decisions regarding the way in which the system should be configured. Levit [[6]] suggests using CMMS representatives as advisors only.

Information gathered in the first phase of this research project will determine how successful users of the CMMS considered the initial implementation of the CMMS, and to what they attribute the successes or failures. The major frustrations experienced by users of the CMMS also need to be identified. The replies will be evaluated before deciding on the need to add this hypothesis to the list to be further investigated in the second phase of the research project.

4.11 Hypothesis 2 related to "CMMS"

Insufficient maintenance of CMMS master data post go-live result in a CMMS not trusted by maintenance personnel

The "go-live" date of a new CMMS is normally broadcast widely in an organisation, and awaited with excitement. After the CMMS has gone operational though, it seems as if people are expected to get on with the "real job" of maintenance, and many organisations seem to limit the time and resources available to review and update the master data in the CMMS (data in the CMMS that do not change regularly as part of the day-to-day operations of the asset). The authors have noted that the maintenance data administrators for example are often of the lowest paid jobs in the maintenance environment. People interviewed by Hägerby and Johansson [2] reported that "*CMMS is used extensively, but these plans are not kept up to date and therefore not trusted by the maintenance personnel*."

During the first phase of the project, people will be asked whether they experienced problems related to the validity of the CMMS master data. They will also be asked whether it was easy to request updates in master data and whether they considered the approval of data changes prior to implementation sufficient. Feedback will determine whether this hypothesis will be addressed in more detail in the second phase.

5 CONCLUSION

Maintenance is a huge and fast changing industry. The main role players in this industry are the organisations with the maintenance needs (and they can spend up to half of their turnover on maintenance) and the providers of software, instrumentation, consulting, training etc. aimed at reducing the organisations' direct and indirect maintenance costs.

Despite the huge amounts spent by companies on maintenance, and despite the availability of tools, techniques, instrumentation, consultants, etc. to support the maintenance optimisation efforts, anecdotal evidence suggests that there are still many problems in maintenance. No structured research could be found on whether the main problems relate to issues with the people involved in the maintenance cycle, whether the issues relate to the strategies and processes applied in maintenance management or whether the majority of the issues are linked to the implementation and support of the CMMS.

This research will attempt to gather information in a structured and unbiased way, analyse the data using techniques that have proven their value in the social sciences research, with the aim of providing a better understanding of the major factors that have influenced (or still are influencing) the effectiveness of maintenance management efforts. This will provide a useful foundation for future research in this field.

OPTIMISING PLANT PERFORMANCE: A SYSTEMS THINKING APPROACH TO PROBLEM SOLVING

A Agresti [a]

[a] *Principal, Asset Capability Management Pty Ltd, www.assetcapability.com.au*

Abstract: Maintenance and Reliability Managers are responsible for solving plant performance problems that relate to maintenance activity or improvement activity within the operating environment. Knowingly or not, they manage maintenance activity using a series of interrelated processes; a system. Management of improvement activity should also use a system as improvement activity competes for resources and priority and adds a different complexity as it brings change; change to both behaviours and practices. Recognising that we operate within systems is fundamental to solving plant performance problems and remaining competitive. Activity within systems requires a different type of thinking to be fully effective. Thinking that fully explores the complexity of the cause and effect relationship between the constituent processes and the behaviours of the people that enact them. Systems Thinking is the key capability required by teams for describing and understanding problems to optimise plant performance. Subsequently, Maintenance and Reliability Managers that are unable to develop an understanding of Systems Thinking and apply it to establish an improvement management system will not realise the full performance potential of their plant.

Key Words: maintenance systems, performance improvement, problem solving, systems thinking

1 INTRODUCTION

Today's operating environment is changing at an increasing pace because technology, information, and competence are becoming business commodities [1]. Any organisation can purchase the latest technology, gain access to the same information, and have their people trained in the latest techniques. One way to remain competitive is for an operation to have the capability to improve plant performance through defect elimination.

The essential purpose of the maintenance function is the removal and elimination of defects to efficiently achieve stable plant performance according to plant availability and production requirements. Defect removal can be managed using either a reactive or planned maintenance approach. In a reactive approach there is an absence of any structured system; defects are dealt with as and when they are recognised. By contrast a planned approach uses a rigorous maintenance work management system (MWMS) which is far more effective as it ensures that resources are used appropriately, tasks are efficiently coordinated and roles are aligned to repeatable processes with managed outcomes such as availability and reliability.

Defects however are much more than technical plant performance problems. They can be caused by any number of interrelated technical, systemic or behavioural events which may happen in isolation or in any combination. To fully eliminate defects at their root cause first requires a comprehensive understanding of the interplays at work.

Systems Thinking is a practice that involves holistic consideration of the interplay between variables that influence a system; the discipline to recognise inherent patterns and related outcomes. It contains distinct principles that can highlight unique problems within an operational matrix of technology, people and work practices (processes). Systems Thinking is a key discipline essential for managing plant performance improvement. By correctly applying Systems Thinking an operation can establish the capability it needs for defect elimination to deliver optimal performance.

2 THE PATH TO SUSTAINABLE DEFECT ELIMINATION

Despite overwhelming proof that our lives and the operational environment are drastically changing, we continue to rely on the application of technically focused problem solving concepts and methodologies for improving plant performance. Maintenance and Reliability Managers, delegated responsibility for realising optimal plant performance, are trained to manage tangibles; equipment and plant performance by review of facts and data using argument and logical conclusion. They are not equipped to deal with the intangibles of individual perspective, knowledge, emotion, time and relationships.

The manufacturing and industrial operations of the future will need to effectively manage knowledge, emotion, time and relationships to realise the levels of productivity required to remain globally competitive. According to Senge [2], we are limited in dealing with such issues by our collective learning capability. The source of the problems that lead to the repeated inability to sustain significant improvement and realise optimal performance can not be solved by more expert advice, better consultants, or more committed managers. The source lies in our most basic ways of thinking; if this does not change, any new ‘input’ will end up producing the same fundamental unproductive types of actions.

Edward de Bono [3] also states that “The difference between brilliant and mediocre thinking lies not so much in our mental equipment as in how well we use it.” To be effective then, problem solving needs to go beyond realising technical outcomes to provide learning outcomes and we need a new way of thinking that incorporates the intangibles.

Systems Thinking provides the means to establish a holistic perspective of the issues limiting plant performance in an industrial operation. It provides learning outcomes that influence existing attitudes and practices within an organisation by allowing underlying norms, policies and objectives to be assessed as well as focusing on specific technical actions and results.

Application of Systems Thinking provides opportunities for collective inquiry so that it is possible for a team to develop new and better understanding of what to do, and how or when to do it. It provides the means to create enduring solutions to recurring or stubborn plant performance problems because performance improvement teams can work on the entire “problem system” rather than on specific elements or symptoms.

By developing an understanding of Systems Thinking, how it can be successfully applied, and its significance to realising sustainable improvement, Maintenance and Reliability Managers will have the means to manage these “intangibles” and realise optimal plant performance more efficiently and effectively than is otherwise possible.

3 AN OUTLINE OF SYSTEMS THINKING

The principles of Systems Thinking are derived from the field of System Dynamics founded by Professor Jay W. Forrester at the Massachusetts Institute of Technology during his work in electrical engineering in the 1950’s. System Thinking is a methodology for studying and managing complex feedback systems such as those found in business and other social systems. System Thinking focuses on feedback flows that occur throughout the parts of a system and the resulting system behaviours that are caused by those flows. Before exploring this type of thinking, let’s consider what is a system.

A system is a combination of interacting, interrelated, and interdependent elements that form a complex and unified whole. There are many familiar examples of systems such as the maintenance (defect removal) function in an operation, the respiratory system of the body, the relationships between predator and prey in nature, and the control system in an item of equipment. Specific characteristics are used to define a system:

Every system has a purpose within a larger system. (The purpose of the MWMS in an operational system is to provide an optimal level of plant availability and performance.)

- All system elements must be present for optimal performance of the system purpose. (The MWMS consists of people, equipment, and processes. If any one of these components are missing the system can not fully function.)
- System elements must be in a specific configuration to realise the system purpose. (Planning must occur before scheduling in the MWMS for work to be effectively executed)
- Systems change (behave differently) in response to feedback. (Feedback is information transmitted and returned through a possible chain of causes and effects from A to B and in turn from B to A that ultimately influences subsequent actions at A. The link between A and B can not be studied independently of the link between B and A to be able to predict how the system will behave. Correct results can only be obtained by a study of the whole system as a feedback system. For example, while snow skiing you negotiate a bend and turn too sharply. You receive visual signals (you see the trees ahead rushing toward you) that tell you that you are turning too hard. These signals form the feedback that stimulate you to change what you're doing (quickly shift your weight to the other leg) so you can get your self back on course.)
- Systems stability is maintained by making adjustments based on feedback received. (The average body temperature is generally around 37 degrees Celsius. If you get too hot, your body produces sweat to cool you down.

Systems Thinking is analogous to having a new set of eyes with which to look at your world to interpret outcomes and predict behaviours. By applying Systems Thinking you are able to distinguish between events, patterns and systems to identify the most appropriate action to take to manage a specific outcome or behaviour. For example suppose you suffer a bearing failure that causes an uncontrolled plant stoppage (a breakdown). This is an event. If you simply replace the bearing and get the plant running again you are reacting. (Nothing has been done to prevent the breakdown recurring.) If you decide to repair the equipment and study the failed bearing you might notice that the bearings in this equipment seem to fail more than in other equipment; you would be recognising a pattern.

If you decide to inspect the bearing more often you are adapting. (Nothing has been done yet to prevent the breakdown recurrence.) If you consider the systems that influence the pattern of bearing failures (e.g., operating practice, vibration levels and the lubricant used) you can decide to conduct vibration monitoring and establishing standards for lubricants and operating practices to introduce (behavioural) change. This is positive action to prevent breakdown recurrence.

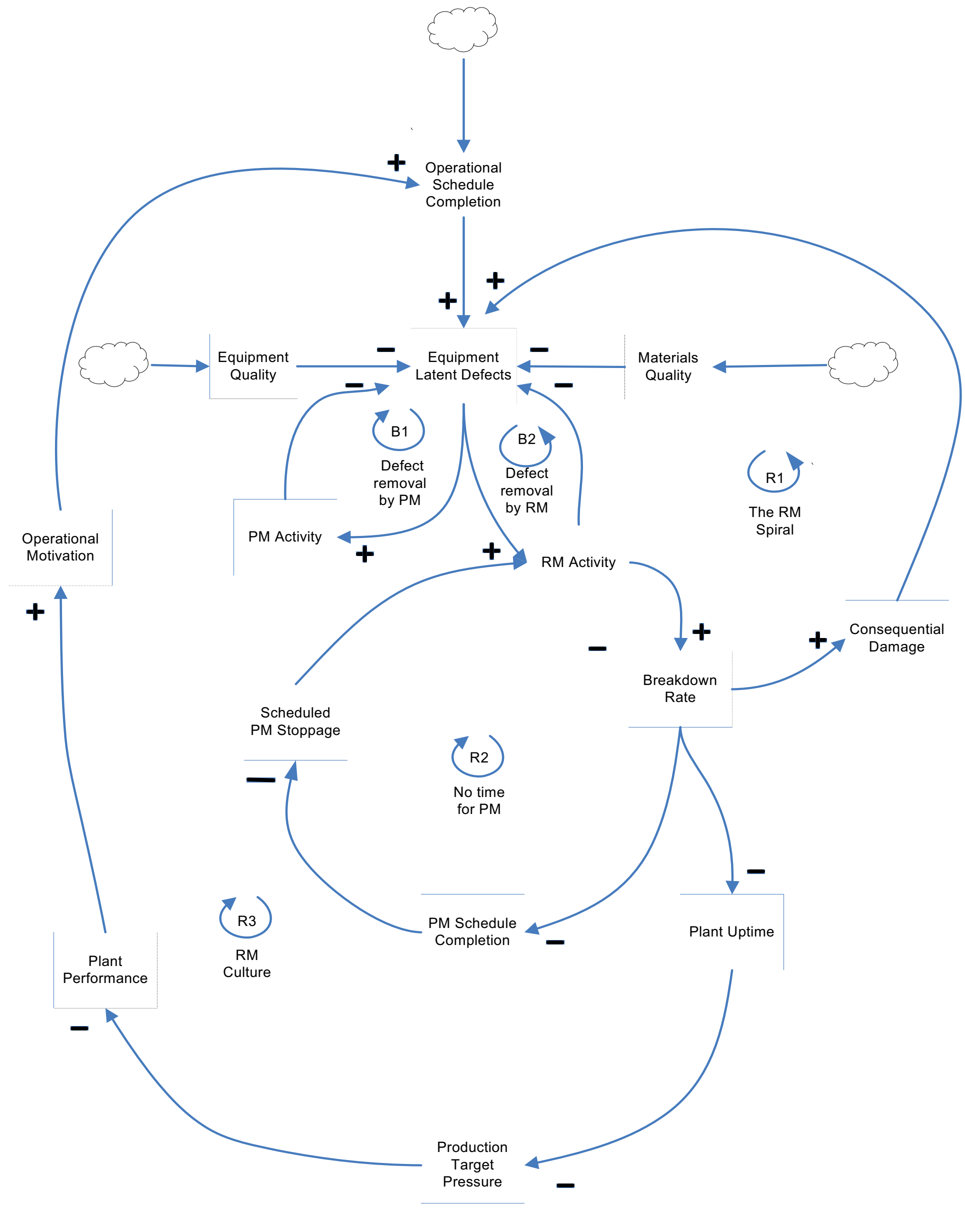

Figure 1 Causal Loop diagram for Defect Removal by RM

Systems Thinking uses casual loop diagrams, like that shown in Figure 1, to graphically depict the range of relationships that exist between variables that form the system under consideration and to develop an understanding of consequential system behaviours. It applies a nomenclature of stocks (variables that change over time) and flows (arrows that indicate how information flows between variables to affect each other) to describe the connections between the various feedback loops within a system and specific terminology to describe system behaviours. This includes the use of cloud symbols to indicate system boundaries.

There are two types of processes used to construct causal loop diagrams like that shown in Figure 1. Reinforcing processes, denoted by an "R", where feedback flows generate exponential growth or collapse and balancing processes, denoted by a "B", where feedback flows help a system maintain stability. Each type of process may include some form of delay, between a cause and an effect, as a regulator of systemic behaviour. The significance of delay is highlighted by considering the possible implications when a specific cause takes a long time to exert its effect, or when cause and effect are geographically separated..

There are many practical examples of reinforcing and balancing cycles all around and within us. The global manufacturing impact of China's industrialisation, the foreign currency trading that lead to massive corporate losses by NAB in 2004, and the potential for a pandemic when gene mutations in Avian flue resulted in the H5N1 virus are all examples of reinforcing cycles. The ability of the human body to maintain a temperature of 37 degrees Celsius, the stability that occurs in natural ecosystems, and the challenges faced by an organisation when trying to make an improvement by changing the way people work are all examples of balancing processes.

4 SYSTEMS THINKING AND DEFECT REMOVAL

A representation of the reinforcing and balancing loops found in the processes used to remove latent defects present in equipment is shown in Figure 1. The cloud symbols used in the diagram indicate that the defect removal system is part of a larger system that includes defect elimination. By way of example, consider what can happen if planned maintenance (PM) activity is reduced in an effort to cut costs and increase plant availability by reducing scheduled downtime:

- the level (stock) of equipment latent defects is primarily added to by operational activity (and potentially reduced by the quality of equipment and materials used)
- defects are removed according to the volume of either planned (PM) or reactive (RM) activity
- reduced PM activity means latent defects will accumulate to the point where equipment reliability (and plant performance) begins to decline without this being obvious (because of the delay between cause and effect) until frequency of breakdown events begins to increase which will increase consequential damage and initiate the RM spiral (R1)
- an increasing breakdown rate compounds the fact that scheduled PM work can not be completed because there is no time for PM, so PM backlog grows as schedule completion falls (R2)
- as plant uptime decreases, production pressure increases and plant performance decreases (operational and safety performance drops off and absenteeism climbs); there will be some delay but eventually people stop reporting identified defects and or providing the level of detail required to effectively plan defect removal work (operations and maintenance people become frustrated and loose motivation). This leads to lower effective completion of scheduled operating activity that results in increased introduction of latent defects. Since in this environment defects are mainly removed by RM activity, maintenance personnel are rewarded for efficient breakdown recovery in an increasing effort to achieve operational output targets (reinforcing a reactive pattern of behaviour: R3 – RM Culture)

If you don't notice this level of feedback for an extended period of time, you most certainly will not realise that the drop in plant performance, equipment reliability and performance of personnel are connected to the reduced plant downtime and cost reductions you introduced "ages ago." (It is quite possible that you might even panic about declining equipment reliability and plant performance and introduce more rigorous PM activity (which will not be able to be completed) to try to correct equipment reliability and improve operational performance!)

This example also shows how systems structure directly influences organisational behaviour. That is, system structure generates recurrent "signature" patterns of behaviours inherent within it. These recurrent patterns of behaviour within the organisation are those balancing processes that become entrenched and difficult to change.

The B2 balancing loop of "Defect removal by RM" is sustained by the R1 reinforcing loop of "The RM Spiral" and the R2 loop of "No time for PM" that further entrenches RM behaviour B2. These recurrent behaviours are represented as System Archetypes within the discipline of Systems Thinking.

If placed in this same reactive "system", regardless of their individuality, all people will tend to produce the same results because a system tends to cause its own behaviour. People within this defect removal system will all behave in a reactive manner because "that is the way we always work here", becomes the generally accepted norm. By recognising these patterns and acting to change behaviour by increasing the downtime rate and subsequently increase PM activity it is possible to shift the defect removal system back into stability that satisfies the maintenance purpose.

Most industrial or manufacturing operations will be using some form of a MWMS and be in either a reactive or planned operational domain. Most will attempt to improve plant performance; move from the reactive domain into the planned domain by introduction of the latest method or technology. This is good but it does nothing to achieve improved plant performance by defect elimination. The prime outcomes delivered from a focus on the planned domain are effectiveness and efficiency of defect removal activity. It does not address organisational and technical system dynamics essential for defect elimination. Eventually, performance will drop below the required plant performance baseline and some intervention will be needed again.

Ledet and Monus [4] give an example of why a focus on what they call "the planned domain" can produce good results but is not sufficient for realising sustainable and optimal plant performance. They explain how Dupont realised a 20% reduction in total annual maintenance cost, which gave a maintenance cost ratio of 2.2%, over a 10 year period across 50 operating plants. After 10 years performance began to deteriorate and 15 years later (the delay between cause and effect) the improvement gains had disappeared and they had to start again. By contrast, a comparison operation realised around an 80% reduction in repair activity and cost as well as improved reliability, production output, and safety performance. This performance was able to be sustained through numerous changes in ownership because the comparison operation "created" more time for their workforce to be proactive and focus on improvement (defect elimination) activity.

5 SYSTEMS THINKING AND DEFECT ELIMINATION

There are two types of systems; natural living systems and created nonliving systems. In a plant operation context these are the organisation's culture (people and attitudes; elements of the natural behavioural systems) and technical (plant and practices; elements of the created equipment and management systems). According to Senge [5], all growth (improvement) is the result of the interplay between growth (reinforcing) processes and limiting (balancing) processes that define a system. Realising optimal plant performance requires understanding of the reinforcing processes and what is needed to activate them, and addressing the balances that keep optimal performance from occurring within an organisation's behavioural and practice systems.

There are two types of leadership; Leadership of Operations and Leadership of Change. In a plant operation context these are the management of defect removal and the management of defect elimination. The former involves establishing and maintaining steady state plant performance using a MWMS. The latter involves development and introduction of change to realise plant performance improvement. Leadership requires guidance of team activity. Making sure that people know what to do and what is expected of them. It makes sense that leadership of change, guidance of teams to identify and implement improvements, requires an improvement management system.

It is a common error for an operation to try to improve plant performance by identifying best practice and then implementing a corporate improvement program. In most cases this does not work because this approach takes no account of the systems archetypes that exist. The problem is that nothing is done to address system archetypes, introduce behavioural change, and ensure the change process is completed. This happens because the effort essential for establishing an effective improvement management system (defect elimination capability) is not appropriately acknowledged and the effect of "systems delay" means that resultant adverse consequences are not appropriately recognised for some time, if at all. Building an improvement management system takes time; usually longer than the typical management position tenure.

Another trap organisations often fall in to is thinking that defect elimination is solely about analysis of plant data or application of panacea techniques such as Six Sigma, Lean, RCM, FMECA, or RCA. It is not. There is definitely a place for this type of activity but it must be considered in the greater context (system) of the operation. Providing consideration for the activities your entire operation performs and the time factors associated with those activities across both the production and maintenance functions. By doing this and applying Systems Thinking concepts an industrial operation will derive the key capability for realising optimal plant performance. Using Systems Thinking to establishing a system for managing improvement (defect elimination) Maintenance and Reliability Managers can ensure improvement initiatives focus on the result they are trying to produce and build a key capability necessary to sustain optimal performance.

6 AN IMPROVEMENT MANAGEMENT SYSTEMS MODEL

Having the capability to effectively conceive, prioritise, deliver and manage a plethora of competing improvement initiatives requires a system for managing improvement to realising optimal plant performance. A system founded on Systems Thinking concepts that make use of both technical (tools and techniques) and learning (new knowledge and attitude) inputs to derive desired plant performance outcomes. The improvement management system (IMS) model shown in Figure 2 is an example of such a system.

The IMS model contains three coordinated and linked levels of "leadership teams" to deliver effective plant performance improvement and realise the operational goals of the business. The lead and steering teams link to ensure all improvement activity is aligned and prioritised according to prevailing business operational requirements and to formulate business policy to ensure consistency and capability of delivery. The steering and project teams link to provide leadership of change and ensure effective resource application minimising chaos within existing processes or operational activity. All levels of people within the IMS are aligned to ensure shared understanding of the improvement management system purpose for realising optimal plant performance.

The IMS model provides a framework whereby the leadership teams share common corporate strategic goals and focus on such strategic objectives as cultural alignment, change management, and resource optimisation. Improvement projects are conceived, substantiated, justified, and prioritised according to an optimisation policy, in preparation for subsequent implementation. The IMS model promotes the use of facts and data to identify and eliminate chronic problems. It facilitates cross functional participation and shared responsibility between maintenance and operations for improvement projects to ensure collaborative learning takes place. This eliminates the risk of competition for priority with day to day functional work, and ensures available resources both across and within functions is effectively deployed. Application of the IMS model ensures a "systems" perspective to minimise risk of improving one aspect of plant performance to the detriment of the whole.

The IMS model describes the stocks and flows of information associated with improvement management. The feedback loops implicit in the model exist by virtue of routine performance monitoring. Performance monitoring of the IMS outcomes (operational performance), the IMS itself as well as measuring the achievement of project outcomes. Business goals are applied to set IMS goals and the system is managed to best achieve steady state performance towards achieving these goals. Improvement projects may be established by either strategic or operational improvement request. However, under steady state business and operational conditions the majority of improvement activity is the result of considering actual plant performance against required standards of performance using "history maps" and deviations are investigated using an RCA methodology.

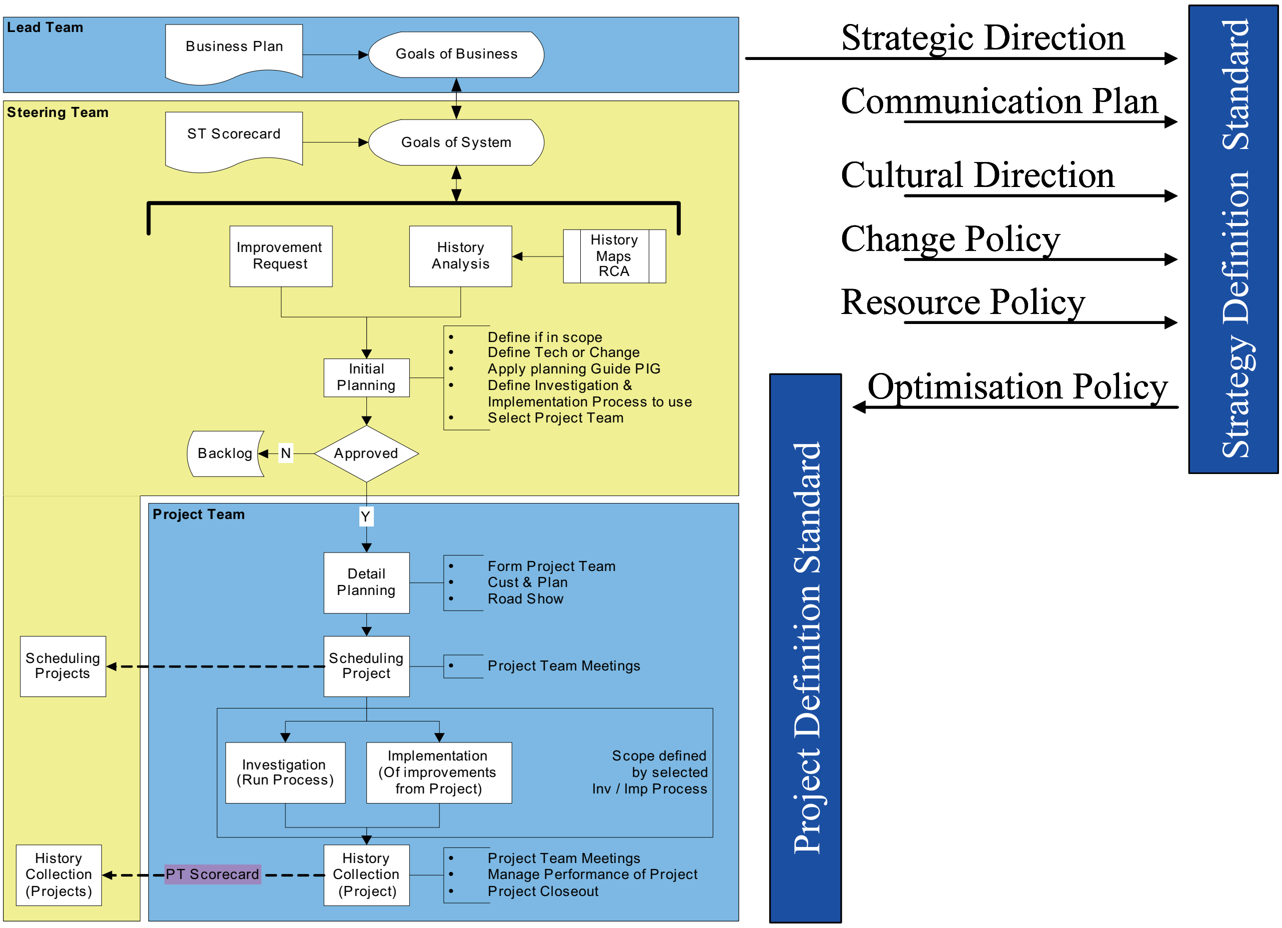

Figure 2 Improvement Management System Model

The IMS model incorporates planning processes to develop understanding of readiness for change and what things must be addressed to ensure performance does not regress. This is done by applying specific actions to:

1. Articulate the business need that will be addressed by making a change.
2. Empower the workforce to change the way work is done.
3. Deal with issues of authority and motivation.

These are addressed in the IMS model through appropriate, meaningful and planned communications, project score cards, investigation and implementation methodologies and selection and assembly of project teams to ensure optimum participation. Planning processes should include consideration of what people across the operation will need to learn to address both behavioural and technical system dynamics. This is made possible by use of a planning guide to define the “problem system” and help people logically identify their assumptions about structure, behaviour, and expected outcomes as part of an improvement initiative.

Additionally, planning considers the three prime dimensions that an operation must consider when determining how to optimise performance; time, quality, and cost. In doing so it provides guidance to select the method best suited to the business need and impact on profitability. Planning within the IMS model incorporates the approach espoused by Nave [6] to select between the high level techniques for improvement such as RCM, Six Sigma, Lean Manufacturing, and Theory of Constraints. All these techniques target improved business performance but each focus on different plant performance dimensions. Selection of the most appropriate technique is a critical step.

Project close out includes activity to ensure the change process is completed and can be locked in to routine practice using performance management to sustain the improvement.

7 CONCLUSION

Making improvement to deliver sustainable and optimal plant performance requires a fundamental shift in thinking. Firstly we need to recognise that there are separate and interlinking management systems required to manage both maintenance (defect removal) and improvement (defect elimination) and that improvement requires change to existing behaviours and practices and is ultimately about cultural change (change the way we do things).

Introducing an improvement management system will ensure best return on both operational and capital improvement resources and achieve sustained optimal plant performance. It will provide a stable and repeatable learning and knowledge management capability. This will provide mutual benefits to both Maintenance and Production managers' of less stress, more time to think, capability to jointly respond with considered haste to changes in operating demands, and high probability of consistently achieving plant safety, environmental, cost and output targets.

Secondly we need to understand the nature of growth processes (forces that aid our efforts) and how to activate them by adopting a systems thinking approach. The application of Systems Thinking will allow the cause and effect relationships within "problem systems" and the timing of subsequent system behaviour to be understood and provide a capability for optimising plant performance that is more than just problem solving. Systems Thinking is a fundamental capability for Maintenance and Reliability Managers to equip them to deal with both the tangibles and intangibles of plant performance. People start seeing and dealing with interdependencies and deeper causes of problems only as they develop the skills of Systems Thinking.

It is naïve and overly simplistic to assume that a change in one part of an operation will not impact in some way on another part. You are never acting alone; you are always part of a bigger system. Finding a solution to 'your' plant reliability or performance problem can affect the entire operation. Establishing an improvement management system developed from a solid basis in Systems Thinking will result in a profound change in the relationships and behaviour of individuals within the operation. Maintenance and production people will be happier, more motivated, and more committed because they will understand how to effectively collaborate to achieve a common goal of optimal plant performance. A goal that includes equal consideration of time, cost, safety (environmental and human) and quality as the key business drivers of operational performance.

Like Solomon said: nothing under the sun is new. The prime concepts and principles assembled in the IMS model, largely based on the published work of Peter Senge, have origins in the early 1930's. It is a matter of combining engineering and management discipline with behavioural science and that is how the IMS model has been developed from its origins in 1995. More than ten years later the IMS concept is still relatively undiscovered. The fact is managers usually prefer to follow rather than lead; it is less risky. Those Maintenance and Reliability managers that choose to be pioneering leaders and establish a capability for realising sustainable and optimal plant performance will provide a valuable solution in the globally competitive market.

A MODEL TO DIAGNOSE THE DEVIATION IN THE MAINTENANCE PERFORMANCE MEASURES

Basim Al-Najjar

Department of Terotechnology, School of Technology and Design
Basim.Al-Najjar@vxu.se

Abstract: In order to achieve the strategic goals, the company should utilise an efficient data gathering and analysis system for mapping the technical and economic situation, following up the development and detecting technical and economic deviations at an early stage to plan and perform necessary maintenance actions on time. In many cases, measuring and following up the development of relevant and well selected technical and economic performance measures can be more applicable for mapping the situation and making cost-effective decisions compared with monitoring big mount of data. But, in many cases it demands a reliable technique for interpretation of the behaviour of these performance measures especially if they are not linearly interrelated and if some of them reflect a combination of technical and financial impact. The problem addressed in this paper is; how is it possible to enhance the ability of detecting significant deviations in the maintenance performance measures at an early stage and tracing their root causes by using data- and knowledge base and inference engine? The major result achieved in this paper is a model developed for interpreting the changes in the maintenance performance measures and tracing their basic causes, which is verified in an example with typical data. The model consists of five modules; what performance measures to chose, how and why an eventual deviation on the performance measures occur, what to do to eliminate and prevent their reoccurrence and mapping of the current situation technically and financially. The main conclusion is that applying the model would enhance the ability of detecting changes in the maintenance performance through identifying the causes for elimination. In Al-Najjar et al (2004), a model for how to identify the measurable variables, which are needed to develop measures for monitoring maintenance performance behaviour systematically, is introduced and discussed. Also, five maintenance performance measures are proposed and applied. Furthermore, an additional model manual analysis of the trend of maintenance performance measures, for an overall assessment of the company's situation, is presented. In this paper, the idea of manual analysis presented in Al-Najjar et al (2004) is systemised.

Key Words: Maintenance performance measures, knowledge base, inference engine, performance measure interpretation

1 INTRODUCTION

In many cases, it is important to apply relevant indicators for monitoring and following up the development of the performance of maintenance and production processes. These indicators can be simple, such as the number of items produced and number of failures, or complex, such as the cost of producing one high quality item and maintenance cost paid for every produced high quality product.

Many authors such as Kennerley and Neely (2003), Al-Najjar et al (2004), highlight the importance of properly identified the performance measures required for following up the work done to achieve company's strategic objectives and survive daily competition. According to Kaplan and Norton (2004), 70 to 90 percent of the companies fail to realize success from their strategies due to lack of relevant data. For companies to be successful and able to accomplish their strategies, it is necessary to implement and control their performance measures in all working levels, such as strategic, operative and tactical daily work, Waeyenberg and Pintelon (2002), Kaplan and Norton (2004) and Al-Najjar et al (2004). Nonaka (1991) argues that it is not just the connection between performance measures and strategy that is important, but also the knowledge required for the organization to achieve their strategic goals. Since this is important there is a need to consistently develop new experience and knowledge in different forma, such as new tools, methods and technologies.

Turban and Aronson (1997), Pintelon and Van Puyvdelde (1997) and Sherwin (2000) argue for the need of investments to secure successful implementation of performance measures and strategies. In general, the major objectives of applying information systems are to gather, analysis and present information and knowledge. Integration of the performance measures with a knowledgebase and an inference engine can provide the manager the required information, knowledge and ability to monitor and interpret the performance measures for making cost effective decisions.

The problem addressed in this paper is; how is it possible to enhance the ability of detecting significant deviations in the maintenance performance measures at an early stage and tracing their root causes by using knowledge base and inference engine? The aim of this paper is to develop a model describing the possibility of using a data- and knowledge-base and inference engine for real-time diagnosis of the behaviour of the performance measures and effectively detecting technical and economic deviations from predetermined values at an early stage. In Section 2, interpretation of maintenance performance measures is discussed. A model describes the utilisation of the data- and knowledgebase together with inference engine for detecting, analysis performance measure deviations and tracing the reasons behind that is developed in Section 3. The model is applied in an illustrative example in Section 4, which is followed by conclusions.

2 INTERPRETATION OF MAINTENANCE PERFORMANCE MEASURES

In this paper the maintenance performance measure is defined as the indicator that provides the information required for mapping and judging the performance level of maintenance technically, financially or combined. Identifying the relevant data required for accurate monitoring of maintenance performance is discussed in Kans (2005) and Al-Najjar et al (2004). Applying few well-selected performance measures for monitoring maintenance makes the procedure of judging its performance and consequently decision-making process much easier compared with the case when using a big amount of data for the same purposes. But, in the same time it demands better techniques to interpret the behaviour of the performance measures and achieve accurate diagnosis of the root causes, Al-Najjar et al (2004). We assume that the measures required for monitoring the performance of maintenance are already selected or developed by applying special techniques, such as top-down analysis method suggested by Al-Najjar et al (2004), Al-Najjar and Kans (2005) and Kans (2005).

Using just one performance measure for detecting changes in any process, such as the case when controlling the quality of a product using specific dimension to judge whether it is accepted or rejected is easy to interpret. But, when the maintenance or production cost is monitored, the increase in any of these two measures may mean many things, such as real increase in the direct maintenance cost, raw material, energy or operating cost.

The increase in the maintenance cost may be beneficial. For example, a chef manager would welcome the increase in maintenance cost if its share in the cost of producing one-item of high quality is reduced, i.e. the number of high quality items has been increased due to more cost-effective maintenance. The same confusion can happen when the production cost increases. This increment is not necessary an undesirable result especially if it is due to the increase in the production time and/or speed and not because of higher maintenance cost per producing one item or due to production losses. The situation will be much more complicated if there exist many performance measures that should be considered for mapping, analysis and evaluation of the production and maintenance processes to make cost-effective decisions.

We can easily trace the root causes lying behind changes in the technical or financial performance measures, such as machine failures and availability, and maintenance cost and production costs, respectively. But, it will not be equally easy to race the root causes when monitoring combined measures mixes technical and financial terms such as direct maintenance cost divided by overall equipment effectiveness, or direct maintenance cost divided by the number of quality items (or tons produced). This is because the increment or reduction in the performance measure value may mean different based on how the measure is developed, i.e. how the information provided by the measure is aggregated. Therefore, interpretation of the changes in the values of the performance measures and tracing the root causes behind them can be a big task, which is not easy to perform manually for achieving cost-effective decisions. This is why systemising this analysis and diagnosing process is important for carrying out a real-time interpretation effectively.

In general, the main objectives of applying relevant performance measures is to detect deviations in the cost and condition of the production and maintenance processes for taking the actions required at an early stage with less labour and cost. Also, the analysis and diagnosis of the deviations in the performance measures will lead to better results if it is associated with identifying the root-causes lie behind changes. Further, recommending what to do for treating the deviations would help avoiding their re-occurrence.

In Al-Najjar et al (2004), a model for identify the variables that are required to develop measures for monitoring maintenance performance behaviour systematically, is introduced and discussed. Also, five maintenance performance measures are proposed and applied. Furthermore, a model for manual analysis of the trend of maintenance performance measures, for an overall assessment of the company's situation, is presented. In this paper, the idea of manual analysis presented in Al-Najjar et al (2004) is systemised.

3 MODEL DEVELOPMENT

In this section, we consider that the model is necessary to detect significant deviations in the maintenance performance when several measures are used for monitoring maintenance and production processes. In order to achieve reliable mapping, analysis and evaluation of the maintenance performance, and to recommend what to do when significant deviations are detected, the model is constructed to perform the following five tasks, i.e. to

1. Identify what to focus on out of all the performance measures being monitored, i.e. performance measures that undergoing significant changes. This step is necessary because, in many cases, there are many monitoring variable

(measures) to be considered. Therefore, identifying where to start the investigation and why it is usually not an easy task

2. Analyse the deviations to answer how it is happened, i.e. describing the mechanisms of the initiation and development of the changes
3. Identify the root causes behind these changes, which is required for the prevention of reoccurrence of the same problems
4. Recommend what to do at an early stage to restore the process to as good as new (or as good as before), and finally
5. Assess the measures that are relevant for mapping and evaluating maintenance performance

These five phases of the model performance are carried out by equivalent number of modules. The first module is called “What to analyse”, which is responsible of, see also Fig. 1;

1. Arranging a list consists of the values of all the performance measures (x_1,..., x_n) that have been selected for performance monitoring
2. Establishing a list of the reference levels (y_1,.., y_n) for every performance measure introduced in 1 above. These reference levels are important for distinguishing the changes in the values of the performance measures and its severity. The number of the reference levels for each performance measure can be considered three; one at the normal level and one at the action level, i.e. an action should be done as soon as the measure value exceeds that level. The third level (warning level) can be positioned in between these two levels (normal and action levels) for indicating if the measure is undergoing a real change (but still acceptable) and not due to temporarily disturbances, Al-Najjar (1997)
3. The trends of these changes, i.e. changes in time of every performance measure, ease following up their developments. Association of these trends with the reference levels, such as normal, still acceptable/warning and action levels would provide the possibility of detecting significant deviations at an early stage.
4. The inference engine completes the work by reading whether any of these changes exceed the warning level and produce a prioritising list to prioritise the investigations

The second module, which is called How is responsible of investigating the root causes behind the deviations in the performance measures. To complete the work done in the What module, the investigation of the performance measures topping the prioritising list, i.e. those which undergoing significant changes, should be analysed by the inference engine in the How module. Previous technical experience, knowledge and analysis results of the possible reasons and the problem developing mechanisms that may cause deviations in the performance measures can be utilised when building the inference engine for identifying where and how to investigate. The reasons behind the changes in the prioritised measures can be several. Therefore, the inference engine investigates all these possible reasons individually and in combination with other reasons to detect possible interactions, see Fig. 1.

The third module (Why) is responsible of summarise the work done by How module by identifying the most probable reasons behind the deviations in the prioritised performance measures. The output of the Why module eases the task of recommending what to do, i.e. to suggest either to just handle the current situation, or to eliminate the roots causes or both, which is the task of the fourth module. The fifth module is responsible of mapping maintenance and production processes technically and financially, which is necessary for evaluating the maintenance performance.

The data- and knowledgebase that are involved in this model ought to include all the relevant data required by the inference engine to perform this task. It includes the knowledge and the previous experience concerning detecting, analysis and the results of handling previous problems. The data- and knowledgebase is necessary for improving the model continuously and cost-effectively. The model provides a possibility to assess not just technical or financial performance measures but also combined measures such as those expressed in the module performance measures assessment, i.e. the fifth module

4 APPLYING EXAMPLE

In this section, the model is described by an example treating one measure for monitoring the performance of maintenance through using the direct maintenance cost (DMC) divided by the high quality production (HQP) measured in tons or items, which is denoted by DMC/HQP. The performance measure DMC/HQP reflects the maintenance contribution in the production of each item or ton assuming that the quality control system is working properly. In other words, it means how much the company pays for maintaining the production system per each item or ton. Also, it describes the reliability of the production process.

When the list of the performance measures and trends of their behaviour are described, the inference engine will be able to prioritise the measures of the most critical values, i.e. the measures whose values exceeded a predetermined level. Let, for instance, one of these levels being the warning level. Assume that DMC/HQP exceeded the warning level. In general, the levels of the performance measures can be decided based on the company's policy.

When a measure exceeds a warning level it is always better to investigate the root causes and the developing mechanisms behind this significant change. Also, it is necessary to investigate interactions of these causes, if it possible, for identifying and cost-effectively eliminating them for restoring the process to its previous condition.

In this example, we considered the following factors are the most probable causes behind the increment of DMC/HQP, see also Fig.2:

1. Less accepted production; lower production quality due to inefficient or lack of maintenance.
2. Higher production rate; high production speed leads to faster deterioration in the machine condition, more stoppages, longer stoppage time and consequently more direct maintenance cost
3. Longer production time; it means also faster deterioration and shorter life length of the machinery, and consequently more direct maintenance cost
4. Quality of maintenance actions; it influences the maintenance impact on the machines and production process. The bad maintenance quality results in more frequent stoppages, less production and higher direct maintenance cost

In order to identify the basic causes behind maintenance performance deviation, the inference engine would analyse technical and financial past data of the machine and process. Identifying the interactions between the root causes those mentioned above are important to clarify the situation better. When the root causes are identified, the recommendation for what to do in order to eliminate the problem and prevent its reoccurrence is the next step to be accomplished by the inference engine.

Reporting what happened together with the assessment of the measures of the maintenance performance eases for decision maker to achieve a cost-effective maintenance action.

5 CONCLUSIONS

Monitoring and following up the development in production and maintenance processes automatically through applying special performance measures demands using special rules to implement a data- and knowledgebase and inference engine to accomplish a cost effective maintenance decision. Applying the model developed in Section 3 offers opportunity to diagnose and interpret the behaviour of the performance measures monitored. In general, the performance measures can be many in complex production processes. Using this model, detecting significant deviations in the performance measures can be done effectively does matter how many they are. Identification of the root causes behind these deviations enables the user to take the cost-effective actions required at an early stage.

It was obvious from the applied example how important are the past data from the working areas related to the performance measure in question. The applied example shows the possibility of monitoring even more complicated performance measures such as direct maintenance cost/high quality production, i.e. combined technical and financial measures, if the required data are available.

The knowledge available that can be utilised for identifying and analysis production and maintenance problems is enormous. This knowledge is not easy to utilise effectively without better data quality and coverage from the working areas relevant to the problems under consideration. A knowledge and data based analysis system using the technology of data- and knowledgebase and inference engine opens for the companies a possibility of applying real-time cost-effective maintenance decisions. At the same time it demands that the company should store specific data and knowledge required for applying and enhancing the model involved. This leads to decisions of less uncertainty, which in turn leads to lower level of risk and cost diminishing. Further, this also leads to more effective and efficient use of the companies' resources for both short and long term towards higher profitability and better competitiveness.

A SOCIO-TECHNICAL PERSPECTIVE ON INTEGRATED OPERATIONS FOR HIGH-RISK AND COMPLEX INDUSTRIAL ASSETS: EXPERIENCE FROM NORTH SEA OIL & GAS INDUSTRY

Jayantha P. Liyanage

Center for Maintenance and Asset Management, University of Stavanger, N.4036, Stavanger, Norway.

Abstract: During 2003 it became very obvious that oil and gas (O&G) exploration and production activities on North Sea was at a crossroad. Norwegian O&G industry during 2003-2004 made a strategic decision to step into a major re-engineering process of offshore activities. Subsequently the concept of 'Integrated eOperations' was born and is currently under a rapid implementation path. So far, the developments have mainly been high-tech driven, but it is widely acknowledged today that human and organizational aspects are the greatest challenges and hence some prudent and long-term measures are necessary to address them strategically. It implies that a more holistic socio-technical approaches are necessary to develop and implement high-performing systems given the level of complexity and the nature of change. This paper brings a brief overview of current developments on the Norwegian continental shelf, and outlines some of the critical aspects from a socio-technical perspective that are central for further advancement towards full-scale offshore-onshore integration by 2010.

Key Words: Smart assets, Asset management, Integrated eOperations, Socio-technical systems, eMaintenance, Asset performance, High-tech applications, Networking, Collaboration, Human and Organizational factors.

1 INTRODUCTION

This is an era when the global oil & gas (O&G) exploration and production activities are constantly challenged by various socio-political and techno-economical sources. Even though the supply-demand gap continuously extends owing to increased energy utilization trends, the harsh history of volatile economy particularly due to drastic reduction in oil price has substantially challenged major producers to draw more prudent operational strategies to enhance profitability and growth. Apart from security of economy, social and environmental uprise have induced various other challenges compelling major producers to re-calculate their risk and to manage uncertainties under complex operating conditions [1].

The current situation on North Sea activities is far more challenging and has already indicated the immediate need for a reengineering process. Various issues have been taken up for discussion over the last few years, ranging from taxation policies to new methods to improve recovery factor to implement feasible and effective solutions to overcome a range of unavoidable circumstances. The worries have been continuous since the uncertainties about the future have become more visible with direct impact on the risk exposure and the value creation. Among the major concerns there have been at least two issues in particular which has indicated that it is the time to 'get back to the drawing board' to engineer a completely new scenario for the entire Norwegian Shelf. These two issues are;

- Declining production
- Rising lifting costs

They have triggered a re-engineering process across the entire Norwegian Oil & Gas (O&G) industry, and subsequently O&G production and exploration activities on the Norwegian Continental Shelf (NCS) are at a major turning point today.

2 MAJOR DEVELOPMENTS ON 'NCS'

As the thorough analysis of the situation convinced the executive boards and the senior policy makers that 'value potential' on NCS is extremely high but the risk exposure of conventional practice is substantial, they began to look into how emerging complexities, uncertainties, and risks can be reasonably managed through smart solutions. Subsequently, the *Norwegian continental shelf (NCS)* made a strategic decision to step into a new integrated asset management scenario termed *Integrated eOperations*. The long-term plan has been on more strategic capitalization of digital technologies and more prudent use of operational networks and collaborative partnerships to establish a completely new operational setting (see Figure 1). For more information see [2], [3], [4], [5], [6], [7].

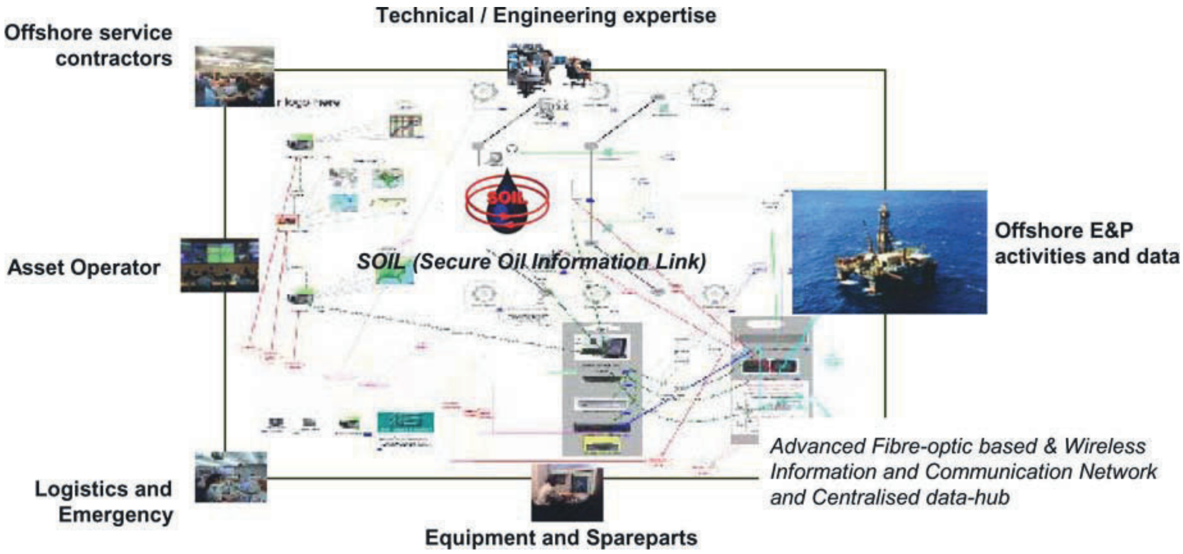

Figure 1. New asset management environment in North Sea.

This new practice has already begun to redefine and re-engineer the conventional setting by establishing online and real-time connectivity and interactivity between offshore production plants and onshore support environments. The traditional support system has been extended to establish more strategic collaborative partnerships with the supply chain and expert services using large-scale IT platforms. In principal, this looks into systematic offshore-onshore integration through application of advanced ICT technologies, and thus building high reliable information and knowledge based networks to remotely manage complex, high-risk, and capital intensive offshore assets, regardless of the geographical location. Ideally the new environment is expected to re-engineer the traditional infrastructure based on new forms of partnerships and cooperation, shared responsibilities and roles, integration of competencies, 24/7 connectivity, real-time accessibility to knowledge and information, and active communication networks. Current developments mainly target building up dedicated and reliable network of discipline experts and organizations, who are actively involved in dynamic sharing of information and knowledge and online real-time communication for fast yet effective decisions and actions based on 24/7 online real-time data exchange solutions (see Figure 2).

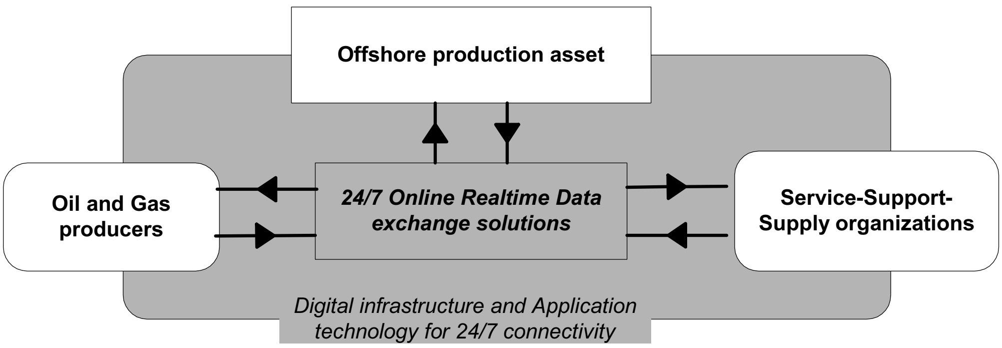

Figure 2. Interactive and connected environment for offshore asset management through smart technical solutions.

The new set up is expected to bring substantial commercial benefits in terms of;

- more commercially attractive offshore oil production,
- improving recovery or production regularity,
- more positive health, safety and environmental results, and
- improving economical performance, particularly by reducing operating costs

3 THE EMERGING SOCIO-TECHNICAL ENVIRONMENT

The major implication of new developments on NCS is that it will introduce a completely new socio-technical setting within the Norwegian O&G industry. Following the much earlier work done by Trist & Bamforth [8] and the Tavistock Institute, Socio-technical systems model in general views organizations as transformative agencies (see for instance [9]). The change dynamics of such agencies rests by far on the relational dynamics between personal, technical, and environmental (internal as well as external) sub systems. It portrays that humans and technologies in conjunction with a particular work system setting, that comprises certain organizational structures, routines, procedures, and work processes, involves in a continuous exchange process with the external environment on which the survival and success depends. Under the current circumstances on the NCS, and certainly in respect of the value creation potential, the conventional socio-technical boundaries are largely challenged and subsequently are subjected to expansion. It implies that the dynamic change largely occurs in such a way that more formal system settings, which have been largely centralised within specific organizational boundaries, are expanded on a networked and a collaborative basis to create an extended operational enterprise based setting. Connections between various actors of the new system is purely high-tech enabled and data & knowledge dependent. The transition towards new socio-technical setting is not going to be a smooth process, particularly owing to;

- complexity
- scale of change
- nature of exchange between different actors

The enhancing complexity is a direct a consequence of advanced application technologies and expanding organizational boundaries that substantially complement developments within techno-organizational space. Such complexity has direct internal organizational and external socio-political ramifications. At the very organizational level, the tendency to induce significant changes particularly within human and work-process related aspects has already become an obvious issue. At the more macro scale, this has also become an issue of national interest owing to safety and security concerns that emerge as a consequence of advanced open data management solutions and web-based collaboration.

The term ‘change’ is at the heart of almost every aspect related to the new development scenario. Changes can occur at various scales ranging from necessary adjustments towards establishing new competence profiles to major ones such as common data exchange platforms between actors based on XML, WITSML languages, O&G ontologies, semantic web, etc. It implies that initiatives and programs for smart change management is extremely critical to avoid negative consequences and serious losses, which may be too costly for the entire Norwegian O&G industry.

The conventional practice of exchange between different actors is largely being challenged, and the timely need for completely new forms of collaborative models has constantly been underlined by major stakeholders. It implies that the nature of exchange between different actors currently undergoes necessary major revisions to optimise collaboration between offshore assets, asset owners, and third party stakeholders that includes engineering, supply, knowledge-based, industry. New collaborations are mainly technology-enabled and web-based, and has brought an array of important aspects such as open data exchange platforms, performance incentives, risk and gain sharing models, organizational trust, etc. for ongoing debates and discussions. It has become very obvious so far that apart from very conventional commercially driven collaboration, the influence from non-commercial collaboration is too high to ignore. Such non-conventional yet critical collaborative models have to be established particularly with trade unions, trade organizations, authorities, and universities and higher educational institutes.

The new socio-technical environment will not be established within a year or two, but the current target is to realize full-scale operations by 2010. The transition will occur through 2 principal stages termed ‘G-1’ and ‘G-2’;

- G-1: Systematic integration between different disciplines. More cross-disciplinary coordination of planning and work execution. ICT applications remain more within defined organizational limits with localised technologies such as VisiWear.
- G-2: Systematic integration between different organizations. More cross-organizational coordination of planning and work execution. ICT applications are more expanded beyond organizational boundaries with more standardised web-based solutions.

As much as there are dedicated ambitions at whatever level, major actors need clear visions, prudent strategies, and smart operational plans to realize their objectives. At the current pace of development, three specific conditions are notable and certainly the entire industry needs more cautiously designed plans for further advancement with necessary checks and balances to ensure that all critical interfaces are well considered and analysed prior to implementation of solutions. Those conditions are;

- ambitions are set at very high levels
- time-scale to realize objectives is substantially reduced, and
- programs are accelerated within organizations to be champions of the new development

While development of technology and its successful implementation are challenges themselves, a major need is also to resolve those critical issues at organizational level that can induce major resistance and act as change impediments. A critical general concern both at socio-political and industrial levels is that ill-defined interfaces and increasing complexities of systems and data solutions can lead to unforeseen consequences, greater vulnerability, and greater risk. This mainly demands further attention to a great extent on the critical interfaces between human, organizational, technical, and work process related aspects in the design of high-performing social-technical systems for Integrated eOperations to realize full-scale benefits of reengineering efforts.

4 SOME CRITICAL SUCCESS FACTORS IN TERMS OF SAFETY AND SECURITY

Reaping the major benefits of Integrated eOperations relies heavily on every possible measure to avoid conventional socio-technical systems design practices that has largely contributed historically towards dys-functional or mal-functional systems development and modification efforts. Hendrick [10] for instance identifies 3 of such flawed design practices, namely;

- Technology-centred design: engineering aspects and technologies take the precedence with improper integration of operators, maintainers, and organizational settings for design, development, and implementation tasks. Particularly owing to cost and time constraints, more humanised, user-friendly, and organizationally compatible approaches are largely limited leaving ‘off the shelf’ or ‘cook book’ type engineering solutions demanding a major changes within human and organizational components at the usage phase.
- ‘Left-over’ approach: this is often a result of high-tech focus where owners, operators, and maintainers do have to take over the challenge of finding solutions for those issues that are left-over by the designers. It implies that design flaws, which largely arise by treating the personnel and organizational components as impersonal elements of the dynamic system, need to be taken care by the users and maintainers at later stage through ‘quick-fixes’ and ‘ad-hoc’ solutions.
- Mal-integration of an organization’s specific socio-technical characteristics: this situation arises when designers fail to fully comprehend the dynamic interactivity of socio-technical components within an organizational setting. The specific relationships, customs, end-user needs and comfort within the organizational setting are left largely ignored resulting in only sub-optimal system development and implementation.

A cautious and a well thought through process is absolutely necessary for NCS today, not purely from financial standpoint but also due to critical safety and security reasons. In relation to current stage of development of leading O&G producers, some of those issues that are considered critical for front-end engineering tasks are highlighted in Table 1.

Any re-engineering effort that is known to introduce major changes within a work system need to adapt much broader criteria to adequately consider key characteristics of the resulting socio-technical system. Sound priory knowledge and understanding of the dynamics of the system is critical for an effective and efficient system design and implementation task. At the end, the principal need is to ensure a more humanised and an organizationally oriented practice. Human factor professionals recommend three such specific criteria to support system design, i.e. joint design, humanised task approach, and organizations’ socio-technical characteristics integration (see [3]).

- Joint design: following a design practice where technological and personnel sub-systems are brought together at very early stages on a concurrent basis rather than a serial basis.
- Humanised task approach: more early and cautious considerations of function and task allocation process for a more humane work system.
- Organizations’ socio-technical characteristics integration: early assess the key socio-technical characteristics of an organization and properly integrate them into the new work system.

It has become more and more obvious at this moment that a comprehensive overview of the new system is necessary to identify sub-disciplines to properly integrate human and organizational aspects to the technological revolution on NCS. Proper set of procedures, routines, and guidelines are necessary to perform analysis, design, implementation, and evaluation tasks professionally to retain the desired level of integrity and consistency across the entire industry.

5 CONCLUSION

Since the high-level policy makers and trade organizations became aware that commercial risks of O&G production and exploration activities on NCS would increase substantially during the next few years, offshore activities on the continental shelf has been undergoing a major re-engineering process. The Norwegian O&G industry today is on a fast track along Integrated eOperations that is widely acknowledged as the best option to capture a substantial portio of remaining value of major reserves on NCS and to prolong the commercial life cycle by 30+ more years beyond 2030-2040. Major initiatives have already been taken by major sources of influence, and NOK billions of more investments will be made during the next few years for further advancement. While high-tech solutions have been a major driver for ongoing developments, it is widely acknowledged that human and organizational aspects perhaps pose as the greatest challenge for further advancement. It implies that there is a need for a proper detailed understanding and knowledge on the critical socio-technical characteristics of the emerging environment to ensure that the industry will not be exposed to unnecessary risks due to poor designing, decision making, and implementation planning. There is also a timely need to adapt more humane and organizationally-oriented approaches as opposed to those for instance as ‘technology-centred’ and ‘left-over’ that are historically known to be dys-functional for new systems development and implementation efforts. This obviously is going to be a major challenge during the forthcoming phases of the development activities.

Organisational change	
Rules and regulations	*Applicable rules and regulations*

STRATEGIES FOR SUSTAINABILITY RISK MANAGEMENT THROUGH ACTIVE *'BAP (BUSINESS-ASSET-PROCESS) PERFORMANCE INTEGRATION'*

Jayantha P. Liyanage

Center for Maintenance and Asset Management (SDV), University of Stavanger, N-4036, Stavanger, Norway

Abstract: This paper sheds some light on the strategies for successful *BAP performance integration* based on knowledge and experience from oil & gas (O&G) industry. It defines and outlines an empirical framework to manage *sustainability risks* through systematic integration of performance across core business, asset portfolio, and core-processes such as operations & maintenance (O&M). It underlines two specific issues of timely significance. Firstly, O&M has a specific role-play towards a sustainable future when the global industrial activity shows an explosive growth, and secondly within sustainable business frameworks O&M process has an important value-adding role.

Key Words: Sustainability risk, Performance, Performance integration, Asset management, Operations and Maintenance, Performance quality, Performance measurement.

1 INTRODUCTION

Sustainability performance today has become an investable concept that effectively and efficiently balances profits and fundamentals for competitive advantage in complex and dynamic environments. It is a forethought business approach dedicated to create long-term value through better embracement of opportunities, reduction of sustainability costs, and management of hidden risks, by paying heavy emphasis on economical accountabilities towards those who bear financial risks, well-being of societies and societal agents, and proper care towards the eco-system. Today it has become an important means to ensure long-term security of investments and to manage enterprise risk exposure in the current socio-economic and political environment (for more information see [1]).

Certainly, decisions and activities at the industrial production/manufacturing asset level and technical-process level have significant impacts on the *sustainability performance*. Even though the impact of *sustainability performance* on the commercial success of the business has become more clear today, there are no proper guidelines, procedures, or frameworks available for systematic integration of performance of high risk & complex industrial production or manufacturing assets and of critical technical processes such as operations & maintenance (O&M), with sustainable business performance criteria. It implies that active *BAP performance integration* process has become a critical and an inevitable requirement for competitive advantage and commercial success in today's industry, and that effective strategies are necessary to steer the integration task.

2 SUSTAINABILITY CONCEPT

The World Commission Report on Environment and Development entitled *Our Common Future* issued in 1987 by Brutland Commission (see [2]) is an important landmark for the growth of the new idea of 'responsible' business. It has given birth to years of debates and discussions, and in principal has brought sustainability issues into limelight as an important concept for the survival and well-being offering a unique vision to achieve economic growth through responsible business practices.

Ever since, various activities and programs around the world by major sources of socio-economical influence, for instance UN, Dow Jones [3] etc. have contributed to bring two issues of interest to the attention of business leaders, i.e. *corporate social responsibility* and *sustainable business*. In fact the origin of both concepts remains more or less the same, and it can be widely seen today that these concepts are used in quite similar contexts without much of a difference in their meanings. In general, corporate social responsibility as a business principle represents a marriage of profits and fundamental socio-oriented principles; principles those emerged consequential to rapid globalisation requiring a far-reaching balance between business, government, and society at large. It covers range of a company's interaction with society ranging from conditions of employment, industry and labour standards, to social development and human rights, etc. It is believed to play an effective role as a strategy that fits with current industrial circumstances for gaining competitive advantage in the eyes of the societies particularly when business activities expand into more hostile regions. In the present context of business applications the distinction between corporate social responsibility and sustainable business is that, while the former mainly rests on the societal impact of corporate performance, the later seek for a blend of economic prosperity, environmental quality, and social equity, and captures a much broader scope and presents a composite picture of a legitimate value-creating business.

In essence, for O&G business, *sustainable business activity* implies; *adapting business strategies and activities that meets the needs of its wider stakeholders and the organization in question focusing on protecting, sustaining, and enhancing human and natural resources for future so that business activities are not only profitable but also importantly remains legitimate in the eyes of those bulk of stakeholders.*

In general this more broadly encompasses:

- social progress that equally recognize, respect, and cater to the needs of societal agents and organizations
- efficient and effective means to protect the eco system,
- cautious and prudent use of natural resources for the benefit of everyone, and
- contribute and sustain high and stable levels of economic growth of those who bear stakes

3 SUSTAINABILITY RISKS AND GAINS

The majority of O&G producers today seems to recognize that sustainable business policies and principles is the pathway to better deal with business uncertainties and risks, and the best option for competitive advantage (see for instance [4]). In essence, sustainability risk encapsulates;

- economical exposure
- corporate reputation
- partner goodwill

Sustainability performance has gained an added momentum ever since shareholders and other venture capitalists have taken serious interests to include similar criteria in the calculation of investment risks. This is highly commended for instance by *Dow Jones Sustainability Index* (DJSI) and policies for *Socially Responsible Investments* (SRI). There appear to be a rapid growth of interest in the investment community to follow the guidelines and policies of DJSI and SRI. Notably furthermore, non-governmental organizations and indigenous communities have begun to take legal steps against illegitimate business exploration and production activities in various parts of the world with serious economical consequences for O&G producers.

The pay back for implementation of prudent strategies to manage sustainability risk cannot simply be projected against purely quartile economical targets. It implies that business frameworks for sustainability risk management is about developing an expression about an organization's commitment towards its stakeholders and defining a clear mandate to achieve competitive advantage aiming a relatively longer-term success. Some of the contributing factors to competitive advantage include [1];

- reduced hidden costs
- created investment options
- attraction of investments
- reputational dividends
- gains in customers
- captured talent
- positive influence on product and service innovation
- creative leaderships, enhanced strategic relationships, etc.

However, it is known that the existing economical theories are not capable of sensibly expressing a major portion of the benefits in pure financial terms.

4 THE PERFORMANCE INTEGRATION CHALLENGE

While the executive leadership set guidelines and policies, and specify objectives abstractly that need to be accomplished at business level (see [5]), at the asset management level it is expected that operations are streamlined to substantiate those specifications and thus business improvements and developments. This implies that there should be an effective and an efficient correspondence between what the asset portfolio does (i.e. performance) and business results, and that there should be criteria to define the link between the two. O&G production assets have a specific role in the sustainable O&G business. In fact this role has to be complimented by various decisions and actions taken across assets at various levels and core processes. Asset processes should adapt performance management practices that allow them to realize their designated mission that directly relates to the asset performance criteria. In offshore O&G exploration and production environment 4 of such core asset processes exist;

- Drilling and well interventions
- Development and modifications
- Operations and maintenance
- Logistics and other support services

Notably, every core process has a pre-defined set of roles and accountabilities on the asset. For instance, *Drilling and Well intervention* largely dedicates to *recovery efficiency*, while *O&M* is more associated with assuring *technical condition* of equipment and systems and *safety integrity* of the asset. It implies that each process has to establish an appropriate framework in relation to its designated asset-based role to optimise its own performance.

Today there is an absence of standard criteria to define operational and technical specifications that explicitly explain what specific issues must be considered at the asset and asset-process levels to comply with sustainable performance. It implies that there is an inherent gap in the performance integrity management process. This can mainly be attributable to inherent complexities of underlying issues and inconsistencies of technical language in use to systematically work towards technical specifications at tactical and operational levels.

5 STRATEGIES FOR SUCCESSFUL '*B-A-P PERFORMANCE INTEGRATION* '

The concept of *BAP performance integration*, as the name implies, underlines a strategic need to streamline industrial activities in production/manufacturing/process plants or facilities and its core-processes with specific sustainable performance frameworks of the business. It is about an attempt, within the business and the manufacturing/production/process asset environment in question, to understand and to express the complex causal phenomenon of performance in a sensible way and to ensure that decisions are taken and activities are conducted on a risk-informed basis, and that those decisions and activities are corporate value-driven.

A successful strategy for *BAP performance integration* process comprises a set of specific tasks in a specific order, i.e. (see Figure 1);

1. *first order task*: Define and develop sustainable performance framework of the business.
2. *second order task*: Identify strategic operational specifications for production/manufacturing/process assets and define asset performance acceptance criteria.
3. *third order task*: Identify technical performance specifications for asset processes and define quality-tracking criteria.
4. *fourth order task*: Define and develop criteria for periodical business impact assessment.

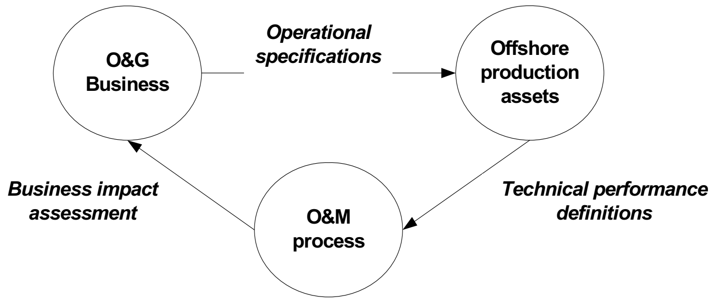

Figure 1. An illustration of *BAP performance integration* task (see [1], [6])

6 FROM FUNDAMENTALS TO DECISIONS AND ACTIONS

The popularising demand for more socially-responsible performance by the O&G business sector involves reconciling their legitimate search for profits with respect to rights and demands of stakeholders. This requires a re-orientation of O&G exploration and development paradigm based on rigorous and responsible assessment of trade-offs between temporary economic gains and the longer term pay back to stakeholders (Tomei, 1998). Such long-term business impact planning and subsequent sustainable business performance framework has to incorporate various social and environmental aspects. Figure 2 illustrates the guiding principals for developing such a framework in O&G business context.

As aforementioned a central challenge lies in the cascading of abstract business frameworks to operational specifications of the asset. It underlines the need of sensible criteria to define operational specifications that explicitly explain what specific issues must be considered at the asset level to comply with sustainable performance. If the asset owners comply with sustainable performance, then the ownership of an operating license of an offshore facility has to bring three-fold important issues into consideration, i.e.;

- *economical interests* (relates to direct financial interests of both the organization and those who bear financial risk, *e.g. actual production*)
- *liabilities* (directly address statutory and regulatory requirements imposed either by local or cross-border authorities, *e.g. safety integrity level*)

- *obligations* (encompass implicit moral and ethical aspects that are largely associated with exposure to vulnerabilities and harmful losses particularly during operational and decommissioning phases of high-risk assets, *e.g. waste handling*)

In that context, Table 1 and Figure 3 illustrate a generic criterion to establish relationships between sustainable business and asset performance.

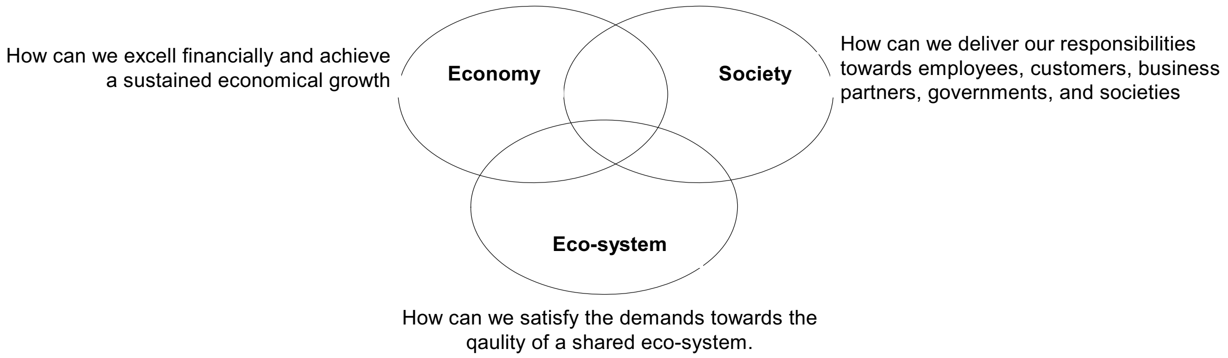

Figure 2. Guiding principals for sustainable business performance frameworks.

Table 1. Defining operational specifications.

	Sustainable Business		
Asset performance specification	**Economy**	**Society**	**Environment**
Economical interests	*e.g. actual production*	-	-
Liabilities	*e.g. insurance and compensations*	*e.g. working conditions*	*e.g. emissions, spills, discharges*
Obligations	*e.g. penalties*	*e.g. reduced health risk exposure and Quality assurance*	*e.g. waste handling*

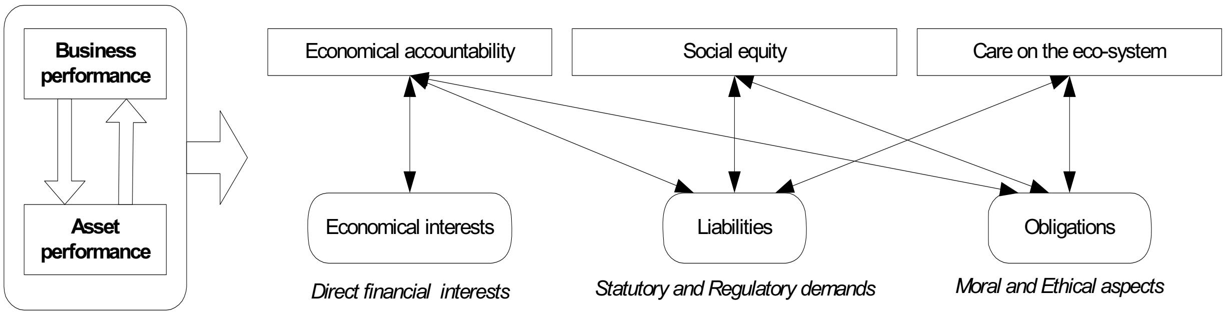

Fig. 3. Cascading from *Sustainable business performance* to *Sustainable asset performance*

The other challenge lies in the task that asset operators/owners have to identify technical performance specifications to shape-guide performance of asset processes. This requires a clear definition of designated function of the process within the asset performance framework, i.e. what a specific process under consideration is supposed to deliver to the asset. For instance, O&M is the process involved in technically conditioning assets. O&M need to explore the landscape for decisions and activities and develop the best strategies to optimise its delivery performance to retain a specific technical condition that contributes to overall commercial vitality of assets.

The establishment of the O&M performance logic in relation to asset performance criteria is essentially a systematic top-down process. It commences by reviewing abstract performance objectives and systematically specifying and defining technical details through the preceding levels. Figure 4 illustrates the core steps in the definition of the logic that convert a set of top-down *principal questions* to a working model that explains bottom-up *causal relations*.

The constituent components are defined and the underlying performance structure is built-up through systematic expansion of the working logic. It implies that the constituent components, which are the building blocks of the performance structure, gradually emerge as the principal questions are directly addressed and systematically resolved. It calls for an attempt to seek for clear technical specifications highly relevant for a given setting.

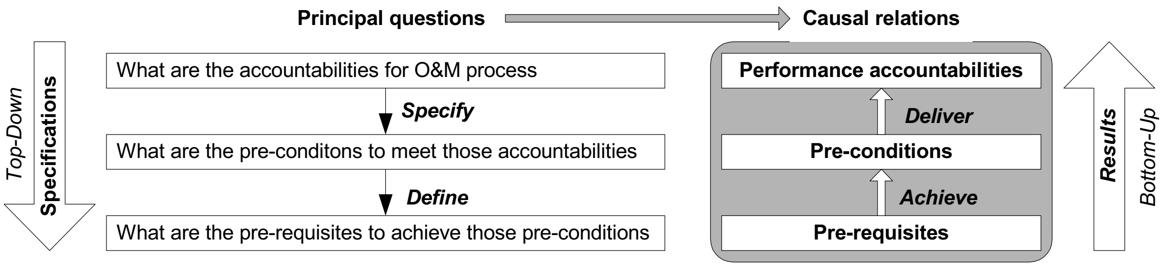

Fig. 4. Working logic to establish O&M performance framework (see [1], [6]).

Obviously, the actual detailed content of those *prerequisites* and formal organizational routines to manage those *perquisites* are fairly complex and hence remains beyond one's comprehension in its full scale. However, an attempt towards performance optimisation requires that such technical issues and adequately specified in relation to important circumstances within a given setting. A proper analysis and specification of technical issues will eventually result in establishing some form of a logic exploring interesting details related to;

- technical condition of the plant/facility
- safety integrity level of the plant/facility
- human factors
- organizational issues
- technologies and technology applications
- operational routines and work-processes

Adapting such a strategy largely helps performance optimization efforts as it helps avoiding specific performance biases. For instance, this particularly relates to abrupt slashing maintenance budgets for short-term cost savings, at the expense safety hazards and environmental damages. Such a framework brings positive effects to the O&M performance management efforts by providing a consistent basis for;

- key performance indicators and a balanced performance measurement system
- periodic performance audits or health checks
- quality assurance system for work processes, decisions and activities
- institution of internal standards and best practice documents for constant reference
- supportive infrastructure and a work setting

The central message here is that in relation to emerging concept termed *sustainable O&G business* and its implications at the production asset, and O&M process level, there is not only pure economical but also importantly legal, moral, and ethical bases for optimizing performance. It implies that the business case for O&M can be better expressed not only in terms of the cost of O&M activities, but also in savings in capital requirements, production regularity, occupational health, safety, and eco perspectives. This provides a stronger basis to express O&M as a *value-added process* rather than a pure *cost center* challenging the conventional thinking and practice. This has been discussed further by the authors elsewhere (see for instance, [7]-[11]).

7 CONCLUSION

This paper briefly discussed important issues related to the emerging concept termed *sustainable business* and strategies for *BAP performance integration*. The central argument brought into spotlight is that the business impact assessment of O&M performance, within emerging sustainable frameworks, should be performed not only in cost terms, but also looking into capital requirements, production regularity, occupational health, safety, and environmental results. It is stressed here that it is such a wider criteria that should be used as a basis model the critical business role of O&M process, particularly when complexities and uncertainties of business environment is too high to ignore and exposes the business to a wider set of risks in more dynamic socio-political settings.

THE NEED FOR AGILITY IN ASSET MANAGEMENT

Harris H [a] and Carapiet S [b]

[a] *Hawke Research Institute, School of Management, University of SA, North Terrace, Adelaide, SA 5000, Australia.*

[b] *School of Management, University of South Australia, North Terrace, Adelaide, SA 5000, Australia.*

Abstract: Increasingly turbulent environments faced by enterprises today have reduced the time available to organisations to prepare and respond to change. Organisational agility, characterized by a rapid and proactive response to opportunities and threats, is a source of competitive strength and adaptive capability for engineering enterprises. Asset management can be an effective source of competitive advantage if it occurs within the broader framework of sustained organisational agility. This paper demonstrates how an understanding of the concept of agility, and obtaining a simple measure of the levels required in an organisation, can help managers to incorporate agility into their asset management programs. The Agility Measure described in the paper draws on experience with a large multi-national project, SYMPHONY, in which many small and medium-sized enterprises participated. A key feature of the Agility Measure is its applicability in medium sized enterprises which tend to have limited tools available to managers.

Key Words: Asset management, Agility, Competitive advantage, SMEs, Adaptive enterprises

1 INTRODUCTION

Contemporary businesses, service organisations and government enterprises face an increasingly turbulent operating environment as a result of globalisation, advances in information technology, rising living standards, increased regulation and corporate governance demands, less cohesion in social values and the rise of post-modernism. Enterprises have responded to these challenges by vigorous pursuit of lower costs, increased clock speed, new organisation structures, increased participation in networks and clusters, and in some cases an involvement in virtual organisations. To be successful in this new environment firms, organisations and employees need capabilities and characteristics which may differ in nature from those needed in an earlier, more certain, age. Not only are additional technical skills needed but systems also may need to be more resilient, structures flatter and more flexible, 'soft' skills more prominent, reporting more open and the organisation as a whole more agile.

These changes impact on asset management activity. The paper shows how the changes in organisational theory and the business environment will impact on key features of engineering asset management. Operating in a turbulent environment has an impact on all aspects of a business, and there is no exception for management of assets – the 'continuous process covering the whole-of-life cycle of an asset from conceptual design through to construction [or] manufacture, operational use, maintenance, rehabilitation and/or disposal' [1]. Agile asset management, the ability to respond to rapid changes in the environment, offers an organisation competitive advantage for instance in product/process flexibility, customer response capability and ability to integrate new technology. We contend that the adoption in engineering asset management of the traits and attributes necessary for agile operation will bring benefits not only to the asset management process but also to the enterprise as a whole.

The paper begins by taking an historical look at the development of business systems and organisation structures, followed by an outline of the elements of chaos and complexity theory which underlie the new paradigm. It then outlines the key features of agile and adaptive organisations before discussing specific implications for engineering asset management.

2 THE EMERGENCE OF THE CONTEMPORARY ENTERPRISE

In the enlightenment of the eighteenth century Adam Smith provided a description of the way in which wealth is created [2] which underpinned a view of business and economics which was to hold sway almost unchallenged for over 200 years. Individual businesses, proprietors and entrepreneurs were to engage in brutal competition for profit, while an 'invisible hand' ensured that the overall economy operated efficiently. The more efficient producer would supplant the less efficient, and those goods which were the more needed in society would be produced to the exclusion of those less necessary.

Classical management theory has its roots in the growing demand for industrial products and the increase in the number of large enterprises which occurred as the industrial revolution gained pace. It was also firmly grounded in the scientific revolution and the Newtonian world view. *The Principles of Scientific Management* was published in 1911 by a mechanical engineer, F.W. Taylor, and the five functions of management – planning, organising, commanding, co-ordinating and controlling – were enunciated by the French engineer Henri Fayol in 1916 [3]. This led to a formal division of labour, even in the executive ranks, with distinctions between line and staff functions, where 'all the thinking is done by the managers and designers, leaving all the doing to the employees' [4]. Power within these bureaucratic organisations rested with fixed offices or roles, not with individual human beings. The role of the leader was to maintain equilibrium [5].

Aspects of this classical approach are evident still in many organisations today. The pursuit of efficiency has led to the appearance over recent decades of a series of techniques for enhancing the efficiency of organisations. Just-In-Time, avoiding waste through lean production, and the pursuit of best practice through benchmarking are just three examples.

It was not until the last half of the twentieth century that any serious challenge to the free market model emerged in the West. The dominance of the shareholder as the proper focus and recipient of business profit was first challenged [6] by the notion that others had a stake in the business. All stakeholders, including suppliers, customers and employees, were to be considered, not just the owners [7]. The 'Triple Bottom Line', which has achieved currency as a way to measure performance, requiring an assessment in each of the economic, social and environmental fields [8], further broadens the area of focus.

2.1 Importance of networks and virtual enterprises

One place where the overwhelming power of the simple, capitalist, view of the business as the unadulterated pursuit of profit in a dog-eat-dog competition has been progressively challenged is in the increasing use of networks, alliances and clusters in business. Maintenance of machinery may be outsourced to a specialist provider, former employees may form a cluster of self-employed contractors with premises on the former employer's site, and IT-based condition monitoring services may be provided by unseen people in another country. The formation of these new business groupings is widely encouraged yet there is less recognition of the significant shift in internal organisation [9] which is needed if networks are to deliver the benefits for which they were praised and taken up. The significance lies not only in the changed view of the purpose of business – co-operation with those who have been (and often still are) competitors is at the heart of the network model – but also in the management skills needed for success in such a business [10].

2.2 The nature of competition

Traditionally, competitive advantage has come from attributes such as location, operating cost and technology. Michael Porter identifies the threat of entry by new competitors, the intensity of rivalry among existing competitors, pressure from substitute products, the bargaining power of buyers, and the bargaining power of suppliers as the five forces that drive competition within an industry [11]. Another view focuses on the strengths and weaknesses of the business and the link between a firm's internal characteristics and its performance. Known as the resource-based model [12], it attributes sustainable competitive advantage to the firm's assets (or core competencies), with particular emphasis on those assets which are valuable, rare, not easily imitable and incapable of substitution [13].

On this view, not only are the physical resources – the rail networks, blast furnaces and large machines – a valuable source of competitive advantage, but so are human resources – as captured by the catch-phrase "our people are our greatest resource" – and also the operating procedures, corporate culture, reporting procedures and planning system. In engineering asset management this means that competitive advantage can come not only from the physical assets and the people who maintain them, but also from the systems used to manage the assets and their maintenance.

Taken together these changes represent such a large change that for those who accept them it has become a new paradigm, a new way of looking at the world [14]. In the following sections we show how this paradigm has emerged from the theories of chaos and complexity, and then show how agility is an important characteristic for enterprises which aim to succeed in this new world. This will set the stage for our discussion of the implications for engineering asset management.

3 A CHANGED VIEW OF THE WORLD: FROM NEWTON TO CHAOS

The Newtonian, scientific paradigm which underpins the traditional organisation structure viewed the world as a well-behaved machine. This has been challenged by the complexity paradigm where there are limits on the ability to predict future events [15-17]. Whilst there have been many best-selling books that have played a major role in enhancing the understanding and popularity of the theories of chaos and complexity [17-22] the relevance to management has seldom been explicit beyond a commitment to the replacement of the older, Newtonian model [23]. Three important elements are discussed below – the limits on prediction, the possibility of self-organisation and organisations as complex adaptive systems.

While the initial impetus for the research in complexity came from the natural sciences including chemistry, physics, biology and mathematics, numerous books aimed at management practitioners [17, 24-31] and the general public [20, 22] have raised awareness for the potential application of complexity theory. Complexity theory has been applied to management [5, 32, 33], self-organisation in entrepreneurial networks [34], self-managing teams [35], strategic processes [36], leadership [37, 38], innovation and knowledge management [39-41], development [42], and project management [43]. However there have been very few empirical studies [33, 41], and 'relatively little work on developing a theory of complex social systems', which is what organisations are [33].

3.1 Limits on prediction

The striking discovery that unpredictable behaviour is generated in simple deterministic systems with only a few elements is the foundation of what has come to be called chaos theory. When meteorologist Edward Lorenz discovered that 'prediction of the sufficiently distant future is impossible by any method, unless the present conditions are known exactly' [44], he termed this the "butterfly effect" - the notion that a butterfly stirring the air today in Peking can transform storm systems next month in New York. This places fundamental limits on prediction, even when there are few elements in the system and the relationship between them is precisely known. Tiny disturbances can produce exponentially divergent behaviour, which is not the case in Newton's universe.

3.2 Self-organisation

The second significant aspect of chaos theory is that 'astonishingly simple rules, or constraints, suffice to ensure that unexpected and profound dynamical order emerges spontaneously' [45]. The generation of new forms from inner guidelines, rather than by imposition from outside, is characteristic of self-organisation in open and living systems [46]. It is 'a process in which pattern at the global level of a system emerges solely from numerous interactions among the lower-level components of the system' [47]. The idea that order in the universe is natural and spontaneous [48] is dramatic and illuminating. Complexity theory takes the concept one step further, contending that organisation not only arises spontaneously but also is adaptive [49].

Communication is the key driver in the self-organisation process as it is the primary mechanism for interaction amongst the individuals (agents) in organisations (complex adaptive systems) [50-55], which leads (after Comfort [54]) to the characterisation of self-organisation as a collective process of communication, choice, and mutual adjustment in behaviour based on a shared goal among members of a given system without external order.

3.3 Organisations as complex adaptive systems

The dynamic ability of complex adaptive systems to evolve and learn over time can provide organisations with increased capability to handle adaptive challenges. Complexity should be seen not as 'a methodology or set of tools' but as a 'conceptual framework, *a way of thinking* and *a way of seeing the world*' [33] (emphasis in original). Viewing organisations as complex adaptive systems [37, 56-61] offers a powerful new lens to study and understand the dynamic emergence of order, structure or patterns from the interactions of the elements inside a system, whether that system be one in the natural world, or a business organisation [15, 57, 62]. Iterative learning within these systems can modify the rules for interaction as the environment changes and this allows the system to evolve and improve its performance in changing environments [63-65].

Self-organisation occurs in open systems that are far-from-equilibrium [66], that is in systems that are characterized by constant change and failure to reach equilibrium as distinct from ones following the Newtonian paradigm and moving towards equilibrium, thus making a manager a facilitator of self-organisation rather than a leader charged with the role of maintaining equilibrium.

Any system shows 'properties which are properties of the whole, rather than the properties of the component parts' [67], and a complex system is not one with many parts but one where the interaction between the parts is complex, while complex adaptive systems have the ability to adapt to the environment in a systematic way [49]. Human systems including organisations are adaptive non-linear feedback systems that exist under conditions far from equilibrium [4, 26, 57].

4 AGILE AND ADAPTIVE ORGANISATIONS

An organisation that can self-organize, a complex adaptive system as described in the previous section, has the internal capacity for spontaneously emerging structures, depending on what is required [17]. Organisations that tap into the property of self-organizing or self-renewing systems have been termed "adaptive organisations" where the task determines the organisational form [68]. An adaptive organisation has also been defined as being able to sense and respond to changes in its environment and learn from these responses to change its behaviour and evolve.

Another term used in the literature to describe organisations with these characteristics is 'agile'. Agile enterprises are described as dynamic and adaptive [69], able to operate profitably in a competitive environment of continuous and unpredictable change [70], and capable of gaining 'competitive advantage by intelligently, rapidly and proactively seizing opportunities and reacting to threats' [71]. The turbulence of the business environment reduces the response-time available to firms to cope with change and thus creates the need for agility. The key drivers of this need for agility are to be found in a company's business environment— such as change in the marketplace, technology, and competition [72, 73].

Agility is related to self-organisation in terms of survival in a turbulent environment. Some characteristics of agile companies bear similarity to self-organising firms. For example, the agile manufacturing reference model developed from research on agility in UK-based SMEs by the Agile Manufacturing Research Group [74] has four interdependent elements of agility – strategy, processes, linkages, and people. Agile people will be found where the organisation structure is adaptable, continuous learning occurs, people are multi-skilled and flexible, and decision making is rapid, based on robust, integrated systems. Closely associated with adaptable structures in this reference model is the concept of 'performing partnerships' in which agile organisations gain new and enlarged capabilities through cooperation, often linking together to form virtual enterprises [74]. Indeed the linking of firms to form virtual enterprises is a core component of the agile enterprise [75]. Thus, along with permeable boundaries, an acceptance of the unpredictability of outcomes, and effective communication between participants to maintain the relationship success in agile enterprises will require the trust, compatible management philosophies, informality and redundancy which are necessary for effective networks and alliances [10, 76].

5 IMPLICATIONS FOR ENGINEERING ASSET MANAGEMENT

Given that agility will be a benefit for an enterprise that faces a turbulent environment, what are the implications for those organisations which have substantial engineering assets and in particular for the management and maintenance of those assets? Thus far, we have shown that the benefits of agility will be compromised if only part of the organisation is agile while the rest continues in the pursuit of an excellence which is grounded in the certainty of the Newtonian model. Thus the engineering asset management system and those who run it cannot be divorced or isolated from the wider organisation. At the ICOMS conference in 2001 Harris [77] argued that the changes in corporate governance brought about by increased stakeholder interest in environmental and social performance would impact the reporting requirements and performance targets for maintenance management, and this paper extends that to include an even greater impact.

Any integrated approach to engineering asset management will included at least twelve elements [1], and one way to examine the impact that an acceptance of the new organisational paradigm will have is to consider how some of these elements will be affected. Three elements – data management, human resources, and condition monitoring – are considered below.

5.1 Data management

The process of asset management requires substantial information to be collected from many different parts of the organisation. Although organisations are generating more and more data, many managers lack confidence that they have enough reliable, consistent, correct and timely data for decision making. Organisations may have far more data than they use; yet not have the data they really need.

The 'soft factors' such as organisation structure, culture, and communication [78] have found to have a significant impact on data quality for engineering asset management which is in line with the ideas of the complexity paradigm. Communication between participants is the key driver of the self-organisation process and effective communication requires a shared language and values. This is one example of how the implications of complexity apply to engineering asset management.

Chaos theory offers companies that need to handle adaptive challenges a view of the world as dynamic where change is the norm not the exception, and where prediction is impossible. There are implications for organisations operating in a dynamic and unpredictable world not to follow the 'command and control' techniques of the past, as they would be likely to inhibit the ability to cope effectively with the changes. A much more viable management philosophy, given the existence of chaos, is to devise ways to embrace change and cope with change by having the capability to respond to unpredictable situations built into the organisation.

5.2 Human Resources

Enterprises which are organized on hierarchical principles, and that will include many asset management departments and maintenance units, require managers who are comfortable and effective in situations where command and control are key management functions. Complex adaptive systems deliver agility and competitive advantage but they require managers with different skills and attributes if they are to deliver these benefits. Technology and context-specific skills and knowledge remain important but the personal traits associated with success now include tolerance of ambiguity, inquisitiveness, and perhaps even love [10]. This is a particular challenge for those who have learnt their trade or gained their experience under an earlier, more certain regime, where organizations placed great store in "one right way".

In addition, as more organizations come to recognize that they are open systems the range of parameters by which performance is judged will broaden. Asset managers will be asked to report on environmental and social performance as well as availability and cost [77], further adding to the change for the manager brought up in the command and control, scientific management era.

5.3 Condition monitoring

Many consider condition monitoring to be 'the most cost-effective way' of maintaining assets as it 'enables deterioration in condition to be detected and remaining life to be predicted' based on regular inspection and measurement [79]. It relies on the predictability of future events. Conceptually, chaos theory cautions that no real life prediction can be relied on because the initial conditions are never fully known. This may be of little practical consequence for those working with the machine, in the same way that relativity and quantum theory have no discernible impact on the sizing of shafts or the measurement of rotation speed. Furthermore, the statistical elements which are found in many condition monitoring techniques reduce any tendency to consider the predictions as absolutely correct. For the researcher and theorist there may be more subtle influences which cannot be ignored.

These three examples are interlinked. Condition monitoring relies on data collection, and a human preference for certainty can encourage both recipients and providers of information to hide or gloss over the inherent unpredictability in it. Viewing an organisation as a complex adaptive system that is an open and non-linear system will lead to changes to the existing closed and linear system of asset management (and accounting). Making actual changes will not be easy, but unless they are made the benefits which agility and self-organisation can bring in response to the turbulent business environment will not be captured. An engineering asset manager has to accept the inability of maintenance systems to provide perfect prediction and work on developing the capabilities of agility, innovation and experimentation in his people and systems to operate in a dynamic world.

6 MEASUREMENT OF AGILITY

This section describes a measure of agility which managers can use to determine the need for agility in their organisations, the readiness of the organisation to become agile, and the extent of agility. The first prototypes of the Agility Measure were developed during a collaborative research project conducted under the Intelligent Manufacturing Systems (IMS) framework. Known as SYMPHONY, the project addressed the need of SMEs for management tools that assist in handling a turbulent environment and included 30 organisations from the European Union, Canada, Australia and Switzerland [80, 81]. Among the companies that participated in SYMPHONY were an Italian automotive parts and manufacturing company, a Swiss shipbuilder, an Australian provider of stormwater and wastewater filtration systems and a Swiss-based electricity distribution line support company.

The Agility Measure draws from the methodology for agility developed by Zhang and Sharifi [72, 73], and three reference models developed by practitioners [74, 82, 83]. The three modules of the Agility Measure provide assessments of the need for agility, the readiness for agility and agility level. The Agility Measure is a self assessment tool, with the first two modules principally designed for use by the manager or management team while the third module, which assesses the agility level of the enterprise, allows for data to be gathered from a wider range of participants, perhaps including those outside the organisation. In each module of the Agility Measure, managers see a list of evaluation questions in a number of categories, which they will need to rate on a scale of 1–5 (similar to a Likert scale). The individual characteristics which make up the assessment in each module have been chosen from the factors identified in the literature and reference models [72-74, 82-84] and are shown in Table 1. Although initially developed as a pencil and paper form, an online version is now available. Each module can be completed in less than 15 minutes.

Table 1

Components of the Agility Measure

Module	Categories included in the assessment	Number of items in each category
Need for agility	Marketplace	10
	Competition	4
	Customer requirements	4
	Technology	2
	Social factors	5
	Suppliers	2
	Internal complexity	6 total = 33
Readiness for agility	Inclination towards risk	3
	Previous experience with novel ideas	3
	Resources	4
	Political commitment	2
	Sophistication	4
	Intensity of rivalry between firms	3 total = 19
Agility level	Sensing, perceiving and anticipating changes	2
	Strategic vision	2
	Delivery speed and timeliness	2
	Time to market	2
	Cost effectiveness	4
	Operations efficiency and effectiveness	3
	People flexibility	2
	Knowledgeable, competent empowered people	2
	Product volume flexibility	3
	Rate of new product introduction	2
	Organisational flexibility	2
	Product model/configuration flexibility	3
	Business network	3
	Sufficient and appropriate technological ability	3 total = 35

The assessment of the need for agility module assists managers in deciding whether there is actually a need for their company to be agile. Essentially the degree of turbulence in the business environment determines the need for agility. The questions in this module assess the paradigm in which the manager is operating. Agility is needed in enterprises that operate in an unstable and unpredictable environment, as in the complexity paradigm.

The assessment of readiness for agility module assists managers in answering the question: how ready is my company for agility? The questions in this module are about the experience of the enterprise with change as a response to the far-from-equilibrium conditions it has faced. The past experience of the enterprise and its earlier achievement in adaptation are reflected in this assessment of readiness for agility. This module relates to the concept of organisations as complex adaptive systems that learn and evolve, based on their experiences. As in the case of self-organisation, the enterprises that learn from their experiences tend to improve their performance over time.

The assessment of agility level module assists managers in assessing the current level of agility of their company. The flexibility of the enterprise in terms of its people, processes, and linkages with other enterprises is part of the agility level of an enterprise. A high level of agility corresponds to a strong adaptive capability, and the indicators captured in this module include the anticipation of change, strength of the company vision, and sharing of information openly.

The measures can be customised to individual organisational requirements in two ways. The measurement proformas each include a section where the degree of importance of each category for the company in terms of its performance success is determined. The respondents simply rate each category as being of low, medium, or high importance. The application of these weightings to the raw scores for each category ensures that the overall score for the module is tailored to reflect the importance of the various categories for the business. In addition enterprise-specific questions can be added, for instance on specific elements of cost effectiveness or to make reference to particular aspects of the environment.

7 CONCLUSION

Globalisation, demands for more stringent and transparent corporate governance, and advances in information technology mean that many businesses, government instrumentalities and service providers face a more turbulent operating environment. These changes have been accompanied by changes in the way in which many people look at the world. As the industrial revolution was accompanied by great changes in science and religion so the concepts of chaos and complexity are increasingly associated with the management and structure of contemporary enterprises. In particular some enterprises are seeking to emulate the capability for self-organisation which is has been identified in many systems in the natural world so that these human organisations might become more agile and better able to adapt to the rapidly changing environment. Those responsible for engineering asset management cannot stand aside from these changes, which require an acceptance of uncertainty, permeable boundaries, high levels of trust and effective communication to support relationships and learning. The Agility Measure described in the paper provides managers with a tool for assessing the need for agility in their organisation or unit, together with the organisation's readiness and agility level.

9 ACKNOWLEDGEMENTS

The authors have benefited from discussion of the concept of agile organisations and the application of chaos and complexity theory to human organisations at a number of conferences including the 7th Stimulating Manufacturing Excellence in SMEs conference in Glasgow and at various events associated with the SYMPHONY project. The Australian Government through the Innovation Access program assisted the attendance of Australian participants at SYMPHONY meetings. Saadia Carapiet's doctoral studies in self-organisation in SMEs has been supported in part by scholarships from Smartlink: National Institute for Manufacturing Management and the Cooperative Research Centre (CRC) for Integrated Engineering Asset Management (CIEAM).

MAINTENANCE RELATED IEC DEPENDABILITY STANDARDS

Per Anders Akersten[a]

[a] *Centre for Dependability & Maintenance, and Division of Operation & Maintenance Engineering*
Luleå University of Technology, SE-97187 Luleå, Sweden

Abstract: Within the International Electrotechnical Commission, IEC, there exists a committee, named IEC Technical Committee 56 "Dependability", TC56 for short. Its history can be traced back to 1965, when the Reliability and Maintainability Committee was formed. In 1990, after contacts with ISO, it was decided that the IEC/TC56 should be responsible for standardization in the field of dependability, in any appropriate technological area, including those normally considered as outside the scope of IEC. The term "dependability" is a collective term, used to describe availability performance and its constituent factors reliability performance, maintainability performance, and maintenance support performance. Within the IEC/TC56 a number of maintenance related standards and guidelines have been produced, covering e.g. maintainability of equipment, reliability-centred maintenance, integrated logistic support, and also an application guide entitled "Maintenance and maintenance support". Also, Chapter 191 of the International Electrotechnical Vocabulary, freely available on the Internet, contains a wealth of maintenance-related terms. This paper is intended to give an overview of the standards available and some insight into the ongoing efforts within IEC/TC56 to produce new standards and to maintain existing ones. It should not be seen as an official promotion of the IEC Dependability Standards series. Instead, it presents some personal experiences and reflections on the use and usefulness of the standards series.

Key Words: standardization, dependability, management, maintenance, maintainability, life cycle cost, logistic support, ILS, RCM

1 INTRODUCTION

The International Electrotechnical Commission (IEC) Technical Committee 56 "Dependability", TC56 for short, performs standardization work within dependability. Its history can be traced back to 1965, when the IEC Reliability and Maintainability Committee was formed. Today, the scope of TC56 is formulated as follows [1]:

"To prepare international standards in the field of dependability, in all appropriate technological areas, including those not normally dealt with by IEC Technical Committees. ... The standards provide systematic methods and tools for the dependability assessment and management of equipment services and systems throughout their life cycle."

The term "dependability" [2, (IEV 191-02-03)] is a collective term, used to describe availability performance and its constituent factors reliability performance, maintainability performance, and maintenance support performance. The various dependability standards are related to product issues, process issues as well as management issues. They do not cover safety, although their applications often address both dependability and safety issues.

Of special interest within maintenance management are the published IEC-standards describing

- Life Cycle Costing (LCC)
- Maintainability
- Reliability Centred Maintenance (RCM)
- Integrated Logistic Support (ILS)
- Maintenance and Maintenance Support

These standards contain general introductions to concepts and provide guidance for applications within different areas. They do not describe detailed procedures and should not be compared to the technical standards, having narrower scopes, covering specific products or approaches.

Different standardization issues have been addressed at previous ICOMS Conferences, see e.g. [3], [4] and [5]. This paper is intended to give an overview of the dependability standards available and some insight into the ongoing efforts within IEC/TC56 to produce new standards and to maintain existing ones. It should not be seen as an official promotion of the IEC Dependability Standards series. Instead, it presents some personal experiences and reflections on the use and usefulness of the standards series.

2 THE STANDARDS PRODUCTION PROCESS

Within the work of ISO and IEC TC 56 is classified as a horizontal Technical Committee. This means that it should exclusively treat fundamental principles, concepts, terminology or technical characteristics that are relevant to a number of other horizontal or product Technical Committees. The other committee type, product Technical Committee, has a scope, covering a specific product or group of related products.

Today TC 56 has 33 member countries, 23 so-called P-members, and 10 so-called O-members. P-members are supposed to participate actively in the work, to vote on all questions formally submitted for voting within the technical committee or subcommittee, and to participate in meetings. O-members are allowed to follow the work as observers and have the right to submit comments and to attend meetings.

The TC 56 Dependability consists of four working groups:

- WG 1. Dependability terminology
- WG 2. Dependability techniques
- WG 3. Dependability management
- WG 4. System aspects of dependability

These groups constitute the four Maintenance Teams and they are responsible for the establishing and managing of Project Teams. Moreover, the Committee has liaisons with several other IEC and ISO committees, e.g. ISO/TC 108/SC 5 "Mechanical vibration and shock – Condition monitoring and diagnostics of machines" and ISO/TC 176 "Quality management and quality assurance".

The production of standard documents proceeds through a number of stages. The IEC and ISO standards production processes are very similar, see e.g. [4]. For the life of IEC standards the following stages can be identified:

Table 1. Stages in the life of an IEC standard

Stage		**Activity**	**Related document types**
Project stages	Preliminary	Introduction of new items, subject to voting among P-members.	PWI (Preliminary work item)
	Proposal	Proposition of a new work item, preparation of first working draft, nomination of project leader.	NP (New work item proposal)
	Preparatory	Setting up of project team, preparation of working draft	WD (Working drafts)
	Committee	The principal stage, containing preparation of committee drafts, circulation of drafts and consideration of comments from national bodies.	CD (Committee drafts)
	Enquiry	Circulation of enquiry draft, voting and submission of comments by national bodies, revision (if needed) of document.	CDV (Committee draft for vote)
	Approval	Distribution of final draft, voting by national bodies.	FDIS (Final draft international standard)
	Publication	Correction of errors (if any) in final draft, printing and distribution of standard.	IEC Standard
Maintenance		Examining need for revision of existing standards, establishing of revision work as new projects.	From CD to updated IEC standard.
Withdrawal		Withdrawal of existing standards.	

3 EXISTING MAINTENANCE-RELATED DEPENDABILITY STANDARDS

Appendix A provides a list of existing international standards, prepared by TC 56 Dependability and related to maintenance. The standards can be seen as organized in four different levels:

1. The top level documents (60300-1) deal with dependability management system and dependability programs.
2. The second level documents (60300-2) give guidance on various program elements and tasks.
3. The third level documents (60300-3) are so-called application guides.
4. The fourth level documents describe different tools, such as procedures and statistical techniques.

The standards related to maintenance management can be found among the third level documents, dealing with

- Life cycle costing (60300-3-3)
- Maintainability (60300-3-10)
- Reliability centred maintenance (60300-3-11)
- Integrated logistic support (60300-3-12)
- Maintenance and maintenance support (60300-3-14)

The series of standards relating to maintainability have been around for some time, and they do not fit perfectly into the four-level scheme. They may be seen as application guides, although they in several cases describe useful tools in more detail.

IEC 60300-3-3 "Life cycle costing" provides an introduction to the concept of life cycle costing, with special reference to costs associated with the product's dependability. The document describes the value of life cycle costing and outlines general approaches. It also covers common life cycle cost elements and guidance for performing a life cycle cost analysis.

IEC 60300-3-10 "Maintainability" is an application guide for maintainability, to be used in the implementation of a maintainability program for the life cycle phases *initiation*, *development* and *in-service* of a product. It gives guidance on how maintenance aspects are considered in design and modification work in order to achieve the appropriate maintainability.

IEC 60300-3-11 "Reliability centred maintenance" provides guidelines for the use of reliability centred maintenance (RCM) analysis techniques in the development of preventive maintenance programs for an equipment or a structure. The present version of the standard is based largely on the procedures in MSG-3. However, it is applicable not only to aircrafts but to a variety of items.

IEC 60300-3-12 "Integrated logistic support" describes the process of the management method ILS, by which the logistic support services required by a customer can be brought together in a structured way. These logistic support services include maintenance, manpower, training, spares, documentation, packaging, handling, storage, transportation, support resources and disposal. The standard provides guidance on minimum activities necessary for an effective ILS implementation.

IEC 60300-3-14 "Maintenance and maintenance support" describes a framework for maintenance and maintenance support and also minimal common practices. It further describes related management, processes and methodologies. The approach is more general than the one used in integrated logistic support (ILS) and is applicable also to cases where maintenance and maintenance support have to be adapted to specific conditions during the various life phases of a system.

It should be noted that several of these application guides are related to the previously issued standard IEC 60706-4 "Guide on maintainability of equipment - Part 4 - Section 8: Maintenance and maintenance support planning".

Another maintenance-related application guide is under preparation. According to the New work item proposal (NP) document, its tentative title is IEC 60300-3-16 "*Guideline for the specification of maintenance support services*" and its scope *"This IEC standard describes a framework for the specification of services related to the maintenance support of products, systems and equipment that are carried out during the operation and maintenance phase. The purpose of this standard is to outline, in a generic manner, the development of agreements for maintenance support services as well as guidelines for the management and monitoring of these agreements by both the company and the service provider."*

4 MAKING USE OF THE STANDARDS

Standards may be used in different ways. They are not laws, but they can be used as a basis for contracts, for evaluation of providers of service, for risk and insurance management, for decisions regarding contract compliance, and possibly also for related litigation and prosecution. The compliance to the IEC dependability standards is voluntary and the benefits from using them have to be identified. The benefits, technical as well as strategic, are very well understood by the experts participating in the standardization work. One main problem is to make decision-makers aware of the strategic and other potential benefits from the use of international standards.

The standards represent a massive amount of knowledge, compiled and condensed by a balanced group of international experts. The published standards also represent a certain degree of consensus (more than simple majority) of the group of experts, as well as of the voting members of the Technical committee, i.e. the participating countries' national committees. This can be utilized by letting the appropriate maintenance related standards constitute a core of a body of knowledge within maintenance management and engineering. This facilitates the dissemination of knowledge to companies, educational organizations and other organizations.

Among other benefits of the use of international standards, product oriented as well as management oriented, can be mentioned, e.g., the following.

- They are used world-wide
- They can be used by companies and organizations, regardless of size
- They provide a common language for description of processes

- They provide checklists of the main issues to be covered
- They provide a framework, facilitating performance measurement and improvement work
- They facilitate education and training within its subject area
- They reduce technical barriers to trade by harmonizing of national standards

Another way of making use of international standards is to participate in the standardization work. The homepage of Standards Australia [2], describes the value of participating with the use of the headings *Value to you*, *Value to your business* and *Value to the nation*. Those of us who have had the opportunity of participating immediately recognize the values *Personal satisfaction, Networking opportunity (national as well as international), Knowledge gain, Familiarity with standards, and Recognition for your organization.*

This section of the paper is closed by a quote from Valter Loll [7], convenor of TC56 WG2: *"If you want to stay updated you have to participate in the standardization work or receive information from someone who does."*

5 DISCUSSION

The use of standards in training and education for emergency management is discussed in [8], and a list of twelve requirements on a standard is provided. Although the application area discussed in the paper is quite narrow, most of the requirement types are generally valid. A few examples are as follows:

- *A standard should clearly define the terms it relies on for explanation.*
- *A standard should aim to be acceptable to as large a body of users as possible.*
- *A standard should seek to homogenise terminology, methods, procedures etc in order to reach consensus about common objectives.*
- *A standard should not be didactic, i.e. it should not seek to train.*
- *A standard should not inhibit the development of higher levels of professionalism.*
- *A balance must be struck between the need for permanence and the need for revisions.*
- *A standard should be freely available and distributed without cost to all who may benefit from it.*

Looking back into the history of the IEC dependability standards we may observe several occasions where some of these requirements were not fulfilled. Some individuals have strongly criticized the standardisation work and the standards published [9] and also comments from national bodies have had an impact on how the committee work is performed today. Most of the requirements listed above are now fulfilled to a large extent. One exception is the last requirement. The IEC offers free access to the vocabulary [2] but not to the individual standard documents.

For the effective use of international standards in the development of maintenance management and maintenance technology we need to stay informed. There exist several standardization bodies beside IEC and ISO; in Europe you will find, e.g., CENELEC and CEN, and in the United States you will find ANSI and IEEE. Moreover, most industrial nations have national standardization bodies. The different actors on the standardization arena do cooperate to a great extent, but the layman needs help to find out about existing standards within a particular subject. The establishment of a comprehensive and updated list of standards related to maintenance and product support should be added as a work item for the national maintenance societies as well as for future ICOMS.

E-MAINTENANCE AND VULNERABILITY

Per Anders Akerstena

[a] *Centre for Dependability & Maintenance, and Division of Operation & Maintenance Engineering*
Luleå University of Technology, SE-97187 Luleå, Sweden

Abstract: Teleservice, utilizing modern information processing and communication tools, is by now a well-known way of supporting a product and we have seen the emergence of e-manufacturing and related types of e-service, in particular e-maintenance. In discussions of the present and future of e-manufacturing and e-maintenance systems are among other things risks and vulnerabilities related to utilization of e-services identified as an important area for further research. In this paper the concepts of e-maintenance and vulnerability are briefly described. The vulnerability of the e-maintenance system and its consequences for the managed assets are discussed to some extent. From different risk analysis approaches, e.g. related to computer and network security, several methodologies and tools for the management of vulnerability can be identified and an analysis methodology is proposed. The paper represents the view of a risk analyst and reliability engineer.

Key Words: e-maintenance, e-service, vulnerability, risk analysis, security

1 BACKGROUND

Teleservice, utilizing modern information processing and communication tools, is by now a well-known way of supporting a product, see e.g. [1]. It has been in use a number of years, e.g. in aviation, manufacturing, robotics and also in medical supervision and treatment. In recent years the concept of product support has been discussed in more detail, and the need for the combination of support to product as well as support to client has been clearly identified, see e.g. [2] and [3]. This development can be seen in the emergence of e-manufacturing and related types of e-service, in particular e-maintenance. There is a continuous development of the approach, as well as of related methodologies and tools – technical and organizational. In the book chapter [4] Koc et al discuss the present and future of e-manufacturing systems and e-maintenance. Among other things they point out the risks and vulnerabilities related to utilization of e-services as an important area for further research.

This paper discusses to some extent the vulnerability of the e-maintenance system and its consequences for the managed assets. After having performed a number of literature searches, using information portals such as Scopus, IEEE Explore and Scirus and reference databases such as Inspec and Compendex, I have identified very few research papers directly related to e-services and risk or vulnerability issues. Nevertheless, the problem area is important and has been recognized within neighbouring areas, such as telemedicine [5] and telematics [6].

The aim of the present paper is to briefly discuss the concept of vulnerability. From different risk analysis approaches, e.g. related to computer and network security, several methodologies and tools for the management of vulnerability can be identified. The paper represents the view of a risk analyst and reliability engineer.

2 THE CONCEPT OF E-MAINTENANCE

In the paper [7] Koc and Lee give the following definition of an intelligent e-maintenance system: “Intelligent Maintenance System (IMS) is an internet-based and web-enabled predictive maintenance technology which consists of intelligent machine degradation assessment, e-prognostics, and e-diagnostics to enable manufacturers and customers to have products and production machines with near-zero-breakdown conditions. Remote and real time assessment of machine’s performance information requires an integration of many different technologies including sensory devices, reasoning agents, wireless communication, virtual integration and interface platforms.”

The e-maintenance system consists of several different elements, e.g. sensors, analysing and reasoning agents, communication channels and man-machine as well as machine-machine interfaces. The system can be described by using a hierarchy of levels, from product or process level via system level to global, world-wide, level. Among its functions can be mentioned

- Real-time monitoring of machine behaviour and health
- Fault diagnostics
- Machine performance degradation assessment and prognostics

- Predictive maintenance
- Exchange of information (product/process level as well as system level) via appropriate information networks. This includes the sharing of information related to similar products or processes between different partners and geographical locations.
- Extraction of information from huge amount of data, data mining
- Provide business related decision support to the user, enabling the optimization of asset management

In [3] the concept of e-manufacture has been described and the relation between the e-manufacture systems and e-maintenance systems clarified. The e-maintenance system gives opportunities for the establishment of new types of relationships between the supplier of the product (or service) and the customer, enabling high quality service during the product's entire life.

3 THE CONCEPT OF VULNERABILITY

The broad term dependability covers several aspects of a system's ability of offering service to the user. The formal definition, taken from the International Electrotechnical Vocabulary [8] is "*The collective term used to describe the availability performance and its influencing factors: reliability performance, maintainability performance and maintenance support performance.*" In [9] the dependability concept is further discussed and the dependability concept is described as containing the following attributes:

- availability, i.e. readiness for service
- reliability, i.e. continuity of service
- safety, i.e. absence of severe adverse consequences on user or environment
- integrity, i.e. absence of improper system alterations
- maintainability, i.e. ability to permit repairs or modifications

Closely related to dependability is vulnerability. The concept of vulnerability is troublesome to define, since the definitions used vary widely depending on context and policy. In many of the definitions the phrase "*susceptibility to injury or attack"* can be found in some form. The concept is used to characterize a system's lack of resilience with respect to different threats that may cause loss of availability, integrity or confidentiality. These threats may originate within as well as outside the system of interest. The vulnerability can be manifested in the system of interest as well as in the supporting or enabling systems.

Related to the concept of vulnerability is the concept of *threat*. A threat may be a natural disaster or other natural phenomenon, a failure of a system element, a faulty system state, an unintentional act by an individual, or a malicious act by an individual or a group. When a threat is present, attempting to exploit vulnerability, this is often called an *attack*.

4 VULNERABILITY AND RISK ANALYSIS

In the analysis of risk and vulnerability of a system, the concept of threat is very useful. It can be seen as a generalization of the concept of hazard, or risk source. Within the field of computer security, many papers discuss the concepts of threat and vulnerability. In the paper [10] is referred to the Common Criteria (ISO 15408) Profiling Knowledge Base (CC-PKB). In the general threat category there are 30 threats, presented in table 1. They can be used for the generation of ideas in a vulnerability analysis of different e-maintenance system functions. Not all of them are applicable to all functions, and the list should not be considered as complete.

Table 1. CC-PKB general threats

1. Administrative errors of commission	16. Malicious code exploitation
2. Administrative errors of omission	17. Unexpected disruption of system or component power
3. Hostile administrator modification of user or system data	18. Recipient denies receiving information
4. Administrator violates user privacy policy	19. Sender denies receiving information
5. A critical system component fails	20. A participient denies receiving information
6. Software containing security-related flaws	21. Legitimate system services are spoofed
7. Failure of a distributed system component	22. Hostile user acts cause confidentiality breaches
8. Hacker undetected system access	23. User abuses authorization to collect data
9. Hacker attempts resource denial of service	24. User errors cause confidentiality breaches
10. Hacker eavesdrops on user data communications	25. User error makes data inaccessible
11. Cryptanalysis for theft of information	26. User errors cause integrity breaches
12. Hacker masquerading as a legitimate user or as system process	27. User errors undermine the system's security features
13. Message content modification	28. User's misuse causes denial of service
14. Exploitation of vulnerabilities in the physical environment of the system	29. User abuses authorization to modify data
15. Social engineering	30. User abuses authorization to send data

A system can be attacked by threats in many ways. In the description of an accident or other adverse event as a combination of events and conditions, the different threats can be described as in Table 2.

Table 2. Threats related to different parts of an accident description

Causes	There are many threats that can directly affect the system or system element under study.
Barriers (probability reduction)	Some threats may attack the barriers, safeguards or safety functions, intended to reduce the probability of an incident.
Incidents	The incident is any event, resulting from an attack.
Barriers (mitigation)	In order to mitigate the impacts of an incident, barriers, safeguards or safety functions are often introduced. They, too, may be subject to threats.
Impacts	An attack may have impact directly on the system under study, on the persons involved and on the physical and business environments.

An important difference between commonly performed risk analyses and vulnerability analyses is how barriers or safeguards are taken into account. In risk analyses they are normally assumed to be active while in the vulnerability analyses they are assumed to be subject to threats as well.

Among the risk or vulnerability analysis methods available, special attention should be given to the well-known FMEA (Failure Mode and Effects Analysis) [11], HAZOP (Hazard and Operability Study) [12] and ETA (Event Tree Analysis) [13]. They all propagate from cause to effect, from threat to consequence, taking the available barriers or safety functions into account. However, there is no need for establishing a brand new methodology, with its own acronym. Instead we can use the possibility of combining a number of tools, chosen according to our knowledge and experience. For vulnerability assessment, one possible set of tools or supporting methodologies consists of the tabular Failure Mode and Effects Analysis (FMEA) sheet, the elicitation of requirements/functions of the system under study, the list (possibly augmented) of general threat categories, elements of barrier analysis, and Event Tree Analysis (ETA). These tools or supporting methodologies have to be combined into a methodology which is systematic, easy to document and verify.

Table 3. Tools and supporting methodologies for the proposed vulnerability analysis approach

FMEA sheet	The FMEA sheet is useful for the documentation of the knowledge gained during the vulnerability analysis process. It should include only the appropriate columns. The analysis is preferably restricted to a qualitative one, leaving out the estimation of probabilities and impact values.
Elicitation of requirements and functions	When performing of risk and vulnerability analyses, the system knowledge is of utmost importance. The knowlege representation can be formalized, making use of a function-malfunction analysis [15]. For the system under study, as well as its elements, a comprehensive list of requirements – in particular the required functions – should be compiled.
General threat categories list	The general threat categories list in Table 1 is one of several possible guides for the identification of possible threats and attacks. It should be used as a set of guide-words (cf the HAZOP methodology [12]) to apply to the different requirements/functions.
Barrier analysis	Threats can be eliminated, attacks obstructed, and the impact of incidents reduced by different kinds of barriers or safety functions. [16], [13]
ETA	The impacts of a postulated incident may differ very much according to which barriers are active and also according to other conditions. The various scenarios are possible to describe, using Event Trees, one separate tree originating from each of the identified incidents.

Experiences from earlier practical work and more recent research [14] indicate that a combination of the afore-mentioned tools and supporting methodologies provides a useful methodology for the analysis of vulnerability of e-maintenance systems and also of the assets to be maintained. The proposed methodology can be schematically described by Figures 1 and 2 below.

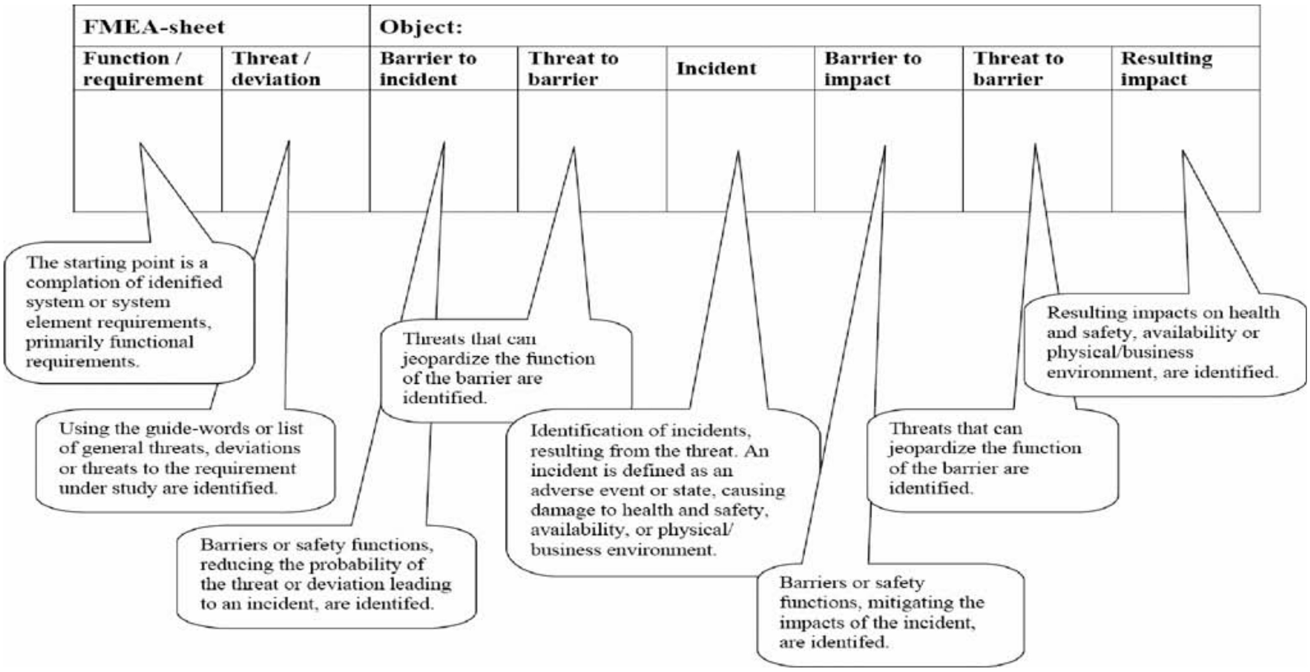

Figure 1. The proposed vulnerabilty analysis methodology

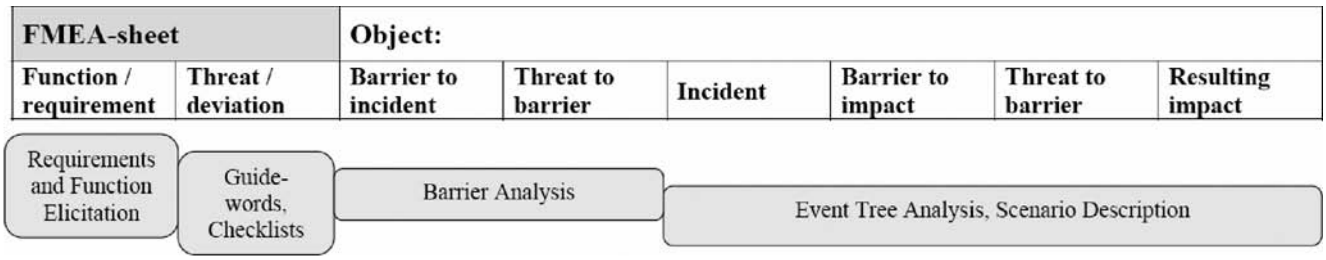

Figure 2. Supporting tools to the proposed methodology

5 CONCLUSIONS

Modern e-maintenance systems, based on the use of information and communication technology, and related assets are subject to many different kinds of threats. The vulnerabilities of the e-maintenance systems, as well as the maintained assets, can be analysed using of existing methodologies and tools. These vulnerabilies should be addressed at an early stage, in the elicitation of requirements on the e-maintenance system. The paper presents one approach, combining a number of well-known tools.

Abstract: For those entering an engineering field for the first time, be it as a research student or industrial practitioner, it becomes quickly apparent that the plethora of academic and popular literature on a subject never paints a complete picture. This is especially true when a field is relatively new. Such is the case for acoustic emission monitoring, particularly when applied to incipient fault detection in rotating machinery. This imbalance causes the uninitiated to perceive AE as the holy grail of incipient fault detection. Conversely, those who in the past tried and failed, condemn AE forever. Whilst newcomers to research or consulting repeat the mistakes of the past as they struggle to make a contribution. This paper moves to restore the balance by discussing some of the problems facing acoustic emission users, as well as suggesting ways forward to overcome present challenges and obstacles.

Key Words: Acoustic emission, condition monitoring, rotating machinery, incipient failure detection, cavitation, slow-speed bearings

1 INTRODUCTION

Success in an academic environment generally depends on having a prolific publication record, particularly in well-recognised journals. This has two relevant consequences to this paper's discussion. Firstly, results need to be published quickly and often. Consequently, many research conclusions are based on very small datasets. The more realistic the experimental setup, the longer meaningful results take to acquire, so data is most often collected from simplified laboratory rigs. Good quality journals carefully scrutinise the submitted work, but in a new field, finding suitably qualified reviewers is difficult. Secondly, data and conclusions are often skewed towards "the good news", whilst contradictory or ambiguous results are explained away or simply ignored. After all, it is basic human nature to promote one's successes and hide one's failures. Positive research outcomes uphold the individual's reputation, promote his or her institution and encourage further funding. Therefore, researchers are naturally reticent to publicize failed hypotheses. Negative or ambiguous results if submitted for publication, are also less likely to be accepted. Unless the work comprehensively and positively disproves a hypothesis, publishers and readers alike can disregard the work with "if only they'd…the outcome may have been different". The consequence is continuously repeated mistakes, slowing the field's overall progress.

Similarly, in the industrial sector, those introducing a new technique or expanding an existing field are often financially dependant on maintaining their intellectual advantage. Mystery equals margin, so to speak. After all, if everyone were to have the same level of understanding, by definition, there would be no experts; therefore no consultants, no patents and no reason to invest in leading edge technology. Therefore, it is in best interests of these experts to keep their knowledge to themselves. Although many publish in popular industry journals (which are rarely peer-reviewed), the content of these articles is heavily skewed towards what they do, rather than how they do it. Again, problems and weaknesses are unlikely to be discussed unless a unique solution is being proposed. Consequently, those starting out take longer to learn the basics (which typically involves significant trial and error). Newcomers are reticent to publicly discuss their epiphanies; more often than not, these revelations are not new to the field, just new to an individual.

A comprehensive review of the AE applied to a range of rotating machines was recently presented in [1] and it is not the intent of this paper to repeat this exercise. Instead, this paper highlights some of the challenges and obstacles facing those attempting to detect incipient faults in machinery components with AE. Unless otherwise referenced, problems and complications are based on the authors' experiences. For the sake of brevity, it is impractical to display the data supporting each of these observations; they are presented to initiate discussion and to raise awareness that certain challenges exist.

2 ACOUSTIC EMISSION OVERVIEW

2.1 Collecting AE signals

Acoustic Emission (AE) is defined as the range of phenomena associated with structure-borne and fluid-borne propagating waves generated by the rapid release of energy from localised sources within and/or on the surface of a material. Typical sources of acoustic emissions include plastic deformation, microfracture, wear, bubble collapse, friction and impacts. When these waves reach the surface of the material they can be detected and measured by acoustic emission sensors (typically piezoelectric devices). Acoustic emission signals are generally only a few microvolts to millivolts in amplitude when measured at the sensing element and range from several kHz to a few MHz. At these frequencies, signals are strongly attenuated in air, so a suitable couplant is required between the sensor and material to ensure signal transmission.

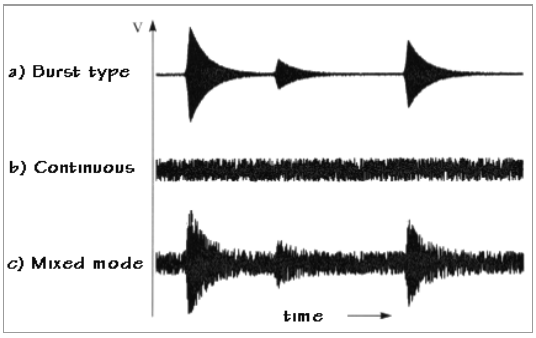

Figure 1: Types of AE signals.

AE pre-processing involves amplification and filtering to refine the bandwidth and avoid aliasing. Signals are characterised as continuous, burst or mixed mode (See Figures 1-2). Burst emissions are typically discrete transients with relatively short decay times and even shorter rise times. Continuous emissions are bursts that occur too closely together to differentiate between individual events, appearing as an increase in the background signal level. They typically have no distinguishing features other than their amplitude and frequency content. As the name suggests, mixed mode AE contains a number of large individual bursts above a background level of continuous emissions. As most AE is broadband, processing is usually done in the time domain.

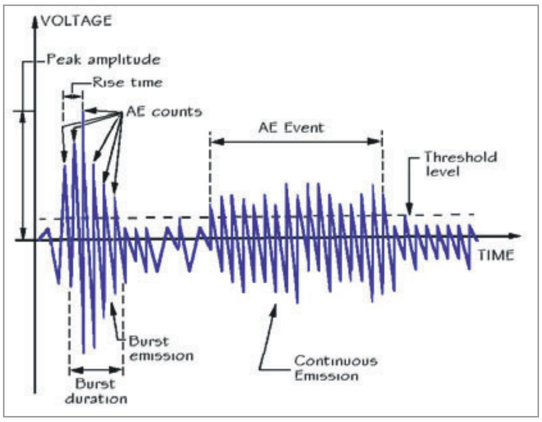

Figure 2: Traditional features of an AE signal.

Hits and events are important concepts to traditional AE signal analysis. A hit is defined as an AE burst that exceeds a certain voltage threshold. Generally speaking, an event occurs when the peak voltage remains above the threshold for consecutive hits. Both hit and event data features are therefore a function of the type and value of the selected threshold. Thresholds are referred to as *fixed*, in which case they are set to an absolute value for the duration of the test (eg. $40dB_{AE}$) or *floating*, where the threshold level is set as a defined amount (a fixed voltage, or fixed number of standard deviations) above the background level. Fixed thresholds are typically used when monitoring static equipment, whilst rotating machinery requires floating thresholds to avoid swamping acquisition hardware when fluctuations in operating conditions cause the background signal level to rise. Unfortunately, the ability of COTS (custom off the shelf) AE hardware to manipulate thresholds is limited. Modern AE systems are theoretically capable of detecting and analysing up to 20,000 hits per second.

Whilst hit features are extracted from a sensor's amplified filtered voltage output, continuous signal descriptors are generally extracted from the signal envelope or from filtered, digitized waveforms. The number of simultaneous waveforms that can be collected depends on the amount of data, which is a function of acquisition rate and resolution, and the acquisition system's digital bandwidth: 4 channels of 16-bit waveform data, collected at 5MHz, will result in 40 megabytes (MB) of data per second. This data must pass across the computer's PCI bus, which currently has a bandwidth of 127MB per second, to the hard disk for storage. Hard disks are typically restricted to writing data at approximately 40MB per second. As a result, undertaking multi-channel AE data acquisition consumes a large proportion of the computing power available in standard desktops and portable computers. It is therefore difficult to perform real-time advanced signal analysis of digitized waveforms, such as discrete-wavelet or short-time-frequency transformation, on unoptimized consumer-grade hardware.

2.2 Processing AE signals

As AE signals travel through a material, they are attenuated, dispersed, reflected and refracted. By comparison with stationary structures, rotating machines are structurally very complex, making interpretation of signals and diagnosis of faults even more challenging than when testing stationary plant.

Depending on the dominant failure mechanism, AE signals collected from rotating and reciprocating machines can be burst, continuous or mixed. Degradation is generally marked by a change in the signal type (eg. continuous to burst), or one or more of its signal features (eg. decrease or increase in burst amplitude). As no two acoustic emission signals are ever the same, most AE processing is strictly statistical. Features, extracted in either hardware or software, are trended over time. Experts peruse the trends for changes and make deductions about the underlying conditions. Due to the signal changes resulting from an AE signal's transmission path, it is particularly important that AE sensors be placed close to potentially faulty components and in the same location from test to test.

Both continuous and burst AE signals from rotating and reciprocating can be highly non-stationary. This further complicates fault identification when using traditional AE approaches. Fortunately, recent work by the first author has shown that this non-stationarity can be managed by grouping data relating to a particular known condition into ensembles and calculating averages for each group. Variability in resulting trends is quantified by calculating confidence limits. Changes in the underlying fault conditions are observed as changes in the mean parameter, and/or its confidence limits [3]. Unfortunately, this process is difficult to do with traditional AE hardware and software.

Neural networks can also be used to find patterns and correlations with the data, and commercial software is available. However, making sense of neural network outputs is not as straightforward as the supplier's brochures might make it seem.

3 GENERIC AE ISSUES

3.1 Signal to Noise Ratio

The most quoted benefit of AE monitoring in the literature is its apparent high signal-to-noise ratio (SNR). This claim is presumably based on its high frequency range when compared to typical mechanical background noise of rotating plant (less than 20kHz). It is true that noise the audible frequency range has limited affect on AE measurement particularly when viewing signals in the frequency domain. However noise refers to more than just extraneous sound. It is defined as any unwanted part of the data set and therefore to ensure valid analysis conclusions, needs to be eliminated (or quantified) at the time of data collection or during post-processing. A variety of techniques have been developed over the past 20 years to denoise condition-monitoring data, with varying degrees of success when applied to AE signals. This is, in part, because what constitutes noise and what is regarded as genuine data changes from one application to the next; thus it is impossible to develop a single set of processing techniques that will be applicable in all situations. As a result, publications relating to noise management tend to be application specific; unfortunately, most relate to traditional AE applications such as crack monitoring.

When collecting acoustic emission data from rotating machinery, noise can originate from some of the following external sources:

(a) Residual, steady background noise from electronic components;

(b) Aperiodic transient events, such as valve activity or electro-magnetic interference (EMI) or radio frequency interference (RFI);

(c) Quasi-periodic transients events that occur approximately the same interval apart, such as rubbing of seals or bearing faults (when not looking for incipient seal or bearing faults);

(d) Low frequency modulation of the background continuous AE level, also common in reciprocating machinery signals or due to misalignment;

(e) Genuine AE from mechanisms not of interest to the analysis being performed.

Separating the wheat from the chaff is problematic and considerable time will be spent analysing data that may in fact have no bearing to the conditions being analysed. Although good acquisition practices can reduce the risk of noise infiltration, there is no way to eliminate it entirely.

Acoustic emission signals, because they are small and weak, are very sensitive to noise ingress. As frequencies get higher, amplitudes tend to decrease and vulnerability to noise contamination increases. Furthermore, certain types of noise only become problematic at higher frequencies. AE signals from rotating machines are even more at risk because they are often collected using broadband non-resonant sensors measuring signals up to 1-2MHz. These are less sensitive that resonant sensors used for structural AE work. Consequently, noise identification, management and mitigation needs to be very carefully considered.

Problems are compounded when machinery is driven by variable frequency drives (VFD). These control the speed of a motor by changing the voltage frequency. Unfortunately, they emit pulses of broadband, high frequency electro-magnetic radiation. This couples to the equipment or AE instrumentation resulting in very large, broadband, impulsive noise bursts superimposed onto AE signals at a switching frequency of 10-500kHz. Noise bursts appear very similar to genuine acoustic emissions, particularly when viewed in isolation (i.e. hit data) and are captured by AE instrumentation as if they were genuine AE hits (See Figure 3).

Furthermore, hydro-mechanical machines such as centrifugal pumps have a number of genuine mechanisms that generate acoustic emissions. Some of these ultimately lead to failure, whilst others are of little consequence and can probably be ignored. Therefore an important part of any fault identification process is separating wanted from unwanted signals. The following key issues relevant to AE machinery monitoring have been recognised or identified [3]:

(a) Current AE hardware does not provide sufficient noise immunity against interference from variable frequency drives. This cannot be removed during post-processing as signals have very similar characteristics to genuine AE events. Therefore, instrumentation source power must be electromagnetically isolated from the VFD.

(b) Electro-magnetic interference (EMI) and radio frequency interference (RFI) often remain after frequency filtering due their very large amplitudes.

(c) Averaging can be used to detect certain noise artefacts in AE signals, such as those associated with exceeding the frequency-amplitude characteristics of on-board amplifiers (a type of clipping). However, a large number of samples per average are required otherwise inadequate resolution in the frequency domain hides frequency peaks.

(d) When analysing continuous AE signals, waveforms must be much longer than individual discrete bursts, so the statistical properties are accurately calculated.

(e) Denoising techniques, such as wavelets (eg. Haar) for waveform data and Swansong filtering for hit features, are very effective at dividing mixed-mode acoustic emission signals into discrete and continuous parts. These can be quantified separately, improving fault diagnosis.

Although adaptive filtering and neural networks have also been applied for segregating specific signals into noise-data components, this paper's authors have not been able to replicate the results for generic signals.

3.2 Hardware Options

In some ways AE hardware is following an evolutionary path well worn by other data acquisition technologies. Traditionally, AE analysis was performed using semi-proprietary systems with 5 or 6 figure price tags. These were primarily designed for structural monitoring and therefore have significant capacity to acquire, characterise and store information pertaining to discrete AE events (i.e. hits). Unfortunately, their capability to capture high-fidelity, high-resolution continuous and quasi-continuous AE signals over an extended duration is severely limited. This was because cheap computing technology was simply unable to process signals quickly enough. As predicted by Moore's Law (which states that the complexity of integrated circuits, the basis of a computer's processing power, doubles every 2 years [4]), over past 10 years data throughput capabilities of desktop PCs have increased a thousand fold and current variants are able to manage several streams of AE waveform data simultaneously. Therefore, it is now possible to continuously monitor AE activity for all speed and load conditions. Outputs can also be feed into DCS (4-20mA) systems [5, 6].

Although handheld "AE" acquisition hardware has been around for some time (in the guise of SPM, SEEPens, Holroyd Memo etc) their functionality was very specific and relevant to particular applications. All were proprietary and as reported in [7] none of these are interchangeable or directly comparable. Fortunately, these technologies are now maturing and more generically capable options are slowly becoming available.

On the horizon, we start to see the next evolution: smart sensors that understand what they are looking at and report their understanding on the state of the equipment, rather than streaming raw data to a host computer for analysis. This facilitates a much more comprehensive and widespread application of AE monitoring. Unfortunately, squeezing a multi-megasample signal processor into a matchbox, running it from batteries and returning the data, is not a simple challenge. Especially when faced with a duopoly of AE equipment manufacturers with a significant investment in traditionally styled hardware. Nevertheless, a Perth company is currently developing this new form of AE technology. Their system involves developing smart, self powered, sensors that report back AE information and its implications over low speed, wireless and internet links. Signal processing requirements are uploaded to the sensor for each application, allowing their use in a wide variety of applications. Targeted at ad-hoc and remote installations, this technology will allow the implementation of scalable AE systems that will integrate into existing SCADA and CBM software.

3.3 Processing Options

Most investigators apply AE technology for one-shot analysis and/or time-based trending, and rely heavily on measurements being collected under the same process conditions. This approach can be fraught with errors as AE varies significantly with most operating variables relevant to the machine (eg. flow, load, temperature, pressure etc). On variable speed and load machines it is particularly difficult to take consistent results. Yet even with consistent duplication of test conditions, one-off testing is not suitable for fast-developing faults, or intermittent problems inexorably intertwined with the machine's operating conditions (eg. seal degradation due to intermittent flashing of the fluid). In these situations, continuous monitoring and real-time (or near-real) processing is the only viable option. Unfortunately, COTS AE systems are poorly suited to this task, particularly if waveforms are to be collected (rather than RMS) for advanced analysis. Fortunately, it is not impossible [5, 6].

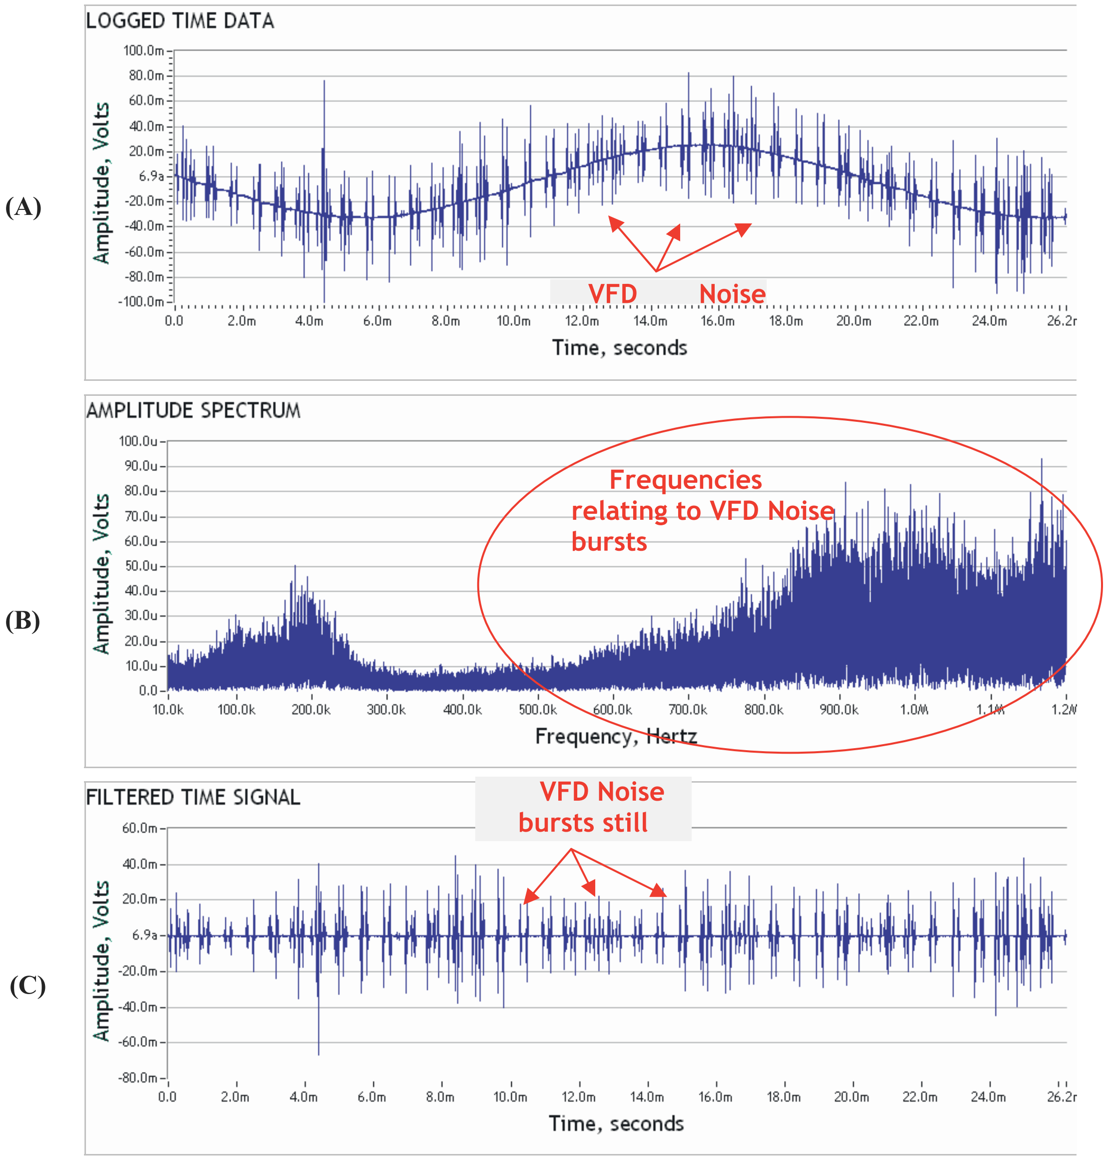

Figure 3: Effect of frequency and wavelet filters on pump AE signal corrupted by a 100Hz frequency sinusoidal signal and high frequency impulsive noise, latter emanating from a VFD. (a) Original time signal, (b) FFT, and (c) 10kHz –1000kHz bandpass filtered.

Traditional AE software packages were designed for structural AE work; their analysis and graphing capabilities are inadequate for condition monitoring. Not only is difficult to suitably digest the data (eg. ensemble averages, confidence limits), time-based graphing functionality is often limited. Each day of continuous monitoring can result in gigabytes of raw data. This volume of information cannot be analysed manually. Very quickly, even accompanying process data and setup conditions become difficult to track. To overcome the limitations of COTS software for continuous applications, a data-driven management system was presented in [5]. The approach is based on a relational database, and has no inherent functional limitations on number of channels, tests or post-processing routines. The number of concurrent users (analysing data) depends primarily on the database management software. Millions of data points can be analysed as desired, with auditable rigour, and minimal manual intervention.

4 APPLICATION SPECIFIC ISSUES

4.1 Rolling Element Bearings

Hertzian contact stress, induced by the relative rolling action of the bearing elements in contact with inner and outer races, and rubbing between damaged mating surfaces within the bearing generate a number of different failure modes. These include flaking, brinelling, fluting, spalling, pitting and seizures. Whilst vibration monitoring, the traditional technique for rolling element bearing fault detection, measures the response of the structure to the developing fault (eg. a change is surface roughness, clearance reduction, developing spall), AE sensors measure the actual degradation mechanism itself.

Therefore it is not surprising that literature extensively reports AE as offering superior early detection capabilities over vibration analysis for bearing faults [8-14]. At low bearing speeds (less than 100rpm), where vibration energy transmitted is small, AE is particularly effective [15-18]. An increase in hit counts is the most commonly reported change with developing outer race defects although the peak amplitude of periodic bursts (at the outer-race frequency) has also been interrogated successfully. Interestingly, although most work rules in favour of AE over vibration for early detection, some contrary reports have been published, particularly when monitoring higher speed bearings [16, 19]. This may be because collective results show that AE counts are sensitive to the level and grade of lubricant within the bearing [20-22], whilst amplitude if affected by speed. Hit features are also dependent on the threshold selected and operating speed (the higher the bearing frequency, the higher the hit rate) [8, 23]. Collectively, these problems make it particularly difficult to identify the origins of a defect using AE hits, although a variant of the standard count parameter has been successfully employed for bearing diagnosis [8]. For most applications however, a multi-feature approach is probably required to successful diagnose outer-race defects using AE.

Due to the sensitivity of AE to surface roughness, recent work has found that defect lengths can be estimated from the AE signal [12, 24]; defects generate AE bursts, the amplitude and duration of which is proportional to defect depth and length respectively (see Figure 4). This information is not obtainable with traditional condition monitoring techniques.

The same overwhelming success has not been reported for inner race defect detection. It has been concluded that emissions from inner race defects are not of sufficient strength/energy to be detectable above the operational background noise [11]. This is probably because of the complex, continuously varying transmission path between the inner race defect and sensors mounted on the bearing casing. The result is an attenuated and amplitude-modulated AE signal (at multiple frequencies rather than just the defect frequency) that complicates diagnosis.

More recently, frequency analysis of AE signals (or demodulated AE) and other advanced techniques have been used to improve defect identification in both inner and outer races. These include autoregressive coefficients, Point Process Spectral Averaging, adaptive noise techniques and pattern recognition analysis. Although, none of these techniques are currently being applied beyond the instigating research institution, this will inevitably change in time.

Proprietary “black box” devices for monitoring bearings, based on a form of AE (called stress wave or high frequency resonance analysis), have been available to industry since the 1970s. To improve detectability, these devices use the transducer’s natural frequency to amplify the signal, later removing this carrier frequency through some form of demodulation. Some systems require a proprietary sensor, whilst others use a generic accelerometer. Systems that necessitate their own sensors claim that the resonant response has been carefully “tuned” to the resonant frequency of the bearing, yet interestingly these frequencies vary from 30 kHz to several hundred kilohertz. Fortunately, impulsive events and lubrication breakdown tend to induce broadband excitations, so will most likely be detected equally well by any of the systems. Although they have been used for some time now, numerous formal and anecdotal reports indicate problems acquiring repeatable and reliable results with these technologies. This is because system outputs often (but not always) depend on equipment load, sensor location and experience of the user. Furthermore, under some fault conditions, background levels increase swamping any increase in impulsive events that form the basis of black box outputs. Unfortunately, not all devices automatically account for changes in operating conditions, requiring the user to interpret the data accordingly. More details on these devices are given in [7]. A recent study reports that traditional AE analysis offers earlier detection of bearing faults than shock pulse (a stress wave variant) monitoring, both of which offering better detection that vibration analysis [13].

Finally, it should be noted that most results on the applicability of AE to bearing monitoring have been performed under laboratory test conditions designed to reduce the effects of background noise. In industrial applications signals will be more complex and in some circumstances advanced denoising techniques may be required. However as [25] describes, adequate indication of incipient failure is still possible in the presence of noise.

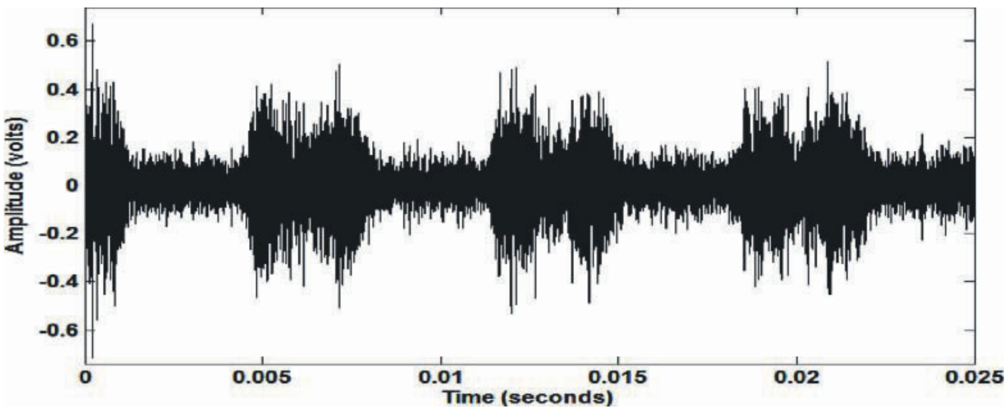

Figure 4: Duration of AE bursts is indicative of the outer race defect length [16]

4.2 Mechanical Seals and Journal Bearings

Lubrication and wear is a major problem for many machinery components, particularly bearings and seals. Collectively, work relating AE signals to wear seems comprehensive. Relationships have been established between many AE parameters and wear variables, including type of wear, rate and volume [26-32], although not all researchers have equal success quantifying all variables. AE has also been shown as very sensitive indicator of lubrication conditions and changes in lubricant properties [21, 22, 28].

Industrial studies have successfully shown that AE is an effective technique for detecting incipient failures of mechanical seals [33-37] with fluctuations in AE energy features relating to instability in the lubricating film. Leakage, dry running and cavitation in the seal gap have also be detected using acoustic emission [33, 35]. Some researchers also determined that acoustic emission variations coincide with torque and temperature variations [34]. Unfortunately, a number of contradictory reports have been published. Presently, the development of a robust detection and prognosis system for mechanical seals is being thwarted by difficulties in generating failures in a controlled, but realistic, environment [3, 38, 39].

The high sensitivity of AE to wear also leads to potential difficulties in interpretation. It is widely reported that AE signals in wear tests on various component types are significantly higher on start-up whilst the surfaces faces “bed-in” [27, 35]; if a test is paused and restarted, signals generally return to their previous levels [40]. In the authors’ work on mechanical seals however, this “bedding-in” process has been observed occurring repeatedly throughout seal’s life without any cessation of operation, probably due to minor changes in process conditions that cause the faces to adjust their relative positions; when the seal was subsequently removed for inspection, no faults or abnormal wear was detected. On other occasions when the seals were left in service, these increased AE levels eventually dropped [3]. Another complication reported with AE seal monitoring, is that some failure modes result in a decrease in the signal amplitude or energy, contrary to expected trends [31, 34, 35]. This may be due to an increase in the lubricating film causing leakage, but decreasing wear and thus AE levels. Alternatively, in certain ceramic materials (from which many modern mechanical seal faces are fabricated), high temperatures initiate the formation of an oxide layer. When this occurs, AE levels have been observed to decrease, despite an increase in wear rate [31]. As most AE wear studies have been undertaken in laboratories with metal on metal samples, the application of results to ceramic seal faces in industrial machines must be undertaken with caution. Fortunately, one or two studies using ceramic materials have been performed, with positive outcomes [3, 29], so incipient failure detection of modern seal faults is certainly realisable. In a practical environment, consideration regarding the positioning of sensors is also required, as AE transducers located on the seal or pump housings will transmit AE signals generated by the pumpage [3].

Interestingly, although the application of AE monitoring to journal bearing degradation is perhaps the most obvious application for the technology in rotating equipment management, it is also the least investigated. Difficulties arise in locating AE sensors sufficiently close the bearing. Additionally, journal bearings are often used in high-speed machinery, where harmonics of traditional mechanical faults (eg. gear mesh frequency) intersect the AE bandwidth and thus can be difficult to remove. Nevertheless, some successes with journal bearing monitoring have been reported [41, 42].

4.3 Gearboxes

In gearboxes, sources of AE include tooth cracking, gear wear and lubrication breakdown [43-46]. Both crack initiation and propagation has been successfully detected, using a variety of traditional and advanced AE signal analysis, and precedes fault identification with traditional monitoring techniques. Gear pitting and cracking has also been detected on individual teeth [45-47]; AE parameters generally increase with pit size. Again, AE appears capable of faults prior to either vibration or wear debris analysis and various failure modes can be differentiated [48]. Unfortunately, under non-isothermal conditions as present in a normal bearing, energy and amplitude features are also affected by load and speed [40, 49], which may complicate diagnosis in an industrial environment; these features do not change when temperature is kept constant [44]. Diagnosis is also more difficult at extremely high speeds [45] or when testing normalised gears [47]. It has also been reported that AE bursts disappear after a defect is established [50]. A similar effect is commonly reported when monitoring AE levels from rolling element bearings due to the disappearance of impulsive events into an increased background level.

Another major drawback is the difficulty of placing AE sensors close to the region of interest. Attenuation in a gearbox can be significant due to the large number of individual interfaces and potential transmission paths [45]. Consequently, researchers have placed AE sensors on the rotating gear and employed a slip-ring to record activity from the rotating sensor [43, 44]. A comparative analysis of the placement of the senor on the rotating gear and the bearing pedestal showed much greater sensitivity on the rotating gear. Consequently, the development of miniature AE sensors with telemetric capabilities will have a major impact the feasibility of AE fault detection for various types of rotating plant.

4.4 Pump Monitoring

Unfortunately, attempts to detect incipient component faults in centrifugal pumps using acoustic emission testing have been complicated by the sensitivity of AE to its operating state [51]. The event of bubble collapse results in release of AE energy and the application of AE to early stages of cavitation has been well documented [51-56]. Once cavitation progresses, AE levels generally drop [57] due the attenuation of signals by large vapour pockets. This effect is more pronounced in larger pumps. Trends at smaller flows seem less consistent, perhaps due to the combination of recirculation and cavitation that results in more complex bubble dynamics. Others have reported that AE signals from cavitation can be differentiated from signals measured under low-flow recirculation and best-efficiency point conditions [53, 58]. Increases in AE signals at low flow, presumed to be from recirculation, may be more significant than changes at high flows [52]. Researchers disagree whether signals are affected by sensor location on the pump [52-54, 56]. This may be because pumps are not equally prone to recirculation, which is the condition that can probably only be adequately diagnosed by mounting sensors on the suction flange [52]. However, more work is required to confirm this hypothesis.

Although not as widely studied as cavitation detection, flow changes under normal suction conditions have also been detected with AE [52]. Results from pump performance tests showed that, particularly in large pumps where hydraulic changes are significant, various AE energy features can be very effective for detecting movement away from best efficiency flow. Unfortunately, results from smaller pumps have been less conclusive, particularly at low flows, probably due to the relatively small changes in hydraulic energy across the range of flows, and consequent sensitivity to the testing process. However, even in these pumps, consistent patterns in hit energies were observed. This suggests that a generic monitoring technique for all pumps may be possible with AE, although more work is required to verify this hypothesis.

A complication is discriminating between collapsing bubbles at pump surfaces and those occurring in the middle of the cavity (and therefore not likely to cause damage). It is generally accepted that bubbles releasing only small amounts of energy are not problematic. Yet large number of small energy events will cause background AE level to rises swamping any underlying problem. Acoustic emissions from other fault mechanisms can also complicate diagnosis, although the converse is more likely. Fortunately, advanced filtering and signal processing techniques can be applied to extract pertinent information from, and/or uncover hidden trends in the AE signal (see Figure 5).

Another challenge that needs to be managed is the large dynamic range required of measurement instrumentation; signal amplitudes can increase by 60-80dB under cavitation or recirculation, as compared to conditions around best efficiency. Therefore if equipment is selected to detect small changes during normal operating conditions, extreme flows will swamp electronics causing unusual artefacts in the digitized signal, leading to possible misinterpretation of data. Even software has difficulty representing both extremes with adequate resolution. In some large pumps, very small deviations from best efficiency cause signal clipping, which easily goes unnoticed. Baseline values from pump to pump can also vary by 40-60dB, requiring the AE user to hold a variety of sensors and preamplifiers.

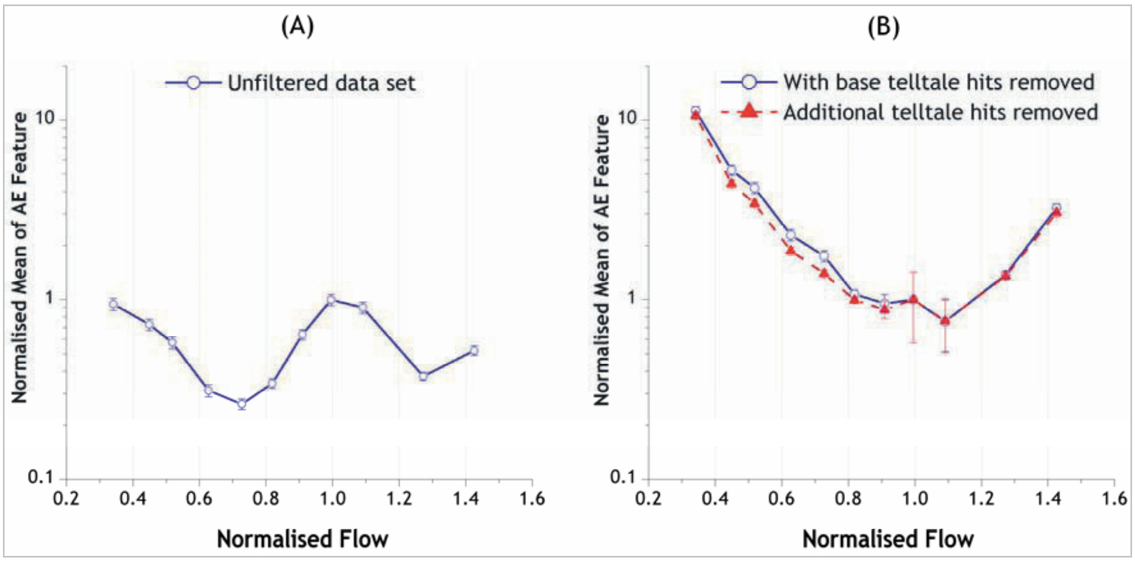

Figure 5: Improved trending is obtained by advanced filtering techniques. (A) Shows an AE feature versus flow without filtering, whilst (B) shows the same feature after filtering. In both cases data has been normalised with respect to the mean feature value at BEP. (Vertical lines indicate 90% confidence limits, which increase because little data remains after filtering.)

4.5 Reciprocating machinery

AE monitoring has been applied successfully to the detection of valve leakage in reciprocating compressors [59] and a hand-held or online device using externally mounted AE sensors is now available to industry. Interestingly, although piston and rider ring wear would seem to lend itself to AE monitoring, no work in this area has been reported. This may change with the advent of cheap, wireless sensors that facilitate mounting on the piston itself.

The application of AE to engine monitoring (both diesel and internal combustion variants) is currently one of the most active research areas. Traditional analysis involved measuring RMS trends and comparing them to known-good conditions. Sources of AE that have been successfully detected include problems with valves or injectors, piston ring with cylinder liner interactions, lubricant flow and/or blowby, as well as the combustion/compression process itself [60-68]. Different failures modes occur at varying times during the engine's cycle, which helps diagnosis [69].

Although the authors have no personal experience with engine AE monitoring, one of biggest issues reported in literature involves discriminating the various AE sources. Thus researchers are actively investigating advanced signal processing techniques and source location algorithms that will better segregate and/or identify faults. Neural networks are being widely applied for detecting and diagnosing faults in diesel engines. In general, acoustic emission is reported as having superior detection capabilities over traditional monitoring technologies for a variety of failure modes. However, neural network classification success is generally improved when a variety of sensor types are used [69]. The outputs of these pattern recognition algorithms also lend themselves to automated faultfinding, which is required prior to widespread industrial application. Detecting fault conditions amidst a high background levels or when faults result in smeared signals, is also challenging. Again, this is currently being tackled with research into the application of advanced signal processing algorithms.

The ability of acoustic emission monitoring over traditional methods for detecting certain will ensure that AE will ultimately be integrated into mainstream engine monitoring systems, however due to the processing challenges, this may take some time.

5 CONCLUSIONS

Although AE may have failed to deliver in the past or may not be living up to current expectations, progress is continuing. With research effort and industrial experience, challenges are being overcome and problems are finding solutions. AE may never the single answer to all monitoring applications, but nor is any other technique. Good engineering is about finding the right tool for the job. In many applications, such as journal bearing wear, slow speed bearing faults, mechanical seal degradation and engine monitoring, viable alternatives simply do not exist. Consequently, acoustic emission analysis will play an increasingly important role.

Relating AE signals to their originating sources is a challenge for all machinery monitoring applications. The AE community is still far from accurately predicting responses to theoretical AE sources on static structures, much less for the complex shapes of typical rotating plant. It is therefore inevitable that problems in interpretation and false diagnoses will occur for some time to come. Error will be reduced when sensors can be placed close to the faults; multiple sensors in some form of virtual array will facilitate mathematical or deductive source location. For this, we need small, cheap, wireless transducers with wide dynamic range and inbuilt analysis functionality. Until then, good engineering judgement, as well as a better dissemination of problems and solutions, is fundamental to ensuring analysis of AE data is robust and reliable.

A FRAMEWORK TO ASSESS DATA QUALITY FOR RELIABILITY VARIABLES

M.Hodkiewicz[1] P.Kelly[2] J.Sikorska[3] & L.Gouws[4]

[1]. University of Western Australia [2]. CASWA Pty Ltd [3]. IMES Group Ltd [4]. Melikon Pty Ltd

Abstract: This paper presents a framework for assessing the impact of the data collection process on the validity of key measures in reliability. The quality of data is affected by many organisational and behavioural factors. The aims of developing this framework are to (1) identify inputs/steps that have the most significant impact on the quality of key performance indicators such as MTTF (mean time to failure) and MTTR (mean time to repair), (2) identify 'weak' links in the data collection process, and (3) identify potential remedial actions. Development of this framework will assist the understanding of assumptions used in reliability calculations and improve the quality of underlying data and the data collection process. Consequently, this is a vital step in the continued development and use of data based decision-making models for reliability assessment.

Key Words: Data collection, Key performance indicators, reliability assessment

1. BACKGROUND

Engineering Asset Managers rely on data to support decisions. There has been little published work on how to assess the quality of maintenance data and its fit-for-purpose to support decisions. This problem is compounded by ambiguity over who is responsible for assuring data quality and appropriate use of the data.

The quality of the data is dependent on various attributes including timeliness, accuracy, relevance, completeness and accessibility [1]. There is currently no widely accepted methodology for (i) assessing the quality of maintenance-related data, (ii) confirming that data is fit-for-purpose or (iii) identifying and managing changes to the data collection, storage and use system. Many of the typical problems affecting data quality are discussed in the case-study based work of [2] and the experiences of [3] in the establishing of the OREDA project.

Previous work has identified three key elements required for data quality: knowing-what, knowing-how, and knowing-why. It also suggests that there are three roles associated with the data process: data collectors, custodians, and consumers [4]. This research work also showed that data quality is highly dependent on data collectors knowing-why.

For equipment maintenance and reliability data, the data collector is predominantly a maintenance or production technician. The custodians are the IT support staff responsible for managing various enterprise databases and systems, whilst the main data consumers are (i) reliability engineers who use the data during the determination of long-term maintenance strategies, and (ii) maintenance engineers and maintenance supervisors who use the data when addressing day-to-day maintenance issues.

The framework described herein emphasises the importance of communication between data collectors and consumers, not only about the use of the data but also the implication of poor quality data on the business process.

2. THE 8 STEP PLAN

A framework for evaluating data requirements is depicted in Figure 1.

Step 1: Identify the business need

Quality data is simply defined as "data that is fit for purpose" [4]. Therefore it must, by definition, be assessed in the context of a specific business need (its purpose). After all, multiple consumers of a particular set of data may use it for different purposes and therefore data that is of sufficient quality for one user may not be appropriate for another. Consequently, before any data quality improvement process can be initiated, there must be a clear understanding of the business decisions that must be supported by the data. We describe this as a context-oriented approach to data quality.

Business needs will generally be defined using words such as "measure", "quantify", "improve", "reduce" or "control". To control and improve a business process, its status first needs to be determined and methods to measure the effect of changes then determined. The word "measure" and its various synonyms imply an inherent data requirement.

Step 2: Identify the metrics that will meet the business need

Once a business need has been identified it is possible to determine what metrics can be used to meet that need. Some of the most common Reliability-Availability-Maintainability (RAM) metrics include mean time to failure (MTTF), mean time between failure (MTBF), mean time to repair (MTTR), availability, reliability, logistical delay time and a variety of maintenance related costs.

In addition to identifying what must be measured, it is also important to identify the level of accuracy required and the frequency at which the metrics are to be recalculated (eg. once a month, once a day, 1000 times per second etc). Again, these are context specific issues.

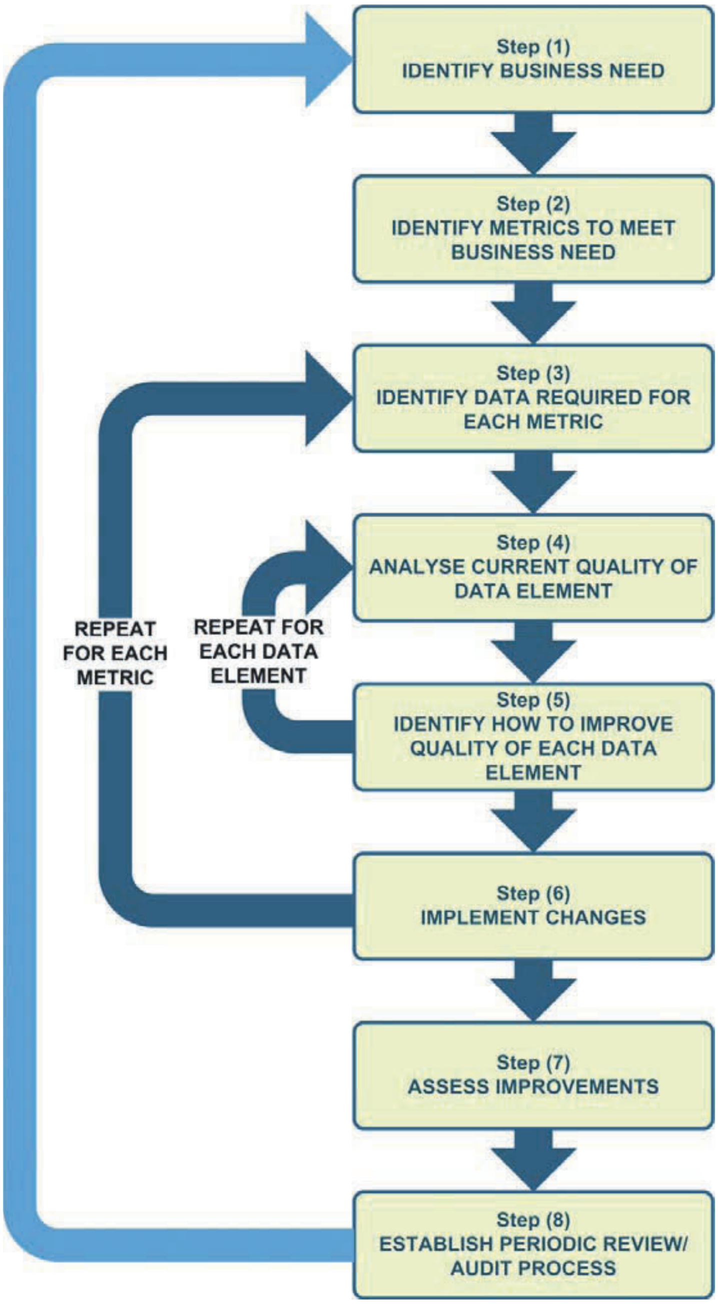

Figure 1: Framework assessing and improving maintenance data quality

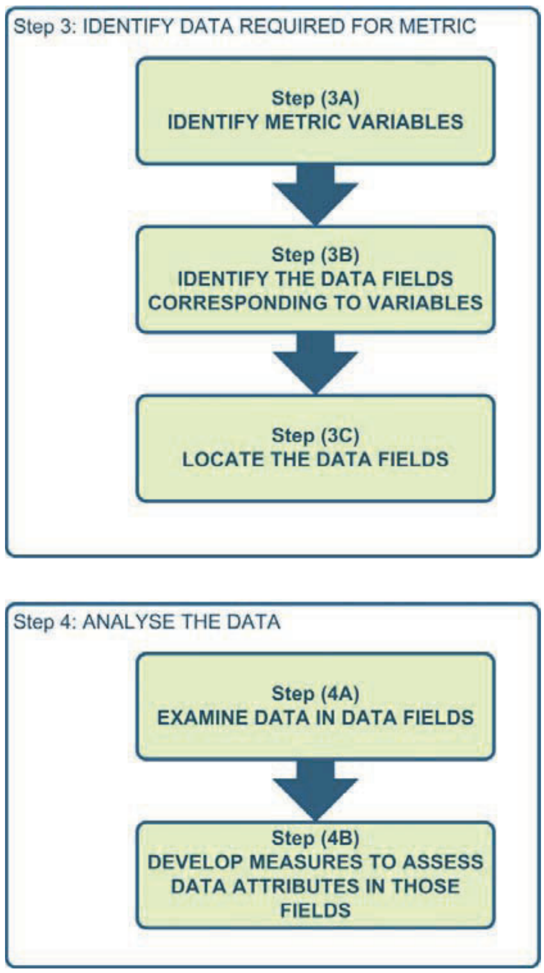

Figure 2: Breakdown of Step 3 and Step 4

Step 3: Identify the data required for each metric

Having selected the metrics, the data required to produce them to the required level of accuracy can be determined. In practice, this actually involves three steps, as illustrated in Figure 2.

A: *Identify metric variables*. By implication, metrics involve some changing variables or dependencies. It is therefore important to identify what the variables are, and how often they need to be acquired.

B: *Identify the data fields that correspond to variables*. Does the variable correspond to a single data field in a database or single gauge to be inspected, or must it be deduced from a number of sources? As the number of data sources increases, so does the risk of error, especially when data is collected manually.

C: *Determine where and how the data is stored.* Data required for RAM analyses is stored in a variety of formats and locations, including equipment databases, computerized maintenance management systems (CMMS) and/or associated ERP systems, spreadsheets, paper records and/or the memories of maintenance and operations personnel. In this paper, we will collectively refer various software systems as Asset Management Databases (AMD).

Step 4: Analyze Data

Once the data has been sourced, its context-specific quality can be assessed. Again, this step can be divided into two smaller steps, shown in Figure 2.

Data sources first need to be manually examined and the current contents qualitatively assessed. *Are the fields full or empty? Is a field codified or free-text? Do the fields contain data relevant to the problem?* This overview influences the development and/or selection of more specific questions for more comprehensive quantitative assessment.

It is suggested that context-specific questions be formulated to collectively determine the following:

Is the data accurate? (Intrinsic data quality)

Is the data appropriate to the business need? (Contextual data quality)

Is the data represented appropriately? (Representational data quality)

Is the data accessible but secure? (Accessibility data quality)

The second step is to develop measures to assess data attributes for the data fields. Required attributes for each of these categories are given in Table 1. The structure and nature of the questions should be dependent on the data variable under investigation and its context. Wherever possible, questions should be designed to elicit a quantitative response. Answers can then be viewed individually and/or as weighted sums, resulting in an overall score of data quality for that particular field.

Table 1: A conceptual framework for data quality (Adapted from [1])

Data quality category	Attributes	Explanation
Intrinsic (Does the data have any inherent quality in its own right?)	Believability	Real and credible
	Accuracy	Accurate, correct, reliable, errors can be easily identified
	Objectivity	Unbiased and objective
	Reputation	Reputation of the data source and data
Contextual (Is the data appropriate to the business need?)	Relevancy	Applicable to task at hand, usable
	Timeliness	Age of the data is appropriate to the task at hand
	Completeness	Breadth, depth and scope of information contained in data
	Appropriate amount of data	Quantity and volume of available data is appropriate
	Value-added	Data gives a competitive edge, adds value to the operation
Representational (Is the data represented appropriately?)	Interpretability	Data are in appropriate language and units and data definitions are clear
	Ease of understanding	Easily understood, clear, readable
	Representational consistency	Consistency formatted and represented, data are compatible with previous format
	Concise representation	Concise, well organized, appropriate format of the data
Accessibility (Is the data accessible but secure?)	Accessibility	Accessible, retrievable, speed of access
	Access security	Access to data can be restricted, data is secure.

Step 5: Identify how to improve the quality of each data element

It is likely that respondents will give very different answers to the data assessment questions posed in the previous step. Ultimately, it will be up to the data consumer to decide whether a piece of data is “fit for purpose”.

Where the data is not fit for purpose, the first step is to meet with the collectors of the data to understand why this is so. One of the greatest reasons for erroneous data is a lack of understanding or appreciation by data collectors on the quality requirements for a piece of data.

Step 6: Implement changes

Unfortunately, a data quality audit will probably result in the identification of more problems than can reasonably be resolved within available timeframes and/or budgets. Therefore, it is suggested that improvements be prioritised based on the complexity of the change required, and the aggregated error caused by data in its present form on the metric and business need(s). A Pareto chart is a good tool to help visualise the changes and decide where time and money should be invested.

Step 7: Assess improvements

By revisiting *Step 3* and using the same measures of data quality, it is possible to express the success or failure of *Step 6* quantitatively.

This (and the next) step require a long-term focus as there may be a significant delay required to allow a meaningful amount of data to accumulate after changes have been made. One of the benefits from *Step 7* is the confidence of having hard data to support “the cause” of improving data quality in the organization.

Step 8: Establish periodic review/order process to verify how well business need is being met.

By periodically reviewing the metrics required to meet the current business needs the relevance of the data is maintained. Realistically, if *Step 7* is to be considered difficult and rarely implemented, then this stage acquires a mythical status. The reality however, is that business requirements change for non-engineering reasons. For example, a decision is made to run the plant at minimum cost, or to ensure availability for a critical period. Or maybe a new CEO is appointed. As mentioned in *Step 5*, the most important people to keep abreast of current business needs and corresponding data requirements are the data collectors; improving their understanding has a profound follow on effect.

3. APPLYING THE 8-STEP PLAN TO ASSET MANAGEMENT DATA

This process described above will be illustrated using one common metric, *Mean Time to Failure*.

Step 1: Define the business need

For the purposes of illustrating the process we are going to assume that the following business need has been defined by a refinery's management team:

"To measure and improve reliability of rolling element bearings in refinery centrifugal pumps."

Step 2: Identify the metrics

The selected metric is: Mean time to failure (MTTF) of bearings in pumps

Step 3: Identify data required

MTTF= Total number of bearing operating hours / Total number of bearing failures

In a perfect system from which only MTTF would ever be calculated, each bearing failure event would have (a) a single unique designator classifying its failure completely (i.e. pump bearing failure), and (b) the age of the bearing at the time of failure. Unfortunately, data storage systems do not always record this information directly. Instead, failure classification or operating hours needs to be deduced from a number of fields, as shown in Figure 3. If age at failure (operating hours) is not available, the date of failure and date of installation are often used instead. Data requirements for this bearing example include the functional location (or equipment number), failure mode (i.e. bearing failure), failure type, event date/time and operating profile. Operating profile is helpful because it can be used to explain extraordinary events (i.e. data outliers) that may not reasonably represent the life of bearings at the refinery, but can significantly skew results.

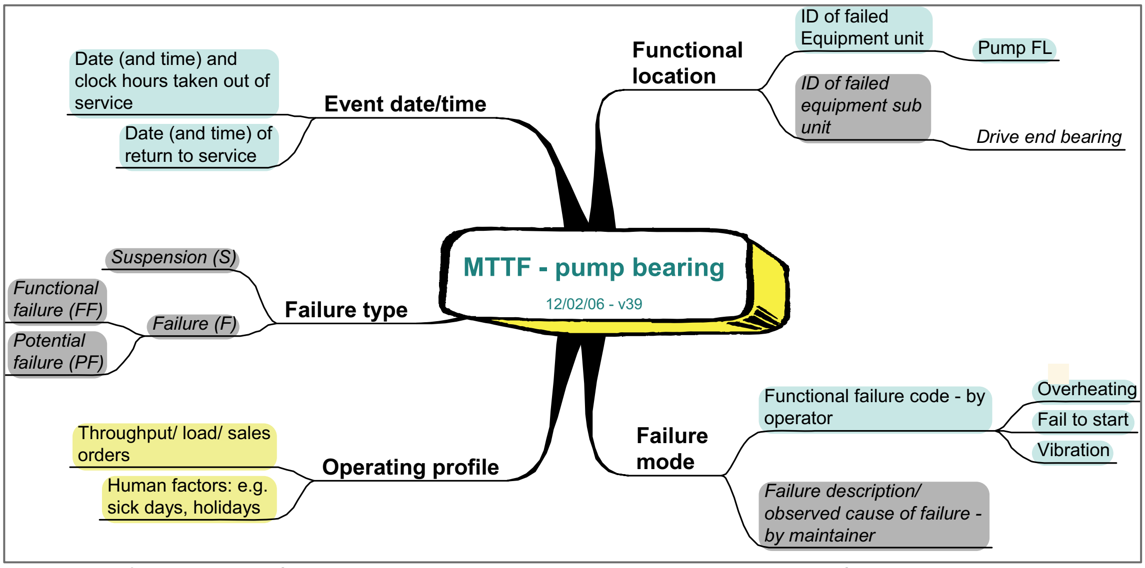

Figure 3: Example of the data required to calculate the MTTF metric for a pump bearing

In Figure 3, the font format (normal/italic) and box colour (grey, yellow, blue) is used to indicate the 'data collector'. In the context of this example,

The operator/ production technician (normal font, blue box) records the date the pump is removed from and returned to service, the functional location of the pump, and the functional failure code. This code identifies 'why' the unit was removed from service.

The maintainer (italic font, grey box) identifies the maintainable item that is the cause of the equipment being removed from service, in this case, the bearing. Further information is then required to describe the failure; example codes are provided in ISO 14224 [5]. Another vital piece of data is to identify if the maintainable item is a *functional failure*, *potential failure* or *suspension*. For this example, a *functional failure* occurs if the bearing has failed causing the pump to shut down. If the bearing is damaged but still functioning at the time of removal, this is described as a *potential failure*. A *suspension* is used to describe the situation when the bearing is replaced in the course of a pump overhaul, when the bearing is still functioning. This may occur if the pump is removed from service to replace a mechanical seal or rebuild the wet-end. The recording of suspensions is vital for the accurate estimation of MTTF. For example, if one pump operating from 1000 hours experiences 2 bearing failures and has a further 2 functioning bearings replaced during replacement of mechanical seals, the true MTTF (accounting for suspensions) is 500 hours. If the suspensions are incorrectly counted as failures, the calculated MTTF is 250 hours. Therefore, omitting the suspension/failure distinction can result in a dramatic under-estimation of the bearing MTTF.

The operating profile (normal font, yellow box) comes from neither the operator nor maintainer. It may include, but is not limited to (1) indicators of the load on the equipment, for example, plant throughput, equipment load, sales orders, (2) the conditions of operation, and (3) who operated the unit. This information is likely to reside in databases outside the CMMS which can be accessed through data warehouses, reports and other IT solutions.

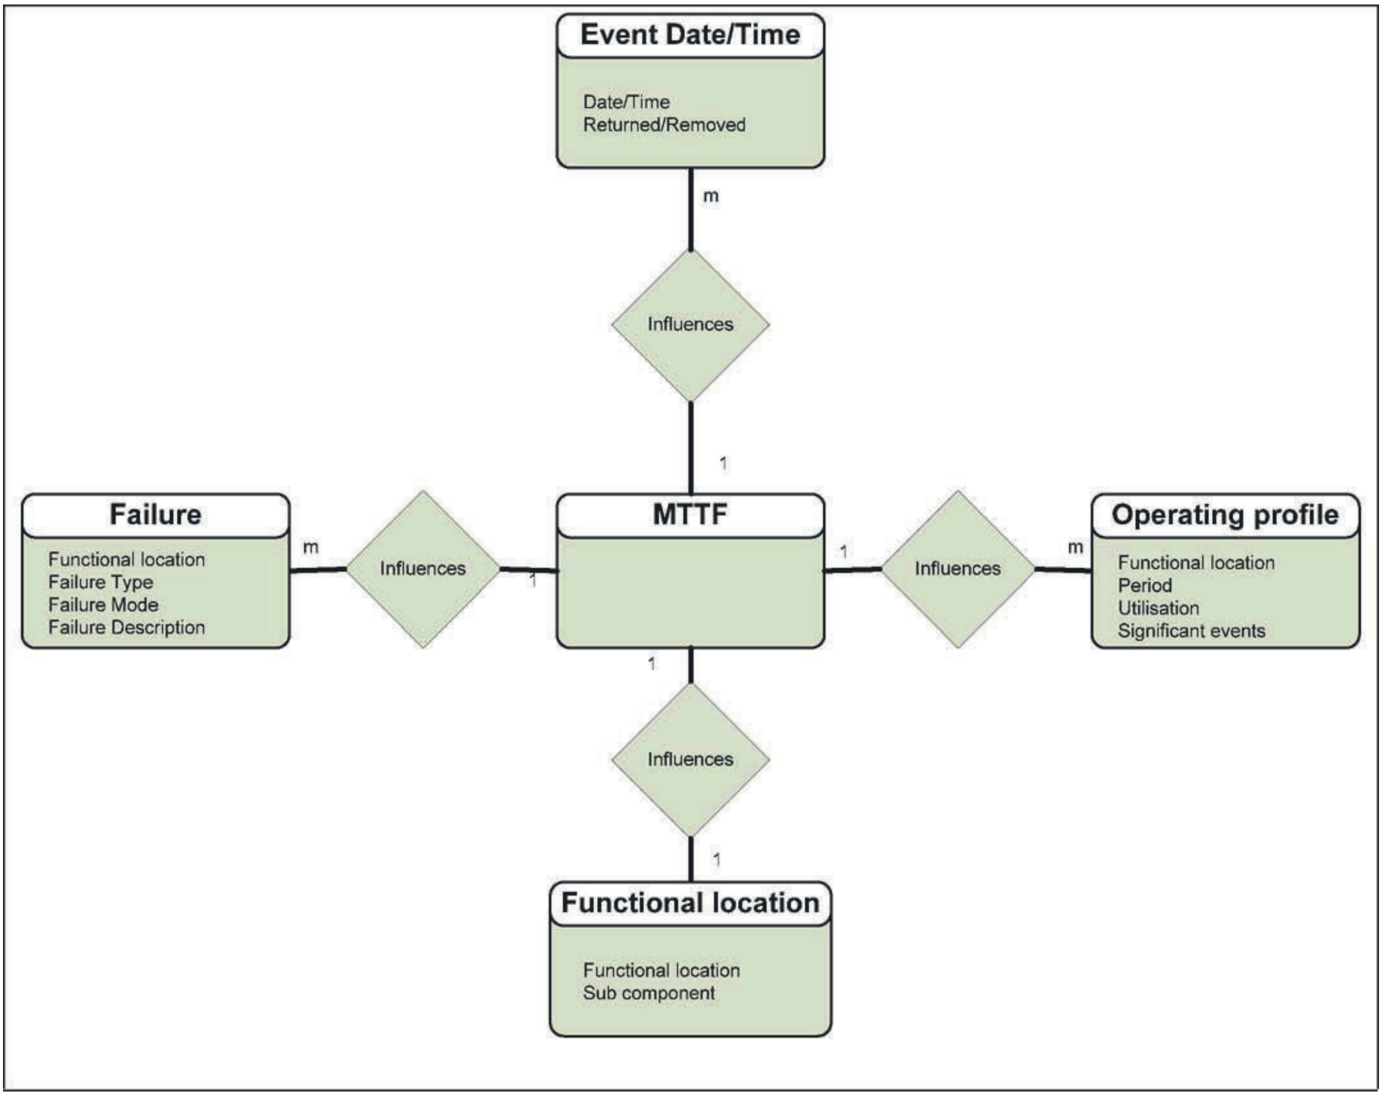

Figure 4: Entity relationship diagram for data shown in the Mind Map in Figure 3

Figure 4 shows the MTTF metric, and its contributing factors from Figure 3, expressed as an Entity Relationship diagram. Database administrators and software developers use ER diagrams to specify the design of data tables and queries. This translation from the data collector's view to the data custodian's without loss of information or form is important as it facilitates accurate communication between data consumers and custodians, this results in better IT systems which result in better quality data.

Step 4: Analyse the data

Step 4a: *Examine data in the data fields*. Investigation of the data may reveal issues such as:

Inaccurate failure date.

Nonsense free-text data (for example "Broken" as a fault description).

Incorrectly selected options.

Prevalence of "other" or "none of the above" selections in restricted entry fields.

Missing data.

Referential integrity problems.

Inappropriate selection of functional location level.

Step 4b: Develop measures to assess data attributes in those fields

In order to measure the data quality of each of the main four fields (functional location, event date, failure mode and failure type) for this example, the authors propose the application of questions about each of the relevant data quality attributes from Figure 1. This is illustrated in Figure 3. For each attribute, one or more questions are required to assess the quality of that attribute in the context of the data field, the Functional location in this example, under investigation. Examples of questions that address each of the data attributes are shown. The questions can be framed to give either yes/no, true/false, scaled (1-5) or numerical (%) replies depending on the data variable under investigation. This illustration is not intended to be comprehensive but illustrative of a general approach.

Table 2: Application of selected data quality attributes to the Functional Location data field

Data quality category	Attributes	Question for the Functional location field in the MTTF calculation	Marking
Intrinsic	Accuracy	The data is correct	Y/N
		The data is accurate	Y/N
	Reputation	I know who collected the data	Y/N
		I know who entered the data	Y/N
		Is the selection of FL affected by who collects the data?	Y/N
		Data in this field is relevant for this analysis	T/F
Contextual	Relevancy	Data in this field is appropriate for this analysis	Y/N
		Data is sufficiently current for our work	Y/N
	Completeness	Data is complete	Y/N
		Are FL data definitions clear to all users (collector, custodian and user)?	Y/N
Representational	Concise representation	Is the information easily retrievable?	Y/N
	Ease of understanding	Are drop-down menus well structured?	Y/N
		If there been changes in the FL structure as the CMMS has been upgraded. Is there a translation between old and new systems?	Y/N
	Representational consistency	Is each FL entered in exactly the same format?	Y/N
		Is the maximum number in any one drop-down menu less than 8?	Y/N
Accessibility	Accessibility	Is the information easily accessible?	Y/N
		Is the information easily obtainable?	Y/N
	Access security	Is there a system to prevent unauthorized changes to the system?	Y/N

Step 5: Identify how to improve the data quality of each element

Based on the results of step 4, we identify that there are some issues with missing data and that some fields are being incorrectly filled in. To address these issues we decide on the following measures:

- Auditing of data at the time of collection.
- Establishing a process for data vetting.
- Careful selection of classifications, Avoid presenting codes.
- Reduce manual data entry. Source date data from other, automated sources (e.g. purchasing system).
- Data entry close to the job in time and space
- Training
- Introduce workflow/process to derive change from exceptions such as selecting "other"

Step 6: Implement changes

The proposed may be ranked in terms of their efficacy and impact. This allows for changes, which have high impact and low to medium cost or difficulty, to be tackled first.

Table 3: Example of table to rank options for improving data quality

Change	Efficacy	Cost/Difficulty
Alter IT systems to check for known garbage values	High	Medium
Two week audit drive on work order data	Medium	Low
Identify data owners and 'goal' them on data quality	High	Very High
Install automated vibration sensors on worst performing pumps	Very High	Medium

Step 7: Assess improvements to data quality

Select a suitable period for review and engage an outside body to apply the metrics of data quality developed in *Step 4* to information collected after the completion of *Step 6*. The resulting independent report will highlight changes that have been effective in improving data quality and assist in identifying where to focus more effort.

Step 8: Establish periodic review/audit process

The executive summaries of all the data quality projects are reviewed annually to assess the relevance of to the current business needs. Operations staff are present at this meeting and feed back their experiences and thoughts on the changes that have been implemented. Where it is clear that the business need has changed, the need to revisit the data quality requirements is discussed. In this case MTTF is a useful base statistic, relevant to a number of business needs. As such improving the quality of its underlying data is likely to deliver value for some time to come.

4. DISCUSSION: GLOBAL ISSUES

Data field links

Figure 4 illustrates how a specific functional location at the unit level is linked to other fields in the CMMS and other databases. The selected equipment component, in this example, a pump bearing, will determine (1) the fields of the sub-unit and maintainable items (2) the equipment-specific corrective maintenance and preventative maintenance activity types, and (3) the equipment-specific failure descriptors and causes. In addition, the functional location may be linked to a serial number and perhaps also a separate equipment identification number (though equipment ID and equipment unit level functional location are often the same number). These numbers are related to installation and design data in the equipment database. There may also be additional links to databases housing reliability centred maintenance analysis or root cause failure analysis information. Careful thought needs to go into both the design and use of functional location structures and the design of links to related fields internal and external to the main database. This mind-map approach to identify all major users of specific data fields coupled with a knowledge of the data required for each of calculated reliability variables can be used to identify (1) key data fields and (2) identify the stakeholders in the data collection, storage and use sequence that need to be consulted if changes are required.

Data collection versus data use

Work by Lee and Strong [4] has shown that data collectors with "why-knowledge" about the data production process contribute to producing better quality data. Overall, improving the knowledge of data collectors is more critical than that of data custodians. *Knowing-why* is gained from experience and understanding of the objectives and cause-effect relationships underlying activities (*knowing-what*) and procedures (*knowing-how*) involved in work processes in organisations [4]. In other words, it is important for the collectors of data required for reliability analysis (the maintainers and operators) to understand why they need to collect the data and how it will be used. If, as is common, the use of the data has not been defined, either copious amounts of data are collected without any defined or proven purpose or, alternatively, insufficient data of any kind is collected. Either situation results in little data of use being available for decision making [6]. The solution is to identify the variables on which key decisions are made, identify the data required for these variables, and communicate both the process and the results to the data collectors. Unless the data collectors appreciate the process and know how, why and by whom the data is being used, they will have no motivation to collect quality data. Furthermore, the more direct and timely the feedback to the data collector about its quality and the direct effect this has on the business need, the more influential this feedback process becomes. Data collectors should know what their data is used for, and given feedback on outcomes following the analysis based on the collected data.

Codes versus text

Many database systems rely on data collectors entering much of their data by making selections from predefined lists, for example, a list of failure mode codes or functional locations. The downside of this is that very little description is supplied to the data collector to help them make their selection, resulting in increased incidence of miscoding or excessive use of exemption codes (e.g. "other"). In extreme cases, normally when using older systems, only the raw codes are presented with explanations given in associated paper manuals or help files. Paradoxically, entering data in a pre-codified form does not make it easier for the computer system to deal with. Choosing a value from a list of options and having the computer generate the code is no harder and represents a very small cost when compared to the subsequent entry and application of inappropriate or incorrect data. Where possible, the authors recommend that data collectors be presented with a rich description of available options. Where there are several similar options available, clarifying text and images should be provided in a context sensitive manner using popup windows or "mouse over" actions. Skilled data entry operators can achieve data entry error rates below 1%[7]. If we charitably describe our operators as being skilled in data entry, that means our 100,000 row maintenance history table may contain 1000 garbage records. The reality is often much more frightening. To pick up on the example presented earlier, screens that allow the input/selection of functional location (equipment/tag/plant ID) are frequently poorly implemented. In the presentation of this data by computer systems, a hierarchical approach is ubiquitous, with much effort and meeting-time devoted to the design of the tree. A problem arises because different users of the system perceive the organization of equipment in different ways. As an example, the electrical system engineer may think of a faulty light globe as '*100W globe in socket 7 of cable run 3 from distribution panel 8*'.Meanwhile an operator sees it as '*100W globe at east end of MCR3 plant west*', and the stores technician as '*100W globe, Supplier 3, electrical consumables*'.

The important point is that the examples in the preceding paragraph are all valid ways of looking at the issue. Ironically, many CMMS only present one hierarchy, thereby disadvantaging users who view the data structure differently. To overcome this problem, a project is currently underway to trial a data-mining portal which allows multiple trees to be used to select items of interest. Results will be presented in a future paper.

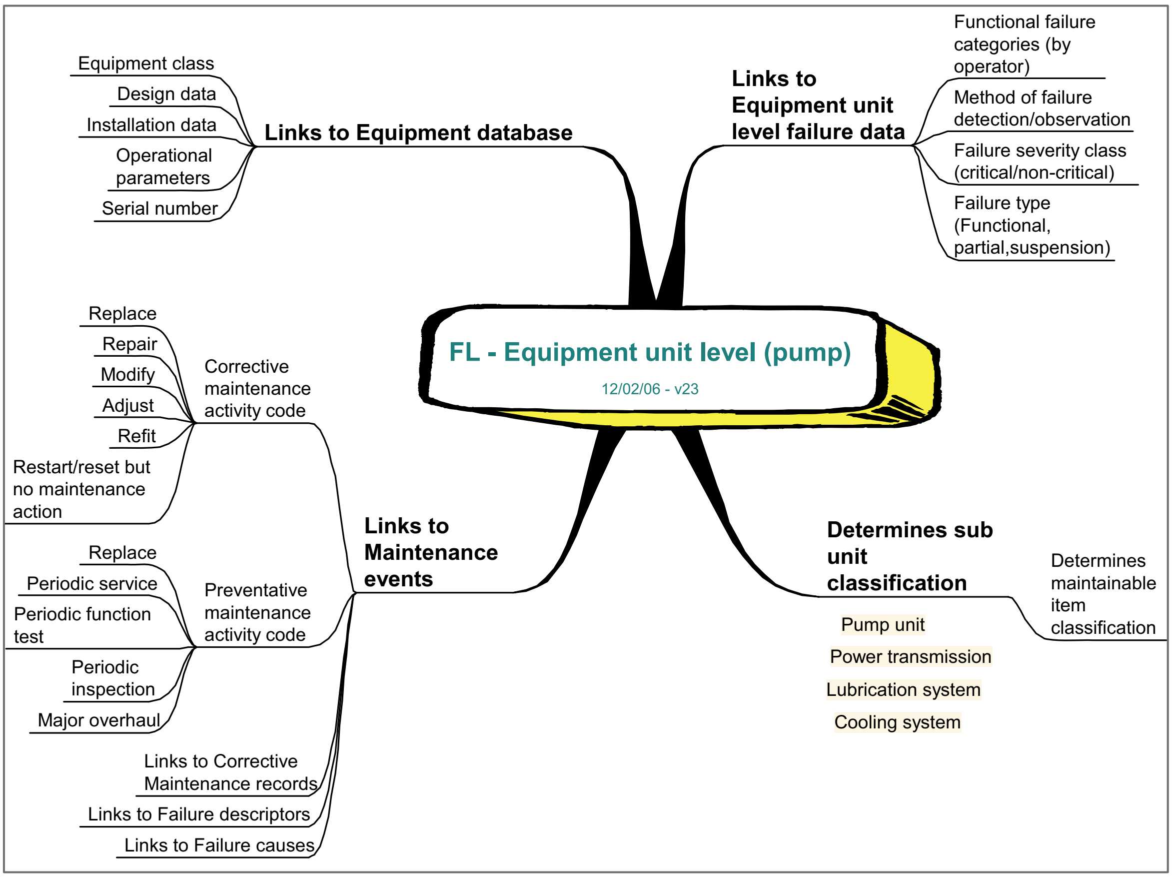

Figure 5: Illustration of the links between a functional location at the unit level and the fields in other parts of the asset management system.

Data ownership

In many ways it is unfortunate that the term "data ownership" was ever coined. The concept of data owner as a role implicitly assigns data maintenance tasks to the data owner. Therefore, by checking our own job descriptions to ensure that the words "data owner" are absent, we, as RAMS professionals, inevitably blame data quality problems on someone else. Yet, as the greatest users of RAMS data, our worth as analysts, engineers and professionals is directly linked to quality of the data on which we base our contribution. Ironically, the reticence of individuals to take on data ownership roles is often not due to an unwillingness to undertake the vetting incoming data, but rather a fear of opening a Pandora's Box of data quality issues that may then become a significant burden for an individual.

It is thus important to define responsibilities when assigning/accepting data ownership roles. Just because someone is prepared to maintain data does not necessarily mean they should be, individually, tasked with rectifying the sins of the past. We suggest that, where significant remediation or change to data management practice is identified, they are written up as separate business cases or project proposals. This helps establish the cost (and hopefully the value) of these changes in the context of the business needs.

5. CONCLUSIONS

There are a great many users of the same maintenance and failure data and considerable care should be taken before any changes are made to the data collection, data structure or data storage processes. This paper presents and illustrates a framework to assess the quality of data and the potential impact of data collection processes on the validity of key metrics used in assessing equipment reliability. We describe the new framework as a 'context-oriented' approach to data quality as the process assesses the data in individual fields in the context of its fitness for purpose; the purpose is the calculation of a specific reliability metric which must be necessary to support a specific business need.

Advantages of this approach include: (1) a structured prescriptive methodology that can be applied to many situations, (2) a direct link between data quality and the business process, and (3) identification of all data inputs and their associated data collector, data storage format and process. In the authors' opinion much more thought and attention needs to be given to the process of collecting, storing and using data for maintenance and reliability decisions. Using the framework described herein will assist in understanding assumptions used in reliability calculations and improve the quality of underlying data and data collection processes.

DETERMINATION OF OPTIMAL PREVENTIVE MAINTENANCE STRATEGY FOR SERIAL PRODUCTION LINES

Yong Sun[1], Lin Ma and Joseph Mathew

CRC for Integrated Engineering Asset Management, Shool of Engineering Systems, Queensland University of Technology, Brisbane, QLD 4001, Australia

Abstract: A Split System Approach (SSA) based methodology is presented to assist in making optimal Preventive Maintenance decisions for serial production lines. The methodology treats a production line as a complex series system with multiple PM actions over multiple intervals. Both risk related cost and maintenance related cost are factored into the methodology as either deterministic or random variables. This SSA based methodology enables Asset Management (AM) decisions to be optimized considering a variety of factors including failure probability, failure cost, maintenance cost, PM performance, and the type of PM strategy. The application of this new methodology and an evaluation of the effects of these factors on PM decisions are demonstrated using an example. The results of this work show that the performance of a PM strategy can be measured by its Total Expected Cost Index (TECI). The optimal PM interval is dependent on TECI, PM performance and types of PM strategies. These factors are interrelated. Generally it was found that a trade-off between reliability and the number of PM actions needs to be made so that one can minimize Total Expected Cost (TEC) for asset maintenance

Key Words: Preventive maintenance, Planning, Decision making, Production lines, Split System Approach

1 INTRODUCTION

The determination of optimal Preventive Maintenance (PM) strategies for production lines, especially over the whole life of these assets, is imperative for their owners as maintenance costs can occupy a sizeable portion of the total costs of business. The need to optimise maintenance of production lines becomes pressing with increasing complexity of machines and competitive market pressure.

Maintenance issues of production lines have attracted much attention from researchers. For example, Dallery and Bihan [1] developed an improved method for analysing serial production lines with unreliable machine and finite buffers. Liberopoulos [2] conducted a case study for the reliability analysis of an automated pizza production line and Miltenburg [3] investigated the effect of breakdown on U-shaped production lines. Some literature on the optimal PM planning for production lines has also been published. For example, see research reports presented by Cavory [4], Percy et al [5], and Chareonsuk et al [6]. Two major issues need to be addressed when making an optimal decision of PM strategy for production lines: (1) the changes in reliability of production lines due to PM and (2) maintenance related costs. Conflicting interests exist between these two issues. More frequent maintenance activities often need to be conducted and more resources need to be consumed if one wishes to maintain a production line at a higher reliability level. As a result, maintenance related costs increase. On the other hand, lowering reliability requirements can reduce the maintenance related costs. However, a lower reliability of a production line usually means that this production line is prone to more breakdowns and greater loss in production. A good maintenance strategy must balance both reliability and maintenance costs. Some analysis has revealed that maintenance cost will increase with increasing maintenance frequency whereas the cost due to breakdown of a production line decreases with increasing maintenance frequency. Hence, an optimal maintenance frequency exists [7]. However, this analysis was conducted qualitatively rather than quantitatively. For quantitative analysis, Chareonsuk et al [6] attempted to optimise PM intervals of production lines under two criteria – expected total costs per unit time and reliability. However, they did not consider multiple imperfect PM actions in their model. To deal with a long term PM schedule for new production lines, Percy et al [5] postulated a new Bayesian method based approach but did not develop an applicable algorithm. **A practical model for determining the optimal PM strategy for production lines over its life-span is yet to be developed**. The major barrier to develop such a model is reliability prediction of production lines with multiple PM actions over a long operational period. Production lines are

This research was conducted within the CRC for Integrated Engineering Asset Management, established and supported under the Australian Government's Cooperative Research Centres Programme.

normally complex repairable systems and PM actions on these complex systems are generally imperfect, i.e., the state of a production line after a PM action is between “as good as new” and “as bad as old”.

A Split System Approach (SSA) based methodology is developed in this paper to remove this barrier. SSA was proposed by the authors [8] recently to predict the reliability of systems with multiple PM actions over multiple intervals. In this paper, the SSA is used to predict the reliability of production lines with multiple PM actions. Only serial production lines are considered. A serial production line indicates that the failure of any machine in this production line will cause the failure of the whole system (production line). Serial production lines are commonplace in manufacturing industries such as automobile manufacturing factories, food processing factories and clothes making factories.

The rest of the paper is organised as follows: in Section 2, the concept and methodology of SSA are reviewed. In Section 3, a methodology for determining the optimal PM strategy based on SSA is presented, and this is followed by an example in Section 4. Conclusions are given in Section 5.

2 THE CONCEPT AND METHODOLOGY OF SSA

The basic concept of the SSA is to separate repaired and unrepaired components within a system virtually when modelling the reliability of a system after PM actions. This concept enables the analysis of system reliability at the component level, and stems from the fact that generally when a complex system has a PM action, only some of components are repaired.

The following assumptions were made in developing SSA based models:

The failure of repaired components is independent of unrepaired components. This assumption means that when a component is repaired, the failure distribution form of the unrepaired components of a system does not change, and the conditions of the unrepaired components do not affect the reliability characteristics of repaired components.

The reliability function of a new repairable system is known. The reliability functions of repaired components are also known.

The topology of a repairable system is known.

The repair time is negligible.

PM time is deterministic variable.

The topology of production lines discussed in this paper is assumed to be a serial system consisting of M components. The original multi-serial system can be converted into a simplified serial system which only contains two virtual parts: “Part 1” includes repaired machines and “Part 2” is the remainder of the production line - often referred to as a subsystem (see Figure 1).

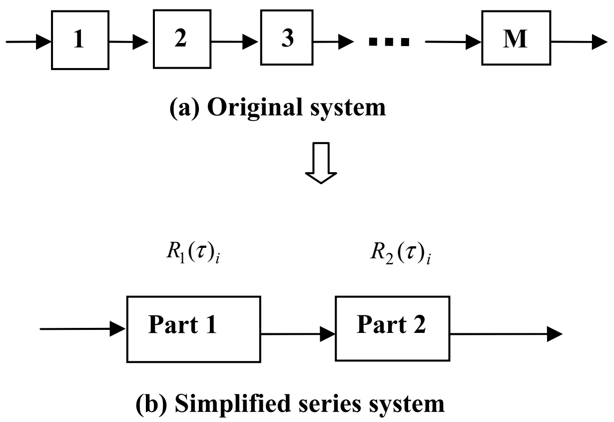

Figure 1. Simplification of production lines

In Figure 1, $R_1(\tau)_i$ and $R_2(\tau)_i$ are the reliability functions of Part 1 and Part 2 after the i[th] PM interval (refer to Figure 2). In this paper, the second subscript i is used to stand for “after the i[th] PM action”. Subscript $i=0$ stands for no PM. The PM strategy is to repair Part 1 whenever the reliability of the production line falls to a predefined control limit of reliability R_0. A possible interpretation for this PM strategy is that the components in Part 1 have a much shorter mean time to failure than the components in Part 2.

As mentioned previously, production lines are often complex repairable systems. The states of machines after repairs in a production line can have a significant impact on the reliability of the entire production line and must be considered while modelling the reliability of the production line covering a series of PM actions. PM actions on a production line often involve imperfect repairs. The reliability of a system after imperfect repairs declines in a manner shown in Figure 2.

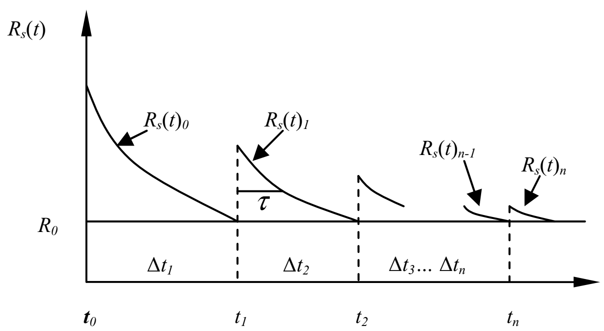

Figure 2. Changes to the reliability of an imperfectly repaired system

Two time coordinates are used in the modelling:

Absolute time scale t: $0 \le t < \infty$.

Relative time scale τ: $0 \le \tau \le t_i$ ($i = 1, 2, \ldots, n$).

In Figure 2, R_0 is the predefined control limit of the reliability level for the production line, Δt_i (i=1,2,…,n) is the interval time between (i-1)th repair and ith repair. Parameter t_i is the ith PM time and also the start time for the production to run again after the ith repair according to Assumption (4).

For a simple scenario that always Part 1 is repaired in all PM actions, the reliability function of the system after the nth PM actions can be expressed as:

$$R_s(\tau)_n = \frac{R_1(\tau)_n R_s(\tau + \sum_{i=1}^{n} \Delta t_i)_0}{R_1(\tau + \sum_{i=1}^{n} \Delta t_i)_0}. \quad (1)$$

Equation (1) can be rewritten using absolute time scale as follows:

$$R_s(t) = \frac{R_1(t - \sum_{i=1}^{n} \Delta t_i)_n R_s(t)_0}{R_1(t)_0} \qquad (t \geq \sum_{i=1}^{n} \Delta t_i). \quad (2)$$

Note that equations (1) and (2) both describe the reliability of a system which has been preventively maintained for n times, i.e., these two equations both describe the conditional probability of survival of a system with n PM intervals. To predict the reliability of a system with multiple PM intervals, the cumulative effect of multiple PM actions needs to be considered, i.e., the probability of survival of the repaired components until their individual repair times should be considered [7].

The cumulative reliability function of a serial system after the first PM action is

$$R_{sc}(\tau)_1 = R_1(\Delta t_1)_0 R_s(\tau)_1 \quad (3)$$

where, $R_{sc}(\tau)_1$ is the cumulative reliability of the system after the first PM action. $R_1(\Delta t_1)_0$ is the probability of survival of Part 1 until time t_1.

Generally, the cumulative reliability of the system after the nth PM action can be expressed as:

$$R_{sc}(\tau)_n = \prod_{i=0}^{n-1} R_1(\Delta t_{i+1})_i R_s(\tau)_n \quad (4)$$

where $R_{sc}(\tau)_n$ is the cumulative reliability of the system after the nth PM action.

3 Methodology for determining an optimal PM strategy

The SSA based PM decision making methodology is composed of reliability prediction of systems and cost analysis.

Estimation of the reliability of production lines

As mentioned in Section 2, SSA analyses the reliability of repairable systems after PM at the component level. Hence, direct application of SSA to estimating the reliability of production lines might be inconvenient because a production line often consists of numerous components. To avoid this inconvenience, a production line can be decomposed at different levels virtually, and then the reliability of the production line can be analysed at these levels using SSA respectively (see Figure 3).

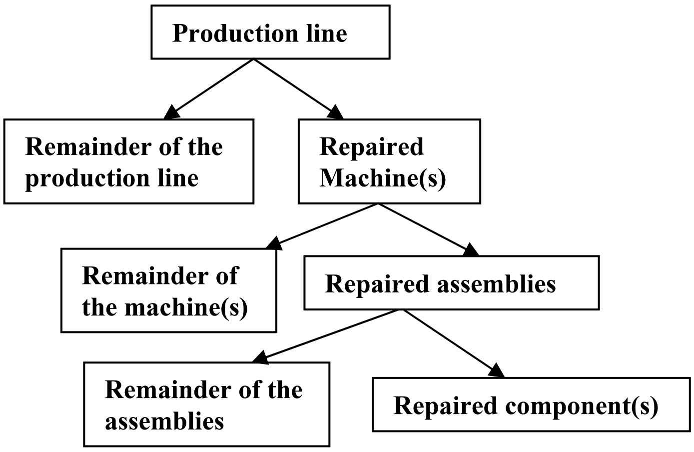

Figure 3. Decomposition of a production line

A bottom-up approach can be used for analysing the reliability of the production line after a production line has been virtually decomposed as shown in Figure 3. The reliability functions of assemblies are estimated firstly at the component level using SSA, and then the reliability functions of machines can be estimated at the assembly level. Finally the reliability function of the production line can be estimated at the machine level. For simplification, only the last step is demonstrated in this paper.

Criteria for optimizing PM strategies

Both reliability of a production line and maintenance related cost are considered in this paper when determining optimal PM strategies for production lines.

Reliability is used to describe the likelihood of failure of a system. Risk due to failure of production lines can be converted into risk related cost, which includes loss of production, penalty for contract breach, machine damages and additional harmful impact on human, products, machines and environment. Maintenance related cost includes material cost, maintenance labour cost and loss of production due to conducting PM. Various asset maintenance cost models have been developed (e.g., see references [9-11]). In this paper, the risk related cost of a production line is assumed to be proportional to the failure probability of the production line and the maintenance related cost is assumed to be proportional to the number of PM actions. Based on these two assumptions, the risk related cost and the maintenance related cost are expressed as:

$$C_r = k_r[1 - R(T)], \quad (5)$$

$$C_m = k_m N_T, \qquad (6)$$

where, T is the operational period of the production line that an enterprise is interested in. Typically, T is the life span of the production line. $R(T)$ is the reliability of the production line at time T. Parameters k_r and k_m are two scale constants. N_T is the required number of PM actions over the period of time T for maintaining the production line above the reliability level of $R(T)$.

Define the Total Expected Cost (TEC) as the sum of the expected risk related cost and the expected maintenance related cost and the Total Expected Cost Index (TECI) as the result that the TEC is divided by k_m:

$$TEC = C_r + C_m, \quad (7)$$

$$TECI = k_{rm}[1 - R(T)] + N_T, \quad (8)$$

where, $k_{rm} = k_r / k_m$. (9)

Parameter k_{rm} is termed as the Risk-Maintenance Cost Ratio (RMCR). It represents the significance of a PM action. A higher k_{rm} indicates that a PM action is more significant, that is, more risk related costs can be reduced due to the decreased failure probability after this PM action. An advantage for using RMCR is that this parameter is dimensionless.

TECI can be used to measure the performance of a PM strategy. The lower the TECI is, the better the PM strategy.

In industry, parameters k_r and k_m may vary significantly and unpredictably. Let K_r denote the cost per PM action and K_m denote the cost per percentage of failure probability. Then K_r and K_m are both random variables. Assume that K_r and K_m both change in $[0, \infty)$ and are independent of the age of the asset and the number of PM actions. If K_r has a distribution density function $f_r(k_r)$, then conditional on $K_r = k_r$, one has

$$C_r[R(T) \mid K_r = k_r] = k_r[1 - R(T)] \quad (10)$$

and on removing the condition, one has

$$C_r = \int_0^\infty k_r[1 - R(T)] f_r(k_r) dk_r$$

$$= E[K_r][1 - R(T)] \text{ ,(11)}$$

where, $E[K_r] = \int_0^\infty k_r f_r(k_r) dk_r$ is the first moment of K_r.

Similarly, if K_m has a distribution density function $f_m(k_m)$, the expected maintenance cost is given by

$$C_m = E[K_m] N_T \text{ , } \quad (12)$$

where, $E[K_m] = \int_0^\infty k_m f_m(k_m) dk_m$ is the first moment of K_m.

In this case, define RMCR as

$$k_{rm} = \frac{E[K_r]}{E[K_m]}, \qquad (13)$$

so that equation (8) still holds.

The approach to determining the optimal PM strategy for production lines presented in this section is best demonstrated using an example in the following section.

4 EXAMPLE

A PM strategy is required for a period of the next two years for an automated food production line that has been operating for some time. This production line can be described as a simplified serial system as shown in Figure 1. Part 1 is composed of those machines that have very short mean time to failure compared with the remainder of the production line and Part 2 is composed of the remainder of the production line. This production line was assumed to operate at its wear-out stage during the next two years. The times of critical failures of Part 1 followed a Weibull distribution and were expressed as:

$$R_1(\tau)_0 = \exp[-\left(\frac{\tau}{18}\right)^{2.1}]. \qquad (14)$$

Part 2 was assumed to have an exponential failure distribution:

$$R_2(\tau)_0 = \exp\left(\frac{-\tau}{400}\right). \qquad (15)$$

Hence the reliability of the entire production line was

$$R_s(\tau)_0 = \exp[-\left(\left(\frac{\tau}{18}\right)^{2.1} + \left(\frac{\tau}{400}\right)\right). \quad (16)$$

Conducting PM on the machines in Part 1 can improve the overall reliability of the entire production line since Part 1 was operating at its wear-out stage. This scenario has been studied in subsection 3.2. The reliability of the entire production line with multiple PM intervals can be analysed using Equations (1) and (4).

Two PM strategies were considered. Strategy one is a type of Reliability Based PM (RBPM) strategy. In this strategy, Part 1 will be maintained whenever the reliability of the entire production line after PM falls to 0.9. The required minimum operational time of the production line after a PM action is 0.5 months (15 days. A calendar system of twelve 30-day months is used in this paper.) The second strategy is a type of Time Based PM (TBPM) strategy. In this PM strategy, PM on the machines in Part 1 starts after one month (30 days) after which it will be conducted in fixed intervals. As mentioned in Section 3.1, the reliability of Part 1 after maintenance can also be predicted using the SSA. However, the derived reliability formula is complicated. In this paper, the following approximate formula was used to describe the reliability of Part 1 after a repair:

$$R_1(\tau)_n = R_1(\tau + f_c \Delta t_{n-1}), \quad (17)$$

where, f_c is termed as the recovery coefficient, which is used to represent the degree of the reliability of Part 1 after a PM action has recovered to its original reliability. When $f_c = 0$, the state of Part 1 after a PM action is as good as new; When $f_c = 1$, the state of Part 1 after a PM action is as bad as old; When $0 < f_c < 1$, Part 1 has an imperfect repair.

The reliability of the entire production line with different PM strategies was predicted using SSA. Two examples of reliability prediction are shown in Figures 4 and 5. In both figures, $f_c = 0.05$. From these two figures, it can be seen that both TBPM and RBPM strategies improved the reliability of the entire production line. One can find that the reliability of the production line with a shorter PM interval is higher, when considering the cumulative reliability with TBPM solely. However, this result does not mean that PM strategy with a shorter interval is superior over the PM strategy with a longer interval because the required number of PM actions corresponding to the shorter PM interval is higher than that corresponding to the longer PM interval during the same period. More PM actions often cause higher maintenance costs. An optimal decision of PM strategy should be based on both reliability requirement and maintenance costs. A trade-off between reliability level and the number of PM actions is necessary to keep the TEC at the lowest level.

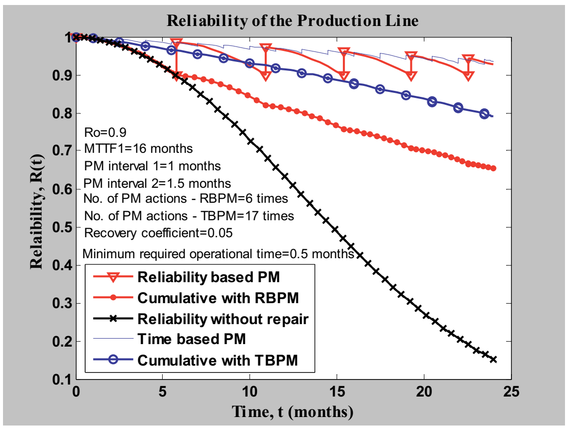

Figure 4. Reliability prediction of the production line – simulation 1

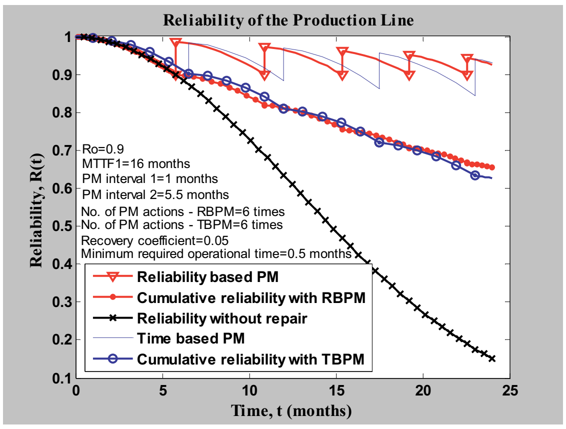

Figure 5. Reliability prediction of the production line – simulation 2

An optimal PM interval exists (see Figure 6). This optimal PM interval is RMCR, k_{rm}, dependent. From Figure 6, it can be seen that the best PM interval is two months when RMCR k_{rm} are 200 and 100. When k_{rm} is 10, the optimal PM interval changes to 8 months. However, when RMCR k_{rm} is 4, the optimal PM interval becomes 24 months. This result indicates that PM is no longer needed in this case because the risk related cost is not significant compared with the maintenance related cost.

The optimal interval is also dependent on the recovery coefficient f_c. From Figure 7, it can be seen that the optimal interval increases with the increase of recovery coefficient. When f_c is greater than 0.75, the optimal PM interval becomes 24 months, that is, no TBPM is required during the scheduled operating period of the production line. This finding can be explained by the property of the recovery coefficient. As shown in Equation (12), the recovery coefficient f_c represents the degree that the reliability of Part 1 after a PM action lowers its initial reliability before this PM. In other words, the recovery coefficient f_c represents the effectiveness of a PM action. A greater value of f_c indicates poorer PM performance. If PM performance is so degraded that it cannot improve the reliability of production lines effectively, it is better that this PM not be conducted.

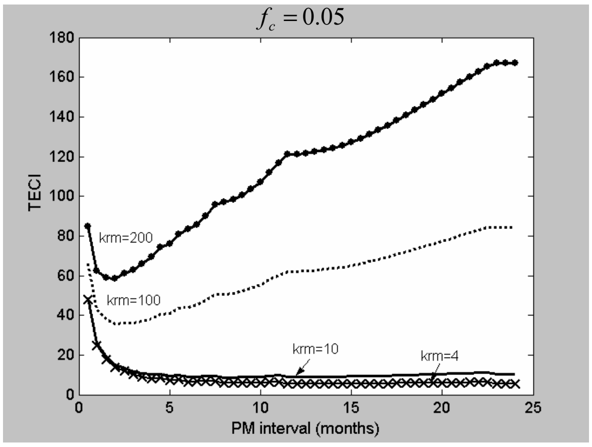

Figure 6. Relationship between TECI and preventive maintenance intervals

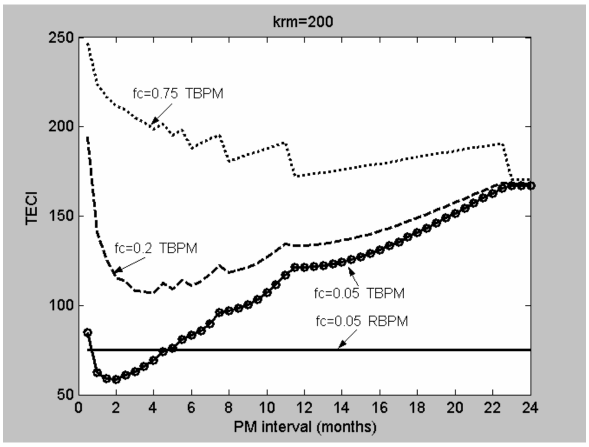

Figure 7. Relationship between TECI and the recovery coefficients

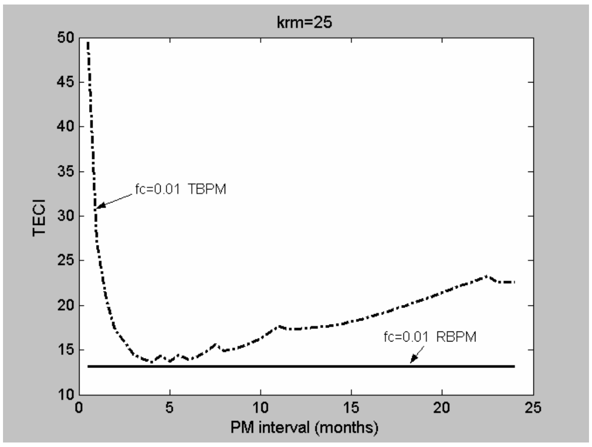

Figure 8. Comparison between RBPM and TBPM

f_c	Optimal PM interval (months)	Lowest TECI		k_{rm}
		TBPM	RBPM	
0.05	2	58.6	75.1	200
0.1	2	75.9	85.5	
0.15	3	92.2	108	
0.2	4	106.9	inapplicable	
0.3	6	129.9	inapplicable	
0.7	11.5	169.4	inapplicable	

Table 1. Relationship between TECI and the recovery coefficients

The above analysis focuses on obtaining optimal TBPM strategy. However, there are times when another type of PM strategy can be better than this optimal TBPM. When determining an optimal PM strategy, one needs to investigate different types of PM strategies. The effectiveness of different types of PM strategies can vary in different scenarios. In the scenario shown in Figure 8, the lowest TECI for TBPM is 13.7 whereas the TECI for RBPM is 13.1, i.e., in this case, RBPM strategy rather than TBPM strategy should be applied. However, in the scenario presented in Table 1, TBPM strategy is better than RBPM strategy.

In Table 1, the word “inapplicable” means that RBPM is not applicable because the PM interval required by this strategy will become shorter than the required minimum operational time of the production line.

5 CONCLUSIONS

A SSA based methodology for determining an optimal PM strategy of production lines was developed in this paper. This methodology is especially useful for long term PM decision making.

The determination of an optimal PM strategy of production lines is essentially a multiple criteria decision making issue. A number of factors can influence production line PM decision making. The major factors include failure probability, costs due to failure of production lines, costs relating to maintenance, PM performance, and the type of PM strategy. The SSA based methodology considers all these factors simultaneously and analyses the effects of these factors on PM decisions quantitatively.

This research work finds that the performance of a PM strategy can be measured by its Total Expected Cost Index (TECI). The lower the TECI, the better the PM strategy. The effectiveness of different types of PM strategies can vary in different scenarios. The optimal PM interval is dependent on TECI, PM performance and the type of PM strategy. A trade-off between reliability requirement and the number of PM actions is often needed if one wishes to minimise the Total Expected Cost (TEC) of using production lines.

THE INTERACTIVE HAZARDS OF COMPONENTS IN A SYSTEM AFTER REPAIRS – A MATHEMATICAL FORMULATION AUTHORS

Y Sun L Ma & J Mathew

CRC for Integrated Engineering Asset Management,School of Engineering Systems,Queensland University of Technology,Brisbane, QLD 4001, Australia

Abstract: This paper develops analytical expressions that enable analysis of the changes of component hazards of systems with interactive failures after repairs. These changes were analysed using probability theory based on the analytical model for interactive failures. It was found that hazards for repaired and *unrepaired* components will change when a system with interactive failures is maintained. The interactive hazards of newly repaired components are higher than their independent hazards; whereas the interactive hazards of unrepaired components will reduce. When two components interact strongly, these two components should be maintained at a similar condition. When establishing effective asset maintenance management strategies one needs to understand the changes in hazards of components when a system with interactive failures is maintained. The proposed model calculates and predicts these changes in the hazard. This work is the first application of the analytical model for interactive failures in the modelling of changes in component hazards of a system after repairs. The outputs of this work can be used to optimise maintenance strategies for systems with interactive failures.

Key Words: hazard, interactive failure, repairable systems, asset maintenance.

1 INTRODUCTION

The majority of physical assets in industry such as machines, buildings and vehicles are repairable complex systems. These types of assets will need to be repaired to recover their functions after each failure. Optimal maintenance of repairable assets is important to enterprises for delivering efficiencies. The development of an optimal maintenance strategy for these assets requires the accurate prediction of their reliability after repairs.

Numerous models and methodologies have been developed to meet this requirement. However, most these models and methodologies are based on the assumption of independent failures. Industrial experience has shown that there are a number of situations where this assumption is unrealistic and will lead to unacceptable analysis errors. To ensure the accuracy of reliability prediction in these situations, dependent failures must be considered. Interactive failure is a type of dependent failure and is typically caused by interactions between components in a system.

The authors' previous research [1] revealed that interactions between components will increase the hazards of the components. This increased hazard is defined as Interactive Hazard (IntH). Correspondently, the hazard of a system without failure interactions is termed as Independent Hazard (IndH). Several researchers [2] have previously observed that the interactive hazards of both repaired and unrepaired components in a system will change after repairs. Understanding these changes of hazards can assist in developing an optimal maintenance strategy for the system. However, an analytical analysis of these changes is yet to be conducted.

This paper quantitatively analyzes the changes of component interactive hazards after repairs using the Analytical Model for Interactive Failures (AMIF) previously developed by the authors [1].

The remainder of this paper is organized in the following manner: In Section 2, the changes of component hazards are described. A quantitative analysis of these changes is presented in Section 3. Section 4 presents the conclusions.

2 CHANGES OF COMPONENT HAZARDS

The reliability of a system is expected to increase after repair because the hazard of this system is reduced. In case of a system with independent failures, only the hazards of repaired components are assumed to be changeable, and the hazards of unrepaired components after a repair are assumed unchangeable. However, if a system has interactive failures, the hazards of both repaired and unrepaired components are changeable. In this case, repairs can improve the reliability of a system in two ways: reducing the IntH of unrepaired components and reducing the IndH of repaired components (refer to Figure 1).

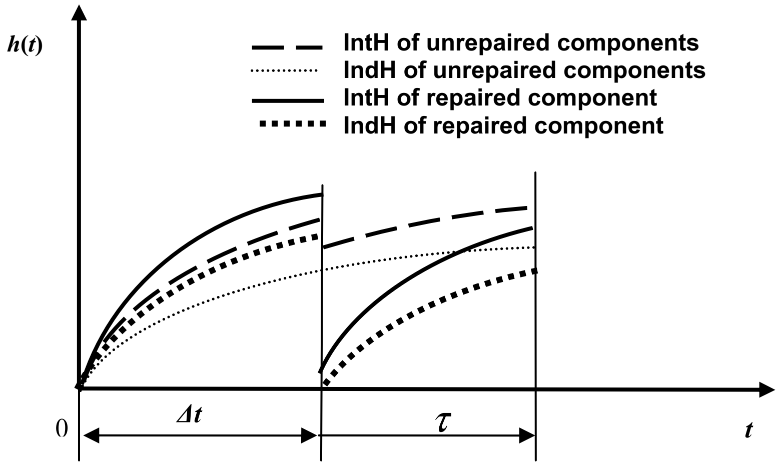

Figure 1. The changes of hazard of unrepaired components and repaired component

In Figure 1, parameter t represents the absolute time scale which changes from zero to infinite, whereas τ represents the relative time scale, which changes from zero to Δt. Parameter Δt is the interval between two repairs. The initial time to calculate the IndH of the unrepaired components after a repair is t_1 and the initial time to calculate the IndH of the newly repaired component after this repair is zero.

The changes of component hazards of a system after repairs is analysed below.

3 MODEL FORMULATION

This paper focuses on calculating the hazards of the components in a system with IntF after a repair. The following assumptions are made:

1. The system is composed of M components and one specific component (Component 1) is repaired.
2. The interactive coefficients are constant and independent of repairs.
3. Repair time is neglected.

In the case of repairable systems with IntF, the initial time for calculating the IntH of newly repaired components can be different from that for remaining unrepaired components after a repair (see Figure 1).

According to [3], the stable IntH of a system is given by

$$\{h(\tau)\} = [\alpha]\{h_I(\tau)\}. \quad (1)$$

where, $\{h(\tau)\}$ is the stable IntHs of a system after failure interaction. It is an $M \times 1$ vector. $\{h_I(\tau)\}$ is an $M \times 1$ independent hazard vector of all components due to their own deteriorations. $[\alpha]$ is the State Influence Matrix (SIM) which is given by

$$[\alpha] = ([I]-[\theta])^{-1}. \quad (2)$$

where, $[I]$ is an $M \times M$ unit matrix. $[\theta]$ is the Interactive Coefficient (IC) matrix of the system [1].

Define all unrepaired components as a subsystem. Equation (1) can be rewritten using the partition matrix as follows:

$$\begin{Bmatrix} h_1(\tau) \\ \vec{h}_{sb}(\tau) \end{Bmatrix} = \begin{bmatrix} \alpha_{11} & \vec{\alpha}_2 \\ \vec{\alpha}_3 & \vec{\alpha}_4 \end{bmatrix} \begin{Bmatrix} h_{I1}(\tau) \\ \vec{h}_{Isb}(\tau) \end{Bmatrix}. \quad (3)$$

where, $h_1(\tau)$ is the IntH of Component 1. Vector $\vec{h}_{sb}(\tau)$ is the $(M-1)\times 1$ IntH vector of the subsystem. Parameter α_{11} is the first row first column element of SIM $[\alpha]$; while $\vec{\alpha}_2$, $\vec{\alpha}_3$ and $\vec{\alpha}_4$ are the $1\times(M-1)$, $(M-1)\times 1$ and $(M-1)\times(M-1)$ partition matrix in SIM $[\alpha]$, respectively. Function $h_{I1}(\tau)$ is the IndH of Component 1, and $\vec{h}_{Isb}(\tau)$ is a $(M-1)\times 1$ vector which represents the IndH of the subsystem.

Let $h_{I1}(\tau)_0$ and $\vec{h}_{Isb}(\tau)_0$ denote the IndH of Component 1 and the subsystem before a repair respectively.

When a repair is conducted, $\tau = t_1 = \Delta t$. Hence, just before this repair, the IndHs of Component 1 and the subsystem are $h_{I1}(\Delta t)_0$ and $h_{Isb}(\Delta t)_0$, respectively. Let $h_{I1}(\tau)_1$ be the IndH of Component 1 after this repair, and then the IndH of Component 1 just after the repair is $h_{I1}(0)_1$. Generally

$$0 \le h_{I1}(0)_1 \le h_{I1}(\Delta t_1)_0 . \qquad (4)$$

If $h_{I1}(\tau)_1 = h_{I1}(\tau + \Delta t_1)_0$, the state of the system after the repair is "as bad as old".

The IndH of the subsystem just after a repair is the same as just before this repair because it has not been repaired, i.e.,

$$h_{Isb}(\tau)_1 = h_{Isb}(\tau + \Delta t_1)_0 , \qquad (5)$$

where, $h_{Isb}(\tau)_0$ and $h_{Isb}(\tau)_1$ are the IndHs of the subsystem before and after the repair respectively.

The IntHs of all components in the system after the repair are given by

$$\begin{Bmatrix} h_1(\tau)_1 \\ \vec{h}_{sb}(\tau)_1 \end{Bmatrix} = \begin{bmatrix} \alpha_{11} & \vec{\alpha}_2 \\ \vec{\alpha}_3 & \vec{\alpha}_4 \end{bmatrix} \begin{Bmatrix} h_{I1}(\tau)_1 \\ \vec{h}_{Isb}(\tau + \Delta t_1)_0 \end{Bmatrix}, \quad (6)$$

where, $h_{I1}(\tau)_1$ is the IndH of Component 1 after a repair. Vector $\vec{h}_{sb}(\tau)_0$ represents the IntHs of Component 1 and the subsystem before the repair; while $h_1(\tau)_1$ and $\vec{h}_{sb}(\tau)_1$ are the IntHs of Component 1 and the subsystem after the repair respectively.

If IntF is stable and the condition of Component 1 just after the repair has not degraded compared to its condition just before this repair, the following inequalities can be obtained:

$$h_1(t_1)_0 \ge h_1(0)_1 = \alpha_{11} h_{I1}(0)_1 + \vec{\alpha}_2 \vec{h}_{Isb}(\Delta t_1)_0 \ge h_{I1}(0)_1 , \qquad (7)$$

$$\vec{h}_{sb}(0)_1 = \vec{\alpha}_3 h_{I1}(0)_1 + \vec{\alpha}_4 \vec{h}_{Isb}(\Delta t_1)_0 \le \vec{h}_{Isub}(\Delta t_1)_0 . \quad (8)$$

The above inequalities can be proved using the following two propositions and a theorem.

Proposition 1: All elements in SIM $[\alpha]$ are nonnegative when $0 \le \theta_{ij} < 1$.

The proof of Proposition 1 is presented in Appendix 1.

Proposition 2: All diagonal elements in SIM $[\alpha]$ are greater than or equal to one.

The proof of Proposition 2 is presented in Appendix 2.

Theorem: Interactive functions $h_1(\tau)$ and $\vec{h}_{sb}(\tau)$ change monotonously with the change of $h_{I1}(\tau)$.

The proof of this theorem is straightforward using Equation (3) and Proposition 1.

Eq (7) is proved as follows:

According to Proposition 1, $\vec{\alpha}_2 \ge 0$. According to Proposition 2, $\alpha_{11} \ge 1$. Hence, the following relationship holds because all elements in $\vec{h}_{Isb}(\Delta t_1)_0$ are nonnegative:

$$h_1(0)_1 = \alpha_{11} h_{I1}(0)_1 + \vec{\alpha}_2 \vec{h}_{Isb}(\Delta t_1)_0 \ge h_{I1}(0)_1 . \qquad (9)$$

If the condition of Component 1 just after the repair has not degraded compared to its condition just before this repair, i.e., $h_{I1}(0)_1 \le h_{I1}(\Delta t_1)_0$, the following inequality holds because of Equation (6) and the theorem:

$$h_1(t_1)_0 \ge h_1(0)_1 . \qquad (10)$$

Equation (7) is obtained by a combination of Equations (9) and (10). Equation (8) can be proved using a similar approach.

Equation (9) indicates that the IntH of Component 1 can be higher than its original independent hazard due to the effect of the unrepaired subsystem. The inequity symbol in Equation (9) becomes the equality symbol if and only if $\vec{\alpha}_2$ is a null vector. A null vector $\vec{\alpha}_2$ means that the failures of components in a subsystem do not affect the failure of Component 1. If $\vec{\alpha}_2$ is a null vector, element α_{11} is equal to one (see Appendix 1). Equation (8) indicates that the IntHs of the components in the subsystem, and hence the subsystem, will be reduced after the repair. The inequality symbol in Equation (8) becomes the equality symbol if and only if $\vec{\alpha}_3$ is a null vector. A null vector $\vec{\alpha}_3$ would mean that the failure of Component 1 does not influence the failure of components in the subsystem.

4 CONCLUSIONS

This study has found that the initial time used in the calculation of the interactive hazards of repaired components after a repair is different from that of the remaining unrepaired components after this repair for a system with interactive failures. Repair can improve the reliability of a system in two aspects: decreasing interactive hazards of the unrepaired components and increasing the reliability of repaired components. The interactive hazards of newly repaired components are higher than their independent hazards; whereas the interactive hazards of unrepaired components will reduce. When two components interact strongly, these two components should be maintained at a similar level for effective maintenance. This paper models the changes in hazards of components in a system after a single repair. The authors are currently expanding on this work to cover systems with multiple repairs.

Appendix 1

The Proof of Proposition 1

Proposition 1: All elements in the State Influence Matrix (SIM) $[\alpha]$ are nonnegative when $0 \le \theta_{ij} < 1$.

Proof

Proposition 1 is proven using the Principle of Mathematical Induction [4] as follows.

According to reference [1], SIM $[\alpha]$ is the inverse matrix of $([I]-[\theta])$:

$$[\alpha] = ([I]-[\theta])^{-1}, \qquad \text{(A1-1)}$$

where,

$$([I]-[\theta]) = \begin{bmatrix} 1 & -\theta_{12} & \cdots & -\theta_{1M} \\ -\theta_{21} & 1 & \cdots & -\theta_{2M} \\ \vdots & \cdots & \ddots & \vdots \\ -\theta_{M1} & -\theta_{M2} & \cdots & 1 \end{bmatrix}. \qquad \text{(A1-2)}$$

M is the number of components in a system. Matrix (A1-2) has the following properties:

1. All diagonal elements are equal to 1.
2. All non-diagonal elements are either negative or zero because

$$0 \le \theta_{ij} < 1 \quad (i, j = 1,2,...,M;\ i \ne j). \qquad \text{(A1-3)}$$

When $M = 2$,

$$[\alpha] = ([I]-[\theta])^{-1} = \begin{bmatrix} 1 & -\theta_{12} \\ -\theta_{21} & 1 \end{bmatrix}^{-1}$$

$$= \frac{1}{\det[([I]-[\theta])]} \begin{bmatrix} 1 & \theta_{12} \\ \theta_{21} & 1 \end{bmatrix}. \qquad \text{(A1-4)}$$

The proposition is true because $\det[([I]-[\theta])] > 0$.

Suppose that the proposition is true when $M = K$, i.e.,

$$\alpha_{ij} \ge 0 \quad (i, j = 1,2,\ldots,K). \qquad \text{(A1-5)}$$

When $M = K+1$, we can rewrite matrix $[\alpha]$ in the form of partition matrix:

$$[\alpha] = \begin{bmatrix} \alpha_{11} & \cdots & \alpha_{1k} & \alpha_{1K+1} \\ \vdots & \ddots & \vdots & \vdots \\ \alpha_{K1} & \cdots & \alpha_{KK} & \alpha_{KK+1} \\ \alpha_{K+11} & \cdots & \alpha_{K+1K} & \alpha_{K+1K+1} \end{bmatrix} = \begin{bmatrix} \vec{\alpha}_{11} & \vec{\alpha}_{12} \\ \vec{\alpha}_{21} & \alpha_{K+1K+1} \end{bmatrix}. \qquad \text{(A1-6)}$$

In Equation (A1-6),

$$\vec{\alpha}_{11} = \begin{bmatrix} \alpha_{11} & \cdots & \alpha_{1K} \\ \vdots & \ddots & \vdots \\ \alpha_{K1} & \cdots & \alpha_{KK} \end{bmatrix}, \qquad \text{(A1-7)}$$

$$\vec{\alpha}_{12} = \{\alpha_{1K+1}, \alpha_{2K+1}, \ldots, \alpha_{KK+1}\}^T, \qquad \text{(A1-8)}$$

$$\vec{\alpha}_{21} = \{\alpha_{K+11}, \alpha_{K+12}, \ldots, \alpha_{K+1K}\}. \qquad \text{(A1-9)}$$

Rewrite the matrix $([I]-[\theta])$ into the same sized partition matrix. Let $[\nu] = [I]-[\theta]$, then

$$[\nu] = \begin{bmatrix} 1 & -\theta_{12} & \cdots & -\theta_{1K+1} \\ -\theta_{21} & 1 & \cdots & -\theta_{2K+1} \\ \vdots & \cdots & \ddots & \vdots \\ -\theta_{K+11} & -\theta_{K+12} & \cdots & 1 \end{bmatrix} = \begin{bmatrix} \vec{\nu}_{11} & \vec{\nu}_{12} \\ \vec{\nu}_{21} & 1 \end{bmatrix}, \qquad \text{(A1-10)}$$

where,

$$\vec{v}_{11}=\begin{bmatrix} 1 & -\theta_{12} & \cdots & -\theta_{1K} \\ -\theta_{21} & 1 & \cdots & -\theta_{2K} \\ \vdots & \vdots & \ddots & \vdots \\ -\theta_{K1} & -\theta_{K2} & \cdots & 1 \end{bmatrix}, \qquad \text{(A1-11)}$$

$$\vec{v}_{12}=\{-\theta_{1K+1},-\theta_{2K+1},\ldots,-\theta_{kK+1}\}^T, \qquad \text{(A1-12)}$$

$$\vec{v}_{21}=\{-\theta_{K+11},-\theta_{K+12},\ldots,-\theta_{K+1K}\}. \qquad \text{(A1-13)}$$

The following equation can be obtained by using the equation $[\alpha][\nu]=[I]$ and matrix multiplying rules:

$$\vec{\alpha}_{11}\vec{v}_{12}+\vec{\alpha}_{12}=\{0\}, \qquad \text{(A1-14)}$$

where, $\{0\}$ is a $1\times K$ null vector.

From Equation (A1-14), one can obtain the following equations:

$$-\sum_{s=1}^{K}\alpha_{is}\theta_{sK+1}+\alpha_{iK+1}=0 \quad (i=1,2,\ldots,K). \qquad \text{(A1-15)}$$

The first term in Equation (A1-15) is equal to or less than zero because of Equations (A1-3) and (A1-5). Therefore,

$$\alpha_{iK+1}\geq 0 \quad (i=1,2,\ldots,K). \qquad \text{(A1-16)}$$

On the other hand,

$$[\nu][\alpha]=[I]. \quad \text{(A1-17)}$$

Then the following result can be gained by using the same inference as mentioned above:

$$-\sum_{s=1}^{K}\theta_{K+1s}\alpha_{sj}+\alpha_{K+1j}=0 \quad (j=1,2,\ldots,K). \qquad \text{(A1-18)}$$

From Equation (A1-18), one has

$$\alpha_{K+1j}\geq 0 \quad (j=1,2,\ldots,K). \qquad \text{(A1-19)}$$

Furthermore, from

$$\alpha_{K+1K+1}-\sum_{s=1}^{K}\theta_{K+1s}\alpha_{sK+1}=1, \quad \text{(A1-20)}$$

the following conclusion can be drawn:

$$\alpha_{K+1K+1}\geq 1. \quad \text{(A1-21)}$$

A combination of Inequalities (A1-16), (A1-19) and (A1-21) gives

$$\alpha_{ij}\geq 0 \quad (i,j=1,2,\ldots,K+1). \quad \text{(A1-22)}$$

That is, when $M=K+1$, the Proposition 1 is also true.

Appendix 2

The Proof of Proposition 2

Proposition 2: All diagonal elements in the State Influence Matrix $[\alpha]$ are greater than or equal to one.

Proof

According to Equation (A1-17),

$$\alpha_{ii} - \sum_{\substack{s=1 \\ s\neq i}}^{M} \theta_{is}\alpha_{si} = 1. \qquad \text{(A2-1)}$$

The second term on the left side of Equation (A2-1) is not negative according to the properties of Interactive Coefficient (IC) and Proposition 1. Therefore,

$$\alpha_{ii} \geq 1 \quad (i = 1, 2, \cdots, M). \qquad \text{(A2-2)}$$

The inequality symbol becomes the equal symbol if all θ_{is}=0 ($s = 1, 2, \ldots, M$).

Propositions 1 and 2 have explicit physical meanings. Proposition 1 indicates that components in a system are subject to stable IntF. Proposition 2 indicates that the IntHs of the affected components in a system are greater than their Independent Hazards (IndHs) due to failure interactions. The failure likelihoods of these affected components also increase. The IntH of a component will be equal to its IndH if the failures of other components do not affect it.

BEHAVIOURAL PREFERENCES FOR ENGINEERING ASSET MANAGEMENT

J Amadi-Echendu

Dept of Engineering and Technology Management, University of Pretoria, Pretoria 0002, South Africs

Abstract: The essence of managing physical assets that form our built environment is to provide benefits to satisfy the continuum of constraints imposed by rapidly changing business strategy, economy, ergonomics, operational and technical integrity, and regulatory compliance. Innovative approaches to enhance and sustain the profile of values required from these assets demands a shift in the behavioural preferences or attitudes of engineering professionals in asset management occupations. This implies that engineering professionals in asset management occupations need to adapt to new thinking styles, and adopt effective cognitive and mental processing modes. Whilst assuming that thinking styles manifest in attitudes, this paper describes the results of a 2005 survey of 190 practicing engineers to ascertain what thinking styles should determine behavioural preferences of engineering-oriented managers of built environment assets of the innovation generation. The study confirms other results from cognitive theory and psychology, highlighting the top ten thinking styles as ranked by survey respondents. The paper is intended to provide a strategic view of Engineering Asset Management within the context of innovation, with particular focus on behavioural alignment towards the modern paradigm of the knowledge and learning economy.

Key Words: Asset Management, Thinking Styles, Behavioural Preferences, Innovation

1 INTRODUCTION

The main elements of our built environment are engineered physical assets which include, for example, airports, buildings, manufacturing and process plant, power stations, road and railway networks and systems, oil, gas and mining installations, telecommunications and utility networks. From an accounting and financial management point-of-view, these assets generally fall into four broad categories – (i) plant and equipment, (ii) buildings and infrastructure, (iii) furniture and fittings, and (iv) information technology. Overall management of built environment assets involves (i) acquisition, (ii) ownership, (iii) control, and (iv) utilisation. The essence of management is to ensure that the value profile defined by all stakeholders, is enhanced in a sustainable manner throughout the asset's life. The value that an asset can provide may be a broad combination of economic and social benefits depending on the preference and composition of the stakeholders. Acquisition, ownership, control and utilisation are high level management processes necessary to satisfy the continuum of constraints imposed by business strategy, economy, ergonomics, operational and technical integrity, and regulatory compliance [1].

From a systems viewpoint, the life of a built environment asset may be described interms of the phases and stages [2] illustrated in Figure 1. The two broad stages of capital development and business operations may be subdivided into four phases and further resolved into dominant activity periods. Successful management of the asset depends on innovative and synergistic integration of a wide range of 'hard' and 'soft' skills through the life-cycle phases and stages. These skills include, for example accounting, communications, engineering and technology disciplines. Whilst a broad range of skills is necessary, however, behavioural preferences or attitudes really underpin effective management of physical assets.

This paper examines the behavioural preferences of engineering professionals as physical asset managers within the context of innovation. In addition to managing the value profile defined by stakeholders at the various levels of the asset heirarchy, *Engineering Asset Managers* also have the responsibility to manage process innovation associated with, as well as technological innovation embedded in built environment assets.

2 THINKING STYLES AND BEHAVIOURAL PREFERENCES

With the advent of the new paradigm of innovation economy, knowledge has become the primary means of production. Thus, the knowledge base and skill set of engineering professionals are prime resources for effective management of physical assets in the new dispensation. *Engineering Asset Managers* form an important *ethnic* group of the innovation generation since they are vital actors in the processes of knowledge creation, diffusion, and transformation. Therefore, the behavioural preferences of engineering professionals affect the motivation, practice, roles and responsibilities, as well as the effectiveness of physical asset management.

From the point-of-view of psychology, it is intuitive to assume that behavioural preferences are external manifestations of internal thinking styles of individuals or groups, and the corollary is that thinking styles preceed or determine behavioural preferences. Maccoby [3] applied the context of cognitive development theory to discern four types of management thinking styles - analyser, energiser, synthesiser, and humaniser. He further argued that successful “information age organisations” require managers with higher preference for synthesising and humanising thinking styles. In a more rogorous approach, Herrmann’s Dominance Instrument [4] articulates twenty thinking styles, classifying them into four quadrants of the Whole Brain Model. Herrmann’s approach as summarised in Figure 2 shows a proforma of “200,000 profiles of the mentality of 200 representative occupations”.

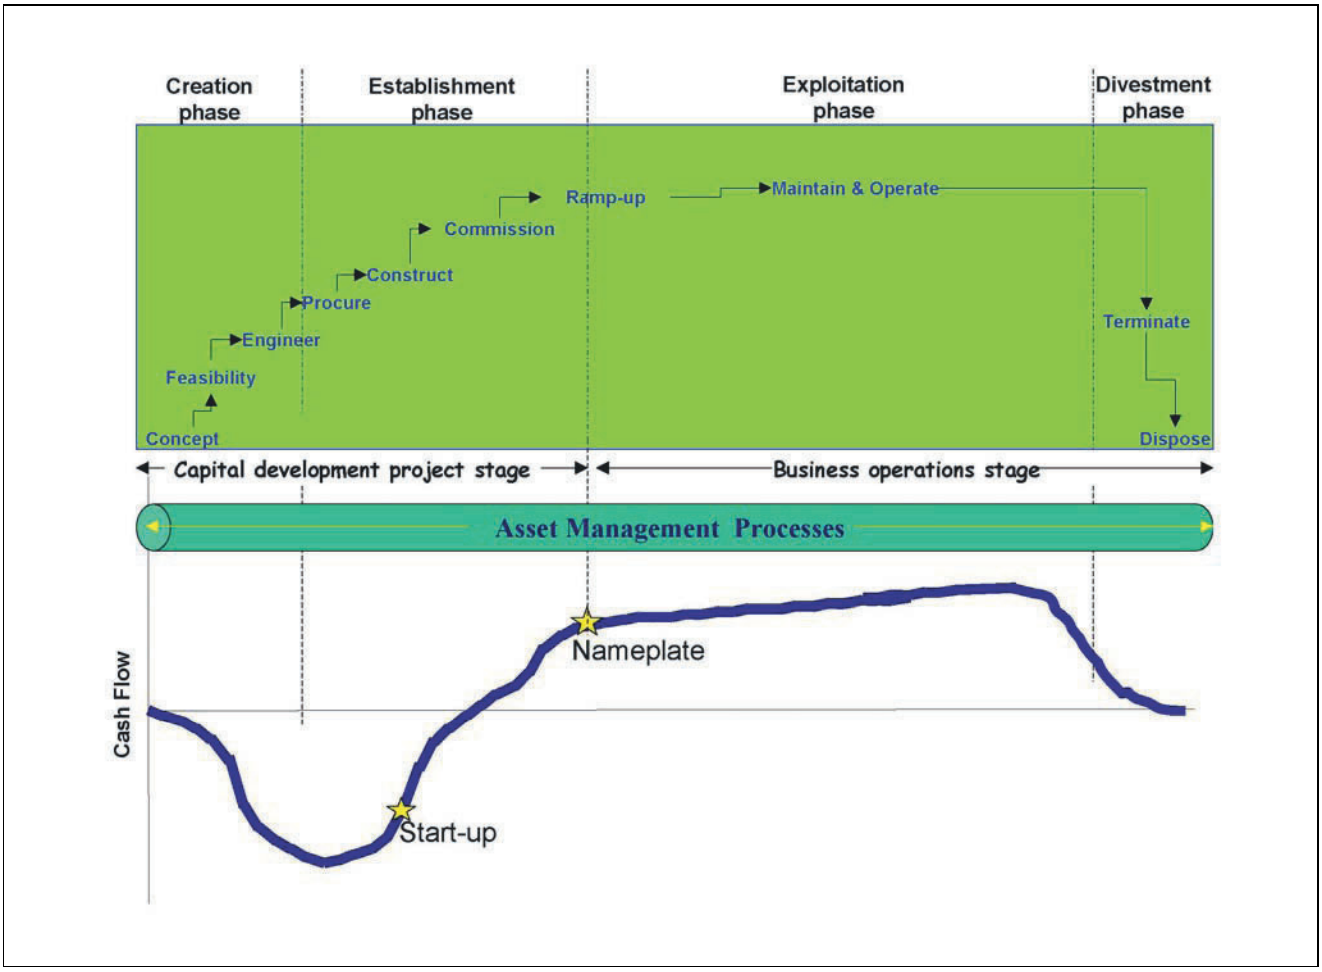

Figure 1. Life-Cycle of Built Environment Physical Asset

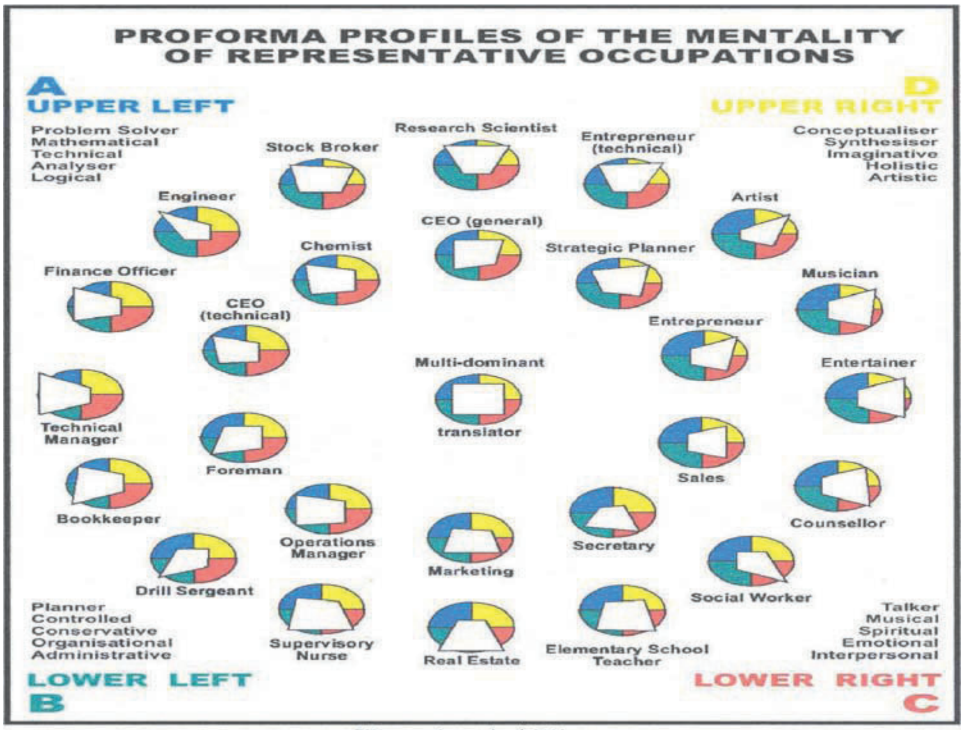
The question that arises from Figure 2 is - what should be the profile for the *Engineering Asset Manager*? What thinking styles should predominate so that appropriate behavioural preferences manifest into attitudes which, when combined with knowledge and skills, provide for effective management of physical assets within the new paradigm of innovation economy? The paradox seems to be the tension between conventional thinking styles of engineering professionals and the new requirement for behavioural preferences that encompass a much wider range of cognitive and mental processing modes. The innovation economy paradigm is characterised by continuous acquisition of new skills, with the corresponding rapid conversion and application of ideas and knowhow towards generating the value profile defined by multifarious stakeholders. Perhaps, the perplexing issue is that the Engineering Asset Manager has to rapidly adapt and adopt new mental processing modes necessary for managing the respective life-cycle phases/stages and complex organisational forms associated with the physical asset base within the vagaries of the innovation economy paradigm.

3 RESEARCH

3.1 Survey

The presentation here is an attempt to identify the dominant thinking styles for engineering asset management within the context of the innovation economy paradigm. Whilst on a speaking tour of Australia, the author requested that attendees complete a one-page questionnaire at the start of the meeting. The audience mostly consisted of practising engineers with primary responsibility for maintenance of physical assets. Considering that the engineering professional of the innovation generation is a knowledge worker, respondents were asked to rank the twenty thinking styles described in the Herrmann Brain Dominance Instrument (HBDI) on a five-point scale, ranging from 'not important (score = 1)' to 'extremely important (score = 5)'. All respondents completed the questionnaire within five minutes. The results are presented here in a manner consistent with the four-quadrant HBDI delineation of whole brain model and dominant thinking styles. For brevity, the focus is on the summarised opinions expressed in the feedback, bearing in mind that the data is non-probablistic, that is, the respondents do not form a statistically representative sample of the entire population of engineering professionals.



©Herrmann International, 2000

Figure 2. Thinking Style Profiles of Representative Occupations

3.2 Results

A total of 190 respondents participated in the survey. Table 1 shows the number of respondents who indicated a ranking for each of the twenty thinking styles. Questionnaire feedback in which a ranking was not indicated for more than fifteen thinking styles was regarded as incomplete and not included in the data set.

Table 1: Number of respondents indicating a ranking for Thinking Styles

HBDI Whole Brain Model Delineation of Thinking Styles	HBDI Thinking Styles	Number of respondents indicating a ranking for each Thinking Style
Quadrant D, Upper Right, Cerebral	Imaginative	187
	Synthesiser	183
	Artistic	184
	Holistic	181
	Conceptualizer	183
Quadrant C, Lower Right, Limbic	Interpersonal	185
	Emotional	186
	Musical	185
	Spiritual	185
	Talker	188
Quadrant B, Lower Left, Limbic	Controlled	185
	Conservative	186
	Planner	187
	Organisational	186
	Administrative	186
Quadrant A, Upper Left, Cerebral	Logical	186
	Analyser	186
	Mathematical	186
	Technical	184
	Problem Solver	187

The relative importance of thinking styles as indicated by the respondents is shown in Figure 3 in a manner consistent with the HBDI delineation according to the Whole Brain Model. This picture shows that a discernible number of respondents did not attach any importance to artistic (9.7%), emotional (10.7%), conservative (21.5%), spiritual (33%) and musical (46%) thinking styles. This could be interpreted to mean that as much as 46% of respondents suggest that musical thinking style should not influence the behavioural preference of the *Engineering Asset Manager* of the innovation dispensation.

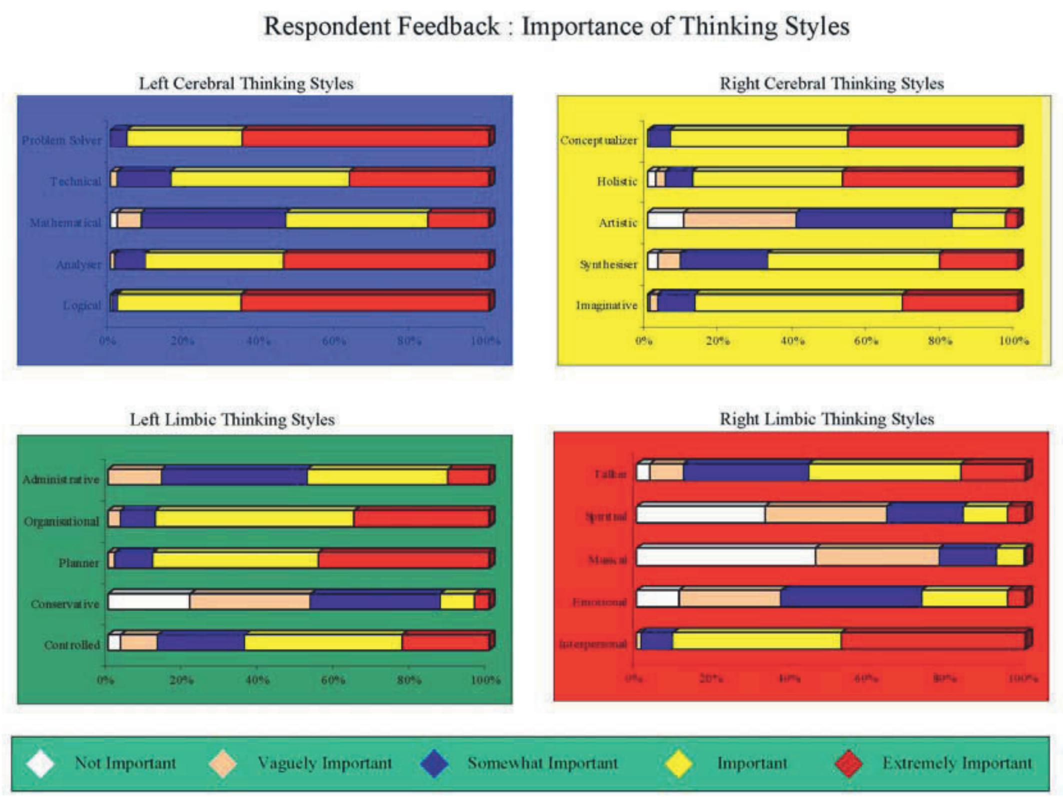


Figure 3. Ranking of Thinking Styles

The top ten thinking styles ranked as extremely important by the respondents is shown in Figure 4 to include:

i. **Logical** – Nearly 66% of respondents indicate that the 'ability to reason deductively from what has gone before' is extremely important.

ii. **Problem solving** – Again, 65% of respondents indicate that the 'ability to find solutions to difficult problems by reasoning' is extremely important.

iii. **Analysing** – 54% of respondents indicate that the 'ability to break up ideas into parts and examining them to see how they fit together' is extremely important.

iv. **Interpersonal** – Nearly 48% of respondents indicate that the 'ability to easily develop and maintain meaningful and pleasant relationships with many different kinds of people' is extremely important.

v. **Holistic** – About 47% of respondents indicate that the 'ability to perceive and understand the 'big picture' without dwelling on individual elements' is extremely important.

vi. **Conceptualisng** – 46% of respondents indicate that the 'ability to conceive thoughts and ideas, to generalise abstract ideas from specific instances' is extremely important.

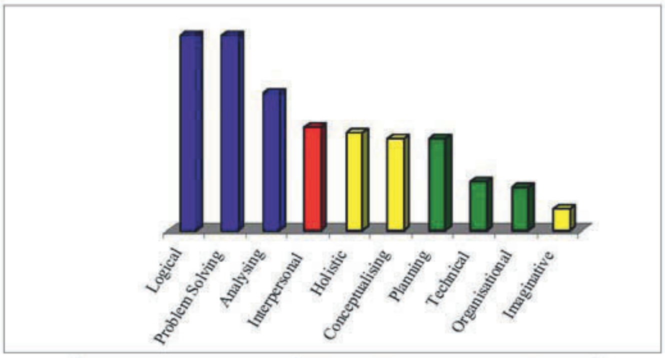
vii. **Planning** – 45% of respondents indicate that the 'ability to formulate methods to achieve a desired end in advance of taking actions to implement' is extremely important.

viii. **Technical** – 37% of respondents indicate that the 'ability to understand and apply engineering and scientific knowledge' is extremely important.

ix. **Organisational** – 35% of respondents indicate that the 'ability to arrange people, concepts, ideas, etc into coherent relationships with each other' is extremely important.

x. **Imaginative** – 31% of respondents indicate that the ‘ability to form mental images of things not immediately available to the senses or never wholly perceived in reality, ability to confront and deal with a problem in a new way’ is extremely important.

Respondent Feedback : Top Ten Extremely Important Thinking Styles



Thinking Style	% of Respondents indicating Extremely Important
Logical	65.5%
Problem Solving	65.2%
Analysing	54.3%
Interpersonal	47.5%
Holistic	47.2%
Conceptualisng	46.0%
Planning	45.0%
Technical	37.0%
Organisational	35.4%
Imaginative	31.0%

Figure 4. Top Ten “Extremely Important” Thinking Styles

4 SUMMARY

Six of the top ten extremely important thinking styles belong to the left-brain quadrants, hence validating the HBDI proforma profile of engineering and related occupations. This is not surprising since all the respondents had engineering background and technical orientation. What is more interesting is the fact that four of the top ten extremely important thinking styles belong to the right-brain quadrants, with three in the upper right mental processing mode. This result also supports the increased shift in emphasis towards behavioural preferences generally refered to as ‘soft’ skills. In comparing the respondent feedback with the HBDI proforma profiles of occupations shown earlier in Figure 2, the suggestion is that the profile for the *Engineering Asset Manager* should lie between that shown for technical chief executive office (CEO) and chemist. The ramification is that right-brained mental processing modes should be combined with scientific knowledge and technical skills to effectively manage the various life-cycle phases, stages, and activities associated with built environment assets.

The essence of managing physical assets that form our built environment is to provide benefits to satisfy the continuum of constraints imposed by rapidly changing business strategy, economy, ergonomics, operational and technical integrity, and regulatory compliance. Innovative approaches to enhance and sustain the profile of values required from these assets demands a shift in the behavioural preferences or attitudes of engineering professionals in asset management occupations. This implies that engineering professionals in asset management occupations need to adapt to new thinking styles, and adopt effective cognitive and mental processing modes. Whilst assuming that thinking styles manifest in attitudes, this paper has described the results of a 2005 survey of 190 practicing engineers to ascertain what thinking styles should determine behavioural preferences of engineering-oriented managers of built environment assets of the innovation generation. The study confirms other results from cognitive theory and psychology, highlighting the top ten thinking styles as ranked by survey respondents. The paper is intended to provide a strategic view of Engineering Asset Management within the context of innovation, with particular focus on behavioural alignment towards the modern paradigm of the knowledge and learning economy.

A CASE STUDY ON MAINTENANCE AND RSA PUBLIC SERVICE DELIVERY

G Stockwell

Masters in Project Management, Department of Engineering and Technology Management, University of Pretoria, Pretoria 0002, South Africa

Abstract: Public sector service delivery is vital in ensuring that priorities determined by government are met. Maintenance is a vital function in the management of public sector physical assets. The goal is not only to ensure that such assets operate as intended but also, that they remain in good condition and provide the capacity for effective and efficient service delivery.

In order to address a historical backlog in the maintenance of public sector assets, the South African National Department of Public Works has implemented a Repair and Maintenance Programme (RAMP). This paper identifies five key implementation factors of RAMP and their influence on efficient and effective service delivery, as viewed from a survey of the respective custodians of the public sector assets. The paper examines the performance of public sector service delivery and provides a comparison pre- and post-implementation of RAMP. The findings of the research is important to government policy makers with regard to the effectiveness of RAMP.

Key Words: Physical Asset Management, Public Sector Assets, Repair and Maintenance, Customer Satisfaction.

1 BACKGROUND

1.1 Introduction

The South African National Department of Public Works, in partnership with other National Government Departments, has been tasked with promoting commercial attitudes within the public sector with regard to efficiency of service delivery programmes. Service delivery is of key importance in ensuring that priorities determined by the National Government are met. These priorities relate to housing, water, sanitation, health, security, social welfare, education and poverty relief, to mention but a few. The South African National Department of Public Works plays a crucial role in facilitating delivery by other National Government Departments through the provision and management of public sector infrastructure.

A vital part of the management of public sector infrastructure is continuous maintenance to ensure that public sector infrastructure is conducive and capable of ensuring effective and efficient service delivery at all times.

Since the first democratic elections took place in South Africa in 1994 the South African Government has set in place many policies to increase inter-continental commerce within Africa. This has resulted in a vast increase in traffic flow through South African Border Control Ports of Entry. Where previously emphasis was placed on Border Control Immigration Enforcement weight was shifted to enforcement of Customs bringing about a need for increase efficiency of the South African Revenue Services: Customs together with increase numbers of personnel. The increased number of personnel places additional load on the infrastructure and thus more efficient maintenance is required.

Statistics have shown that the prison population in South Africa has increased drastically over the past 20 years. Research conducted by Oppler indicated an increase in the prison population from 109,000 in 1984 to 146,000 in 1997 and further indicated a projected increase to 156,000 in the years 1998 and 1999 (1998, pp.2-3). Oppler stated that the increase in prison population was in line with international trends and that the same phenomenon was evident in the UK and US. The Times accounted that the increases prison population could be attribute to sentencing reforms rather than an increase in crime (1996). Despite the vast increase in the prison population over the above period insufficient additional prisons (additional prisons with a capacity of approximately 10,000 were constructed) have been built and as a result prisons are over-populated resulting in increased maintenance strain on the facilities.

The above two paragraphs serve as examples of the amplified requirements of South African public sector infrastructure over the past 20 years.

Currently the repair backlog of public sector infrastructure in South Africa is estimated at R12.5 billion. Faced with the challenge of reducing the RSA public sector repair backlog over a period of ten years as well as promoting commercial attitudes with regard to service delivery, the South African National Department of Public Works developed the Repair and Maintenance Programme (RAMP) methodology in January 2000. The Repair and Maintenance Programme (RAMP) is a multi-disciplinary programme aimed at repairing public sector infrastructure to a functional condition and maintaining such infrastructure in a functional condition in order to ensure the required service delivery by other National Government Departments.

Since the RAMP was initiated in 1999 and pilot projects implemented for the Department of Correctional Services the programme has escalated to include over 199 facilities for 10 National Government Departments.

To date 615 Professional Service Providers and 390 Contractors have been appointed. Status quo reports to the value of R 5.9 billion have been developed. Expenditure to date on the RAMP amounts to R 3.0 billion.

1.2 Research Problem

The RAMP is currently in the fifth year of implementation and to date the level of service delivery that the RAMP offers to the User Clients/National Government Departments has not been formally assessed, evaluated or quantified.

The expenditure achieved through the implementation of the RAMP for the 2004/2005 financial year amounted to R 1.2 billion. As future planning the National Department of Public Works has developed a holistic maintenance plan that indicates a required R 30.8 billion over a period of 10 financial years.

From the above paragraph it is evident that the RAMP is responsible for a large portion of the National Department of Public Works' yearly budget allocation and expenditure. The findings of this study will be of importance to the South African National Department of Public Works policy makers in order to assess whether the RAMP offers the level of service delivery expected by the National Government Departments and thus assess whether the RAMP offers "value for money" and should be extended in future.

In order to assess the service delivery offered by the RAMP it is firstly required to gauge the effectiveness of the RAMP compared to the previous maintenance methodologies employed namely; (1) day to day maintenance, (2) year/term contracts and (3) own resources. Given the results of the above, the level of improved service delivery post implementation of the RAMP will be assess in terms of a pre- and post- RAMP appraisal.

The performance based maintenance methodology put into action as part of the RAMP relies on 5 key implementation factors namely; (1) monthly site progress meetings, (2) monthly maintenance scoring, (3) logging of breakdowns, (4) feedback of breakdowns repaired and (5) performance based payment. The contribution of each of the factors toward service delivery as well as the ability of User Clients to influence service delivery through their involvement in the 5 factors will be assessed and presented. This will aid the Department of Public Works and User Clients to place emphasis on the correct aspects in order to optimise service delivery.

In order to assess the service delivery offered it is firstly required to establish what factors are of importance to the User Client in the quantification of service delivery. Through cooperation with the User Clients and the Department of Public Works the major factors which are used by the various Government Departments to quantify service delivery will be identified. This will aid the Department of Public Works in future assessment and quantification of service delivery offered to the User Clients.

2 THEORETICAL FRAMEWORK

Literature advocates that (1) Maintenance, (2) Commercialisation of the Public Sector and (3) Outsourcing are factors which significantly contribute toward service delivery.

Coetzee reports that maintenance is the fastest growing discipline in the world (1997). "In the last decade, industrial firms in different industries are increasingly tempted to follow a" life-cycle strategy (construction, development, maintenance etc.), "thus offering total need fulfilment to customers through product/service bundles" (Stremersch, 2000, p.1). Stremerch *et al.* concluded that the reputation of the Contractor and the level of detail and information provided regarding maintenance activities are the two most prominent factors for service delivery in full-service maintenance contracts (2000, pp.9-10).

Brown *et al.* indicated "There is an international trend to contestability and marketisation in the delivery of public services" (2000, p.206). Commercialisation can be defined as "a compromise between traditional style of public administration and marketisation in the form of privatisation, contracting-out and contestability" (2000, pp.206-207). In their research Brown *et al.* explore how the commercialisation of government services result in "greater efficiency, higher quality of service, a clearer focus on customers and better value for money" while Stewart and Walsh indicate the strongest justification for introducing private market-orientated delivery systems are usually based on the need to reduce government expenditure, improve cost efficiency and provide more accountable and transparent delivery systems (1992, pp.97-110). Brown *et al.* also identifies the capacity of government departments to deliver services as a driving factor for commercialisation. One of the major problems identified with public service delivery has been identified by Brown as "fragmentation and the lack of appropriately coordinated government services" (2002, p.439).

Teresko reported that in 1995 Peter Drucker predicted, "in 10 to 15 years organisations may be outsourcing all work that is 'support' rather than revenue producing, and all activities that do not offer career opportunities into senior management" (1999, p.38-45). Since outsourcing was first identified as a business strategy 16 years ago outsourcing has gained acceptance in the marketplace and a growing trend established amongst international organisations and corporations to outsource their services, day-to-day activities, maintenance requirements amongst others (Mullin, 1996, pp.28-36). Outsourcing has gained respect in the market place as “top-performing companies outsource to perform even better” (Teresko, 1999, p.45).

The foremost factors listed for the outsourcing of services was cost-effectiveness and improved customer satisfactions (service delivery). According to Sam Amore and others, in considering outsourcing one should “Evaluate the concept from the standpoint of what the value-added is as opposed to what the reduction in cost is going to be” (Chalos *et al.*, 1998, pp.901-919).

Clarke reports that 92% of companies who outsource listed cost as the driving factor. However Clarke says that the underlying management philosophy, the notion of “core competency” is just as important as the cost aspect (2004, pp.33-35). According to Quinn *et al.* possibly the greatest leverage obtained through outsourcing is that of specialised professional capabilities that would be prohibitively expensive or even impossible to duplicate internally (1994, pp.43-56).

Mullin however indicates that various outsourced contracts are not successful as a result of “many consultants, outsourcing suppliers and companies that outsource agree that businesses have virtually abdicated the management function in outsourcing contracts, creating and environment where suppliers manage the relationship” (1996, pp.29-36). Goldman says that the lack of performance expectations, measurement criteria, procedures for amendments and lack of continuity in personnel involved are the major factors which plague outsourcing (Mullin, 1996, p.29).

3 RESEARCH DESIGN AND METHODOLOGY

3.1 Research Strategy

The research population includes the Department of Public Works (as service provider) and the various User Departments for whom the RAMP is currently being implemented. Data gathering was divided into three hierarchical levels; (1) Department of Public Works Head Office, (2) User Client Head Office and (3) User Client Local Representatives. Separate questionnaires were administered at the three hierarchical levels. Questionnaires were administered by means of a call centre in order to increase the response rate and to further eliminate some potential bias.

Questionnaires at levels 1 and 2 were aimed at obtaining high level information regarding the factors used for quantification of service delivery, input of the RAMP toward a commercialised mindset and the role of the 5 key implementation factors toward service delivery. An evaluation of the success of the RAMP compared to previous maintenance methodologies was conducted. The questionnaires administered at level 3 focussed specifically on an evaluation of service delivery pre- and post- implementation of the RAMP as well as the contribution of the 5 key implementation factors toward service delivery.

For the purposes of the research at hand the 3 independent User Departments with the highest number of facilities where the RAMP is currently being implemented were selected as the sampling frame. The three User Departments selected are; (1) Department of Correctional Services, (2) Department of Justice and (3) Border Control Ports of Entry.

3.2 Data Analysis

Data was collected and analysed per User Department. The data presented here illustrates an overview of the data gathered for the three User Client Departments.

3.2.1 Quantification of Service Delivery

The quantification of service delivery was only assessed at User Client Head Office level as it is at Head Office level that service level agreements are agreed upon. The research highlighted 6 key factors that could be used for quantification of service delivery namely; (1) Expenditure vs. Budget, (2) Number of contracts completed successfully vs. the number of contract not completed successfully, (3) Contract completed on time vs. contract not completed on time, (4) Contract cost, (5) Continuity of work and role-players and (6) Time from planning instruction to site handover. The User Client Head Office level rated the 4 factors most and equally important for the quantification of Service Delivery as being time for completion, contract cost, continuity of work and time from planning instruction to site handover. Expenditure vs. budget is least important for the quantification of service delivery.

The User Department listed the following factors which should additionally be considered in the quantification of service delivery; (1) Personnel wellness, safety and health and happiness, (2) User Client Local Representative satisfaction, (3) Shorter planning and implementation times, (4) Quality of work and (5) Follow up service.

3.2.2 Commercialisation

By definition the RAMP can be classified as a programme which contributes toward the commercialisation of the public sector. All User Client Department confirmed that the RAMP contributes toward a commercialised mindset within the RSA Public Sector.

3.2.3 Effectiveness of Previous Maintenance Methodologies

The vast majority of the User Clients at Head Office and Local Representative Levels rated the effectiveness of previous maintenance methodologies as less effective than the RAMP as illustrated by Figure 1.

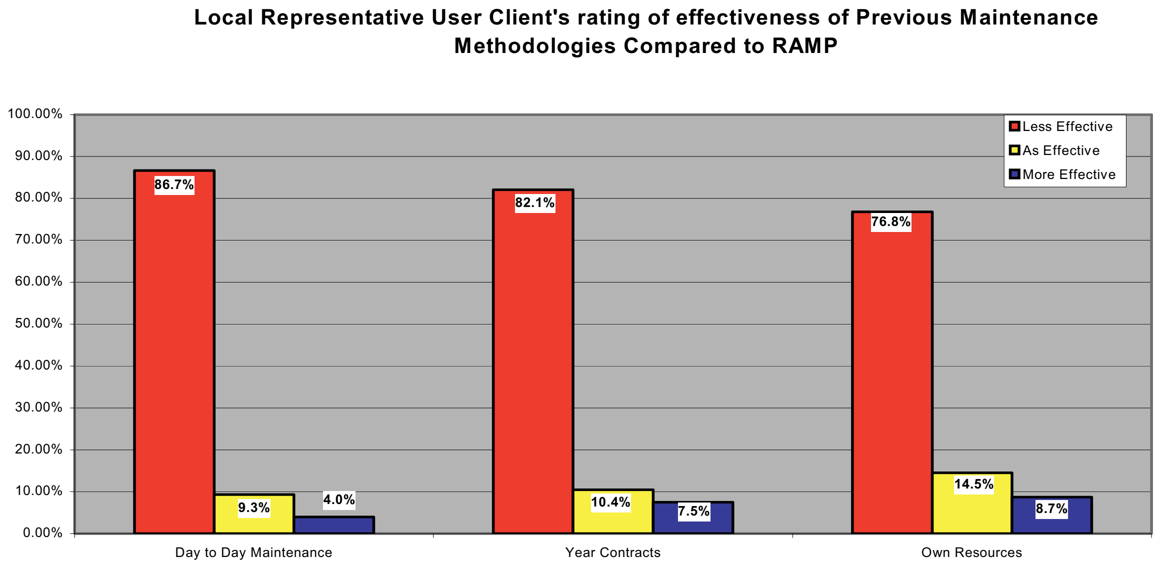

Figure 1: Effectiveness of previous maintenance methodologies compared to RAMP

3.2.4 Contribution of the 5 Key implementing factors of the Performance Based Maintenance Methodology toward Service Delivery

The 5 key implementation factors employed as part of the performance based maintenance system are; (1) Monthly Progress Meetings, (2) Monthly Maintenance Scoring, (3) Logging of breakdowns, (4) Feedback of breakdowns repaired and (5) Performance based payment. The contribution of each of the above factors was rated by the User Client in terms of major- (5 points), strong- (4 points), medium- (3 points), minor- (2 points) and no- influence (1 point).

The Head Office User Clients rated feedback of breakdowns repaired, logging of breakdowns and performance based payment as being the major contributing factors toward service delivery. The Local Representative User Clients identified monthly progress meetings, logging of breakdowns and the feedback of breakdowns repaired as the major contributors toward service delivery.

3.2.5 Improvement of Service Delivery through User Client's Involvement in the 5 Key implementing factors of the Performance Based Maintenance Methodology

The Head Office User Client views the User Client's involvement in monthly progress meetings and logging of breakdowns as paramount to their contribution toward improving service delivery followed by their involvement in the monthly maintenance scoring and feedback on breakdowns repaired.

The Local Representative User Client views their involvement in monthly progress meetings, logging of breakdowns and feedback on breakdowns repaired as major contributors toward service delivery.

3.2.6 10 Core Business Requirements: Before & After Ramp And Impact Assessment

Each User Department was requested to identify their 10 core business requirements. The service delivery prior to and post implementation of the RAMP with specific focus on their 10 core business requirement was then rated by the User Clients at Local level. The impact of the improved level of service delivery was assessed in terms of the User Clients increased ability to perform their core business.

Figure 2 indicates a marked overall improvement post implementation of the RAMP for the 10 core business requirements for the Border Control Ports of Entry.

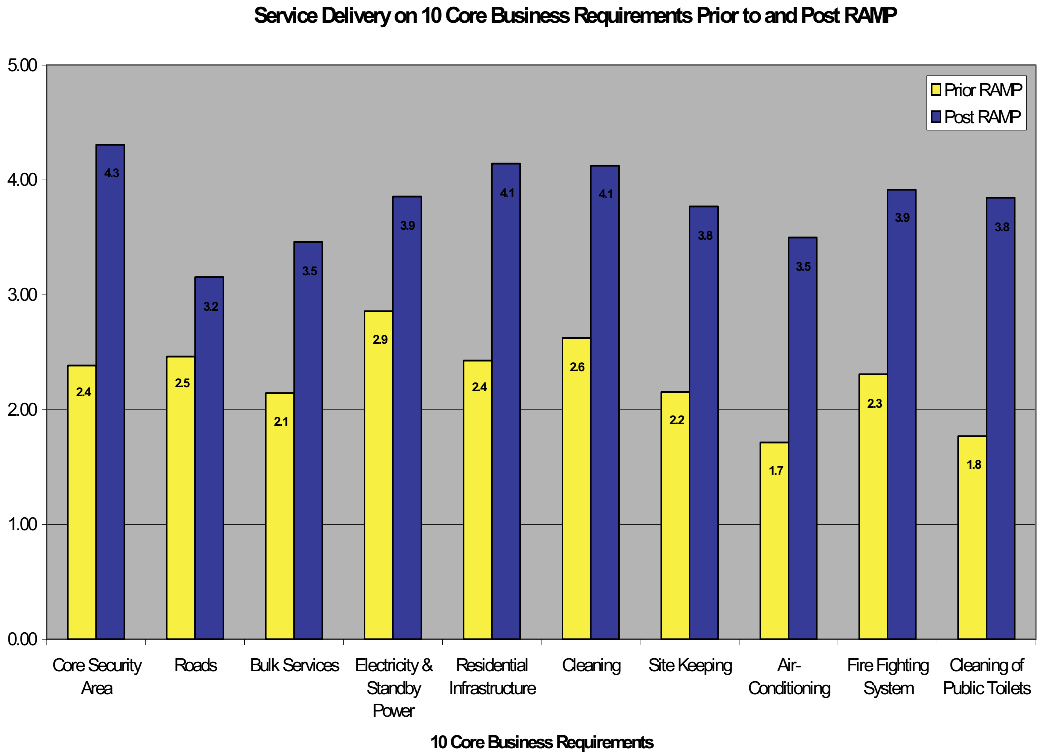

Figure 2: Service Delivery prior to and post the RAMP with reference to the 10 Core Business Requirements

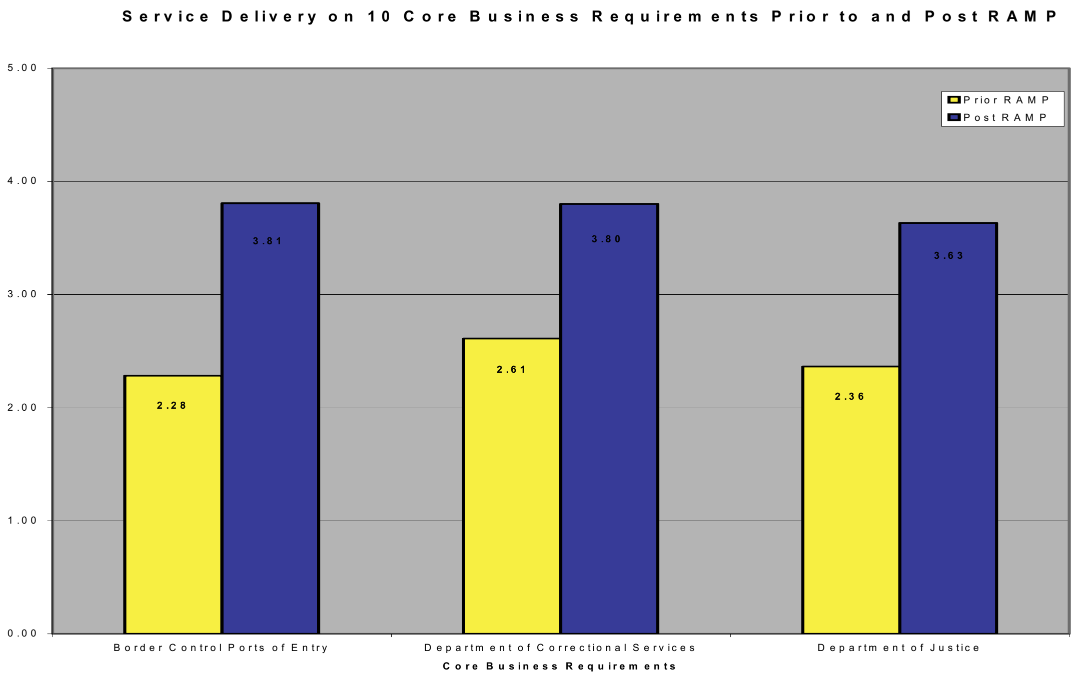

Figure 3: Service Delivery prior to and post the RAMP with reference to the 10 Core Business Requirements.

Figure 3 indicates the average service delivery levels pre- and post- RAMP for the 10 core business requirements of each User Client

4 CONCLUSIONS

4.1 Research Results

The results clearly indicate that maintenance, within the RAMP, contributes toward service delivery within the RSA Public Sector. A clear improvement in service delivery pre- and post- implementation of the RAMP is noticeable. The study further ascertained that the User Client has a substantially improved ability to perform their core business functions as a result of the improved service delivery offered by the RAMP.

The study indicated the RAMP proved to be substantially more effective than any of the previously implemented maintenance methodologies. A far greater structured approach to maintenance is achieved through the implementation of the RAMP compared to the previous maintenance methodologies thus offering greater utility of the facilities.

The implementation of the RAMP has alleviated the burden of maintenance on the User Client (as compared with previous maintenance methodologies) as the burden is now born by the Department of Public Works. This provides the User Client with the opportunity to apply greater focus on performing their core business responsibilities.

The research further yielded factors which can be used for the quantification of public sector service delivery by the User Client Departments and the implementing Department (I.e. National Department of Public Works). These factors may be employed by the Department of Public Works in future service level agreements with other National Government Departments.

The 5 key implementing factors of the RAMP were assessed and found to contribute greatly toward RSA public sector service delivery within a maintenance programme. The two most important factors to both Head Office and Local Representative level were found to be the logging of breakdowns and feedback on breakdowns repaired. Local Representative User Clients also viewed monthly maintenance control meetings as a major contributor toward service delivery.

4.2 Contribution to Practise

The research clearly identified the need for maintenance as a service delivery characteristic within the public sector. The Department of Public Works is in the process of implementing a Service Delivery Improvement Programme (SDIP). The research conducted will aid the Department of Public Works in assessment of the current contribution of maintenance toward service delivery and possible methods for improvement of the current maintenance methodologies to achieved improved public sector service delivery.

4.3 Recommendations

The research has indicated that the User Client's involvement in the key implementing factors of the performance based maintenance methodology is paramount to improved service delivery. It is this essential the User Client is properly informed and involved with the implementation of the keys aspect of performance based maintenance methodology in order to ensure that service delivery to the public sector is optimised.

It is thus suggested that the Department of Public Works imposes more stringent implementation, integration and coordination criteria between the Repair and Maintenance Programme management team and User Client. The User Client is to be actively involvement in the implementation of the 5 key implementing factors of the performance based maintenance methodology.

4.4 Concluding Remarks

The Repair and Maintenance Programme implements a structured approach to maintenance thus providing the User Client with more effective use of public facilities and in so doing lessens the burden of maintenance on the User Client. User Clients are thus able to focus more on performing their core business competencies.

The research has indicated greater efficiency in terms of the maintainability of public sector assets. Although various facility specific problems were identified during the course of the study it can be concluded that the RAMP provides the User Client with greatly improved service delivery in terms of maintenance.

The research has indicated that greater emphasis should be placed on User Client involvement and high-level management within the RAMP.

The RAMP offers more efficient and effective performance compared to any previous maintenance methodologies implemented within the public sector in South Africa. However by applying greater focus in the areas identified by this study public sector service delivery can be further improved.

CRITICAL SUCCESS FACTORS FOR BROWN-FIELD CAPITAL AND RENEWAL PROJECTS

J Warchol [a] and Prof J Amadi-Echendu [b]

Abstract: Manufacturing companies operate in a business environment where, due to the factors such as cost and location of the infrastructure, incremental growth and competitive advantage may be a result of in-house construction projects. Competitive advantage may be realised by effective management of the critical success factors of in-house construction projects. These projects often tend to be of a brown-field nature and are characterised by a high degree of uncertainty, predominantly due to the interaction between the project and the existing physical asset base. In this regard, it is vital to understand the factors that influence the success of capital and renewal construction projects in the brown-field context. Although each project has unique features, there are critical success factors which can be customised towards successful outcomes in the brown-field environment. Based on a survey of recent projects, this paper examines critical success factors applicable to brown-field capital and renewal construction projects. The paper also provides an empirical assessment of the degree of managerial focus on the critical success factors and its impact on the outcome of brown-field construction projects.

Key Words: Physical Asset Management, Brown-field Projects, Critical Success Factors.

1 INTRODUCTION

Project Management is a well-structured discipline offering approaches that may be applied to almost any activity or aspect of human life spanning across the cultures, industries and organisations. Project Management evolves all the time in order to accommodate the latest requirements demanded by the new circumstances or by the social or technological developments. It is widely acknowledged that successful companies increase their market share through the successful execution of their projects. The market environment of the 21st century demands high quality of products within an acceptable price range and delivered in the shortest possible time. As a result, organisations must continually improve the quality and the efficiency of their processes as well as the cost effectiveness of their products to remain competitive. In order to survive in such a competitive market, organic growth of an existing asset base is essential. This necessitates a strategically planned and executed portfolio of projects to create economic value and competitive advantage.

Manufacturing companies operate within very specific business dynamics that require a focus on sustained growth. These companies increase their competitiveness through unit cost reduction and compliance with contractual obligations (quality of product and reliability of product delivery) rather than price setting. As a result, there is an ongoing need within these organisations to continually improve their production facilities and processes. While growth provided by completely new plant facilities is not uncommon, the incremental growth of a manufacturing company may be a result of a revolving program of in-house construction projects. Due to the factors such as cost, location and presence of an existing infrastructure, majority of these projects tend to be of a brown-field nature.

Brown field denotes “a land previously built on” (Encarta Dictionary, 2005). Accordingly, *brown field project* may be defined as a project executed within the existing facilities and requiring some demolition or remediation (Corman, 2004). Brown-field construction project is typically executed within, and usually at the mercy of, an existing asset (plant) environment. High degree of uncertainty is a predominant factor influencing project success as unexpected schedule or scope changes due to the plant operating requirements or scope changes are not uncommon. Project Management process must also accommodate the over-riding focus of management on the performance of the asset in use.

By comparison, *green field* project may be defined as a project executed on a virgin land and not affected by the existing production facilities. As a result, the uncertainties associated with the impact of the existing production facilities on the project do not feature in the project’s overall risk profile.

Although project success is critical to any organisation as its survival often depends on it, success is difficult to achieve. By definition, every project is a unique endeavour and is subject to uncertainty. Ideally, project uncertainty should be gradually resolved during the project execution. To facilitate this process, it is essential to establish and exploit factors which are critical to the project success (critical success factors). Due to the uniqueness of all projects, each project may be dependent on a different set of critical success factors. The body of knowledge available, however, indicates that projects executed in a similar environment and having similar goals exhibit a marked similarity in terms of the applicable clusters of critical success factors. As a result, brown-field construction projects should have a specific set of critical success factors which, if exploited, should increase chances of the project success.

Previous experience in the execution of brown-field construction projects indicates that the generous body of knowledge available in the Project Management domain needs to be customised in order to address the practicalities of such projects. Above all, it is necessary to identify the relevant critical success factors applicable to brown-field construction projects and manage these factors on an ongoing basis in order to improve success rate. Unfortunately, little information exists in the public domain regarding the identification of the critical success factors for brown-field construction projects. It is also unknown to what degree a managerial focus on the critical success factors improves the success rate of brown-field construction projects.

The research objective is to identify a set of critical success factors specific to brown-field construction projects and to establish correlation between the management focus and project outcome. This paper attempts to answer the following questions:

- What critical success factors are applicable to brown-field construction projects?
- What is correlation between managerial focus (effort) on the critical success factors and the overall outcome (success) for brown-field construction projects?

Two hypotheses arise:

- Hypothesis 1: A project-specific set of critical success factors exists for brown-field construction projects.
- Hypothesis 2: An increased managerial focus in the areas affected by the critical success factors results in higher rate of success of brown-field construction projects.

2 THEORETICAL BACKGROUND

Project Management is usually tracked back to the precedence network diagramming techniques developed for the Polaris Submarine project in the 1950's (Fondahl, 1987). Today, virtually all construction, product development and engineering efforts use some formal Project Management structure (Cleland & King, 1983). There is seemingly no common definition of Project Management. Oisen (1971) defines Project Management as " ... a collection of tools and techniques ... to direct the use of diverse resources toward the accomplishment of a unique, complex one-time task within time, cost and quality constraints …". Atkinson (1999) points out the link to some project success measures such as cost, time and quality.

“Grow or die” is a well-known business adage that symbolises why many companies have a long-term goal of sustained growth (Bloodgood & Katz, 2004, p.60). This goal necessitates a strategically planned and executed portfolio of successful projects. Since projects are a part of the organisation’s strategic management, defining and assessing project success is therefore a strategic management concept (Shenhar, Dvir, Levy & Maltz, 2001). Building on this view, it is critical to identify success measures, and their respective sensitivity to project success. Cost, time and quality (the Iron Triangle) have become inextricably linked over the last 50 years with measuring the success of a project. Atkinson (1999, p.339) proposed two-stage framework viz.: criteria for success in the delivery stage ("doing it right") and criteria for success in the post-delivery stage ("getting it right"). Cost, time and quality fall into the former group while impact on customer, business success resulting from the project and how well the project prepared the organisation for the future fall into the latter part of the framework. Other researchers generally support this line of thinking. Shenhar et al (2001) identified four major distinct success dimensions: project efficiency, impact on the customer, direct business and organisational success and preparing for the future. White & Fortune (2002) conducted a survey which indicated that even though most of the respondents judged the success of their projects by means of the criteria of time, budget and specification, they were also concerned with the impact of the project on the organisation involved. Some studies suggested adding a new element to the notion of project success - client satisfaction (Lim & Mohamed, 1999 and DeCotiis and Dyer, 1979). Baker & Fisher (1988) went one step further to include the level of satisfaction of four different stakeholders: the customer, the developer, the project team and the end user. Some researchers investigated the issue in the reverse manner, by researching the causes of project failure. Resulting from this approach, Pinto & Mantel (1990) identified three aspects of project performance as benchmarks for measuring the success or failure of a project: the implementation process, the perceived value of the project and the client satisfaction with the result. Shenhar et al. (2001) and Pinto & Mantel (1990) also indicated that the concept of project success was contingent on the specific project characteristics.

Project success and failure were first introduced by Rubin and Seeling (1967). Shultz, Slevin and Pinto (1987) were among the first to classify the critical factors. Unfortunately, there is little agreement on the casual factors of project success (Pinto & Slevin, 1987). Belassi and Tukel (1996) proposed to group factors into four areas: those related to project, those related to project manager and the team, those related to the organisation and those related to the external environment. These groups are interrelated such that a factor in one group might influence a factor in another group (Dvir, Lipovetsky, Shenhar & Tischler, 1998, Belassi & Tukel, 1996, White & Fortune, 2002 and Westerveld, 2003). Although each project is unique, similar types of projects may exhibit distinctive patterns of factors associated with success or failure (Pinto & Mantel, 1990).

While each project might require a different set of critical success factors, similar projects should have similar groups of critical success factors. It is, therefore, possible to define groups of success factors for any type of project. These groups of factors must thereafter be carefully managed throughout the project lifecycle in order to achieve success.

3 RESEARCH

The first purpose of the study was to identify a cluster of critical success factors affecting the outcomes of brown-field construction projects. The second purpose was to establish the relationship between managerial focus on these factors and project outcome. The set of applicable success factors was established based on the selection and ranking of the most common factors as viewed by a sample project population. Project success measures were established in a similar manner by surveying another population group. Managerial focus on the identified set of critical success factors was evaluated by means of structured interviews conducted with the key personnel of a selected group of projects. The correlation between the managerial focus on the critical success factors and the project outcome was thereafter established through the analysis of the collected data. Our study concentrated on three distinctive areas, each of them requiring its own process.

3.1 Critical success factors

Twenty factors were selected based on literature review. A survey questionnaire was used to test the perceptions of the project community with respect to the importance of each identified factor. Respondents were requested to asses the impact of each factor on both green-field and brown-field project environment as well as to assess the importance of each factor for the success of brown-field construction projects. All success factors were subsequently ranked in terms of their importance and the five highest ranked factors which were considered to have more impact on brown-field projects as compared to green-field projects were selected as the critical success factors for brown-field construction projects.

Table 1 illustrates the selection process for the critical success factors. The impact rank indicates the perceived impact of the success factor on brown-field construction projects while the importance rank indicates a perceived importance of each success factor within the brown-field project environment. The critical success factors are those which have the highest combined level of importance and impact.

Table 1

Identification of the critical success factors

DESCRIPTION OF SUCCESS FACTOR	HIGHER IMPACT ON BROWN-FIELD PROJECT	IMPACT RANK (A)	IMPORTANCE INDICATOR	IMPORTANCE RANK (B)	RANK TOTAL (A + B)	CSF NUMBER
Consultation and communication with client	37	4	144	3	7	CSF 1
Recognising complexity	44	1	127	10	11	CSF 2
Commitment of end user	39	3	130	9	12	CSF 3
Flexible approach to change	34	5	125	12	17	CSF 4
Taking account of external influences	41	2	115	17	19	CSF 5

The relationship between the responses of the three stakeholder groups was investigated to establish the accuracy of the collected data with respect to the importance of each critical success factor. Figure 1 indicates a high correlation of the obtained responses between all sub-groups of the respondents.

The statistics related to identifying the critical success factors are summarised in Table 2.

Table 2

Statistics for CSF identification

	POP TOTAL	POP%	OBS FREQ (O)	EXP FREQ (E) = POP% * N	CHISQ CALC = $(O - E)^2 / E$
Client team	23	41.1%	72	76.39	0.052
Consultants	11	19.6%	38	36.54	0.109
Contractors	22	39.3%	76	73.07	0.123
TOTAL	56	100.0%	186 = N	186 = N	**0.285**

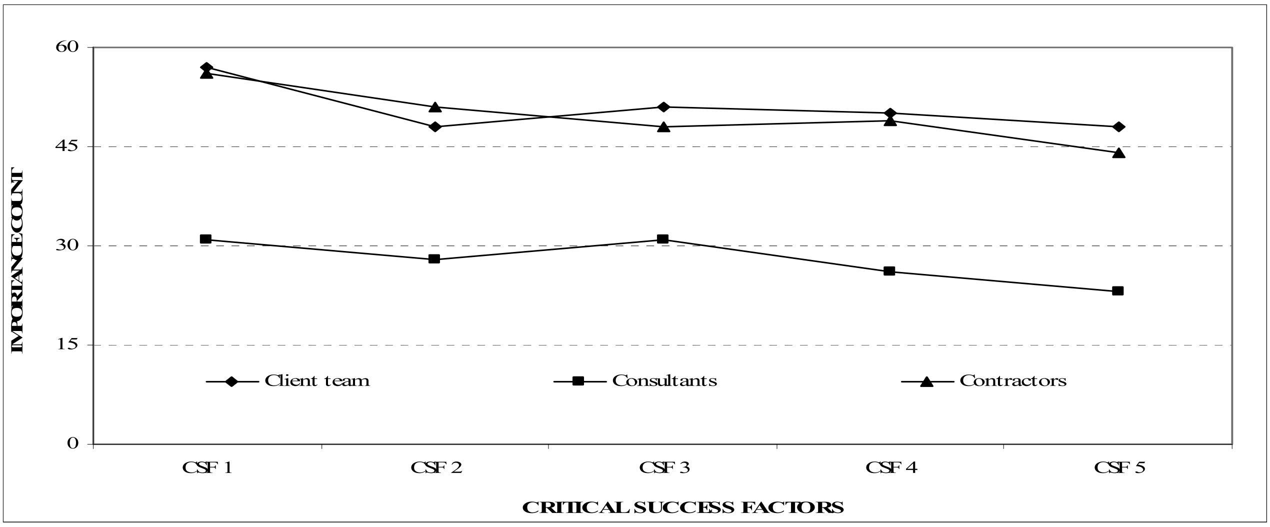

Figure 1. Correlation between respondent sub-groups for the importance of CSF's

3.2 Project success measures

Identification of project success measures for brown-field construction projects commenced with a literature review to establish the most common models for the assessment of the project success. Model proposed by Lim and Mohamed (1999) was selected as we deemed it most suitable for the type of the researched project environment. Ten measures were also selected based on literature review to characterise either the project implementation process or the client satisfaction from the project results. A survey questionnaire was used to test the perceptions of the project community with respect to the importance of each identified factor. Respondents were requested to asses the impact of each factor on both green-field and brown-field project environment as well as to assess the importance of each measure as perceived contribution of each measure towards the project success. All success measures were subsequently ranked in terms of their importance and the five highest ranked measures were selected as the success measures for brown-field construction projects.

Table 3 illustrates the selection process for the success measures. The impact indicator indicates a perceived impact of each success measure on the project, combined for all respondents.

The relationship between the responses of the four stakeholder groups was investigated to establish the accuracy of the collected data with respect to the importance of each success measure. Figure 2 indicates a high correlation of the obtained responses within the project team and the client team but no correlation between the project team personnel and the client team personnel.

3.3 Correlation between the managerial focus on critical success factors and project success

A two-step process was applied to establish the degree of correlation between the managerial focus on critical success factors and project success. Firstly, a suitable database of projects was examined and ten projects were selected to cover most of the variables associated with brown-field construction projects. The following factors were taken into account in the selection process: technological advancement, project size (planned budget), access restrictions (resulting in delays and increased logistical difficulties), project duration (planned duration), impact of project on the exiting asset (plant), impact of the exiting asset (plant) on project and project type. The data was derived from a historical database of projects executed in the period 2002 – 2005. Secondly, the degree of managerial focus on critical success factors was evaluated for each project in the database. At the same time, the success of each project was also evaluated. Finally, the relationship between the two variables was examined.

Respondents were requested to assess managerial focus on each of the five critical success factors for every project in which they participated. Respondents were also requested to rate project success by evaluating each of the five project success measures.

The results obtained from the research were totalised per project - separately for critical success factors and for project success measures. This resulted in an array of x-y parameters describing two variables: critical success factors (independent variable) and project success measures (dependent variable). The findings are represented in Figure 3.

Table 3

Identification of the success measures

MEASURE NUMBER	DESCRIPTION OF SUCCESS MEASURE	IMPACT INDICATOR
SM 1	It solves problem for which it was created	121
SM 2	Customer uses its end product (plant, service etc)	119
SM 3	Customer / user is satisfied with its end product	119
SM 4	It meets operational performance (end product performs designed functions)	117
SM 5	It meets technical specifications (end product conforms to technical specifications)	116

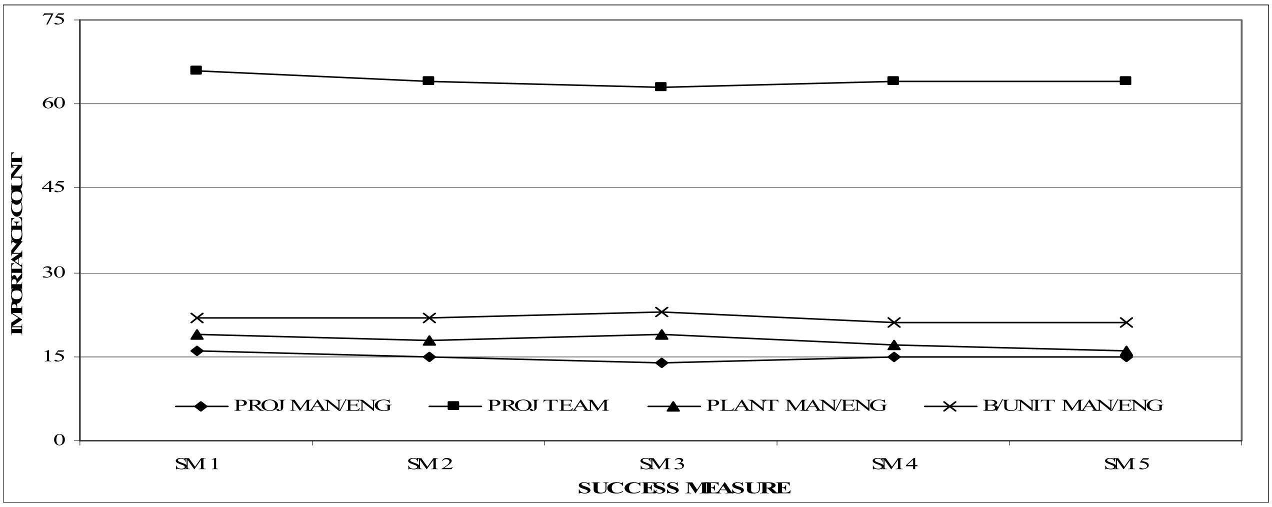

Figure 2. Correlation between respondent sub-groups for the importance of success measures

4 SUMMARY AND RECOMMENDATIONS

Brown-field projects may provide strategic weapon to create economic value and competitive advantage. Although each project may be a unique endeavour, the study supports the idea of clusters of success measures and critical success factors for the brown-field construction environment. In addition, the study points to the conclusion that there is a positive relationship between managerial focus on critical success factors and project outcome.

Test results also indicate a possible perception differences between various project stakeholder groups in two areas: the relative importance of each success measure and the perceived focus of the project team on the critical success factors.

Based on the study results, it is proposed that the success rate of brown-field construction projects may be improved by increased focus on the project – client communication as well as adequate understanding of the complexity associated with this type of projects.

In order to improve the accuracy of the study, it is proposed that further studies be carried out comprising wider study population.

Abstract: Bearing failure is often attributed to be one of the major causes of breakdown in industrial rotating machines that operate at high and low speeds. This paper presents results of a comparative experimental study on the application of the ultrasound technique for condition monitoring of low speed rolling element bearings and conventional vibration measurements with seeded faults on inner-race defects. The effectiveness of the ultrasound technique is demonstrated through signal processing techniques; use of statistical parameters derived from the time domain, and enveloped spectra in the frequency domain. The results reveal that the ultrasound technique is more effective in detecting low speed bearings failure than that of the vibration measurement.

Key Words: Condition Monitoring, Low Speed Machinery, Rolling Element Bearings, Ultrasound Technique, Vibration Measurements

1 INTRODUCTION

Condition Monitoring (CM) is the process used to determine the operational state and health of a machine for the purpose of detecting potential failures before they turn into functional failures. The CM process consists of periodical or continuous data collection, data analysis, interpretation and diagnosis. Condition Monitoring is an integral part of Predictive Maintenance (PM) which is a widely used maintenance philosophy (also known as Condition-Based Maintenance - CBM). This philosophy is based on scheduling maintenance activities only when a possible functional failure is detected. CBM enhances operational effectiveness and safety through research and development of technologies to accurately and reliably predict the remaining useful life of in-service equipment. CM optimizes equipment readiness while reducing maintenance and staffing requirements. Typical CM techniques include vibration analysis, oil analysis, wear particle analysis, ultrasonic analysis, thermographic analysis and motor current signature analysis [1, 2].

One of the more popular tools in the condition monitoring of rotating machinery is vibration analysis. By measurement and analysis of the vibration in rotating machinery, it is possible to detect typical faults such as unbalance, bent shaft, cracked shaft, misalignment, looseness, rubbing, gear faults, motor faults and impellor/blade defects. However, whilst these faults are common, they occur primarily in high speed machinery (> 600 rpm). There is limited information on faults which occur exclusively in low speed machinery, other than those initiated by rolling element bearing defects [3].

Numerous research works have been published on the detection and diagnosis of rolling element bearing defects. Tandon and Nakra [4] presented a detailed review of different vibration and acoustic methods, including vibration measurements in the time and frequency domains, sound measurements, the shock pulse method and the acoustic emission technique. Tandon and Choudhury [5] subsequently updated the reviews incorporating more recent works and advanced techniques currently being adopted in bearing defect detection. Most of the research on bearing diagnosis can be categorized in the time domain and frequency domains. The RMS, crest factor, probability density moments (skewness, kurtosis) are the most popular statistical time domain parameter for bearing defect detection [6-10]. In the frequency domain, the enveloping method, also known as demodulation or HFRT (High Frequency Resonance Technique), have been proven to be a very efficient and popular technique for detection of the characteristic frequencies of bearings [11-16]. Wavelet analysis has also been successfully applied to bearing defect detection [17-21]. In recent years, artificial neural networks and fuzzy logic have also emerged as popular tools for automated fault diagnosis [18, 22-25].

The ultrasonic technique has more recently been proposed as a powerful tool for condition monitoring of bearings in industrial applications particularly for low speeds. This technique captures and processes sound waves that manifest above the human hearing range and has been presdominantly applied in leak detection, crack detection, bearing defect detection and detecting lack of lubrication. Ultrasonic analysis is one of the less complex and less expensive CM techniques [26]. Its simplicity is directly related to the size and ease of use of handheld detectors, and the relatively straightforward presentation of measurement data on meters or digital readouts. However, a quantitative analysis of the signals from ultrasonic detector has not been conducted for condition monitoring of low speed bearings. Furthermore, traditional techniques involving vibration acceleration may not be able to detect an incipient failure due to the low impact energy generated by the relative moving components in low speed bearings.

In this study, the effectiveness of the ultrasonic technique for condition monitoring of low speed bearings is examined using on an experimental approach. An artificially induced fault in the form of a minute scratch on the bearing inner-race was utilised for this comparative study. The ultrasound signal from a normal bearing and a defective bearing are compared with vibration signals through time-domain statistical parameters and frequency-domain envelop spectrum at shaft speeds ranging from 1200 rpm to 30 rpm.

2 THE ULTRASOUND TECHNIQUE

Ultrasound is defined as sound waves that have frequency levels above 20 kHz; higher than what the unaided human ear can normally hear. Most machines emit consistent sound patterns under normal operating conditions. These sonic signatures can be defined and recognized; and changes in these signatures can be identified as components begin to wear or deteriorate. This enables technicians to identify and locate bearing deterioration, compressed air or hydraulic fluid leaks, vacuum leaks, steam trap leaks and tank leaks [26]. Airborne ultrasound operates in the lower ultrasonic spectrum of 20 kHz to 100 kHz. A compressed gas or fluid forced through a small opening creates turbulence with strong ultrasonic components on the downstream side of the opening. Also vacuum leaks produce turbulence similar to pressure leaks; however, the ultrasound is generated within the system. Poorly seated valves can also be detected.

It is worth noting that the Acoustic Emission (AE) technique also deals with signals in the high frequency range and has been increasingly used for condition monitoring of rotating machinery as well as structures. However, the AE technique differs from the ultrasonic technique in terms of the frequency range of interest and parameters for condition assessment. The AE technique generally operates in the 100 kHz to 1 MHz while the ultrasonic technique focuses on the frequency range of 20 kHz to 100 kHz. Parameters such as ring down counts, events, rising time, duration and peak amplitude are normally used in the AE technique to examine abnormality. In the ultrasonic detector, abnormality is usually detected by listening to the characteristics of sound or RMS indicator on the panel.

The heterodyne circuit is the main component in ultrasound detectors. It takes the ultrasound signal detected by the transducer, and converts it into an audible signal (< 20 kHz). This heterodyned signal can be enhanced by an audio amplifier to be heard using standard headphones, or can be processed through a converter to obtain a quantitative output in decibels (dB). The heterodyned signal can also be recorded through conventional data acquisition system.

This study uses the heterodyned structure-borne high frequency elastic waves between 20 - 100 kHz. The main advantage of ultrasound is the high signal-to-noise ratio detection ability. This advantage allows the exact localization of the energy source of the ultrasound activity, regardless of environmental interferences (i.e. noise) [27]. Although the ultrasonic technique using commercial ultrasound detectors is known to have the capability for detecting bearing defects, literature on the application of ultrasonic techniques for bearing condition monitoring using advanced signal processing techniques is generally absent. This study attempts to fill the gap where advanced signal processing techniques in the time and frequency domains are applied to signals obtained from both the ultrasonic technique and vibration measurements.

3 SIGNAL PROCESSING TECHNIQUES FOR BEARING CONDITION MONITORING

3.1 Time Domain Method

The time series signal can be used to perform fault and failure diagnosis by analysing vibration or acoustic data obtained from the equipment. Statistical methods are widely used to investigate the random characteristics of a physical system. It is important to be able to summarize the data obtained and be able to draw meaningful and useful results. The simplest method is to use overall root-mean-square (RMS) level and crest factor, i.e., the ratio of peak value to RMS. This method has been applied with limited success in the detection of localized defects [28-30]. Probability density has also been used popularly for bearing defect detection [8, 9, 29, 31, 32].

This study presents the analysis of vibration and ultrasonic signals with statistical parameters to detect the presence of defects in low speed bearings. The focus of this study lies in determining the relationship between the rotational speed of the bearing and the statistical parameters. This study presents the use of statistical parameters such as RMS, crest factor, skewness and kurtosis, to analyse an induced localized defect at low speeds.

- RMS –suited for steady-state signals
- Crest Factor – a trendable parameter which gives the ratio of the peak to RMS levels.
- Skewness – measures the relative energy above and below the mean level.

• Kurtosis –a compromise measurement between the insensitive lower moments and the over-sensitive higher moments. It is particularly useful in the detection of bearing failure.

3.2 Frequency Domain Method

The Frequency domain refers to the treatment of signals expressed as a function of frequency using the time domain signal. Whilst certain information is more easily interpreted in the time domain, the most detailed analysis of rotating machinery vibration data is often conducted in the frequency domain. Frequency-domain or spectral analysis of the vibration signal is perhaps the most widely used approach for bearing defect detection. It is often the case that signature spectral comparisons are not suitable for detecting damage to rolling element bearings. This is because the energy produced by the bearing defect is overpowered by more dominant signals from other rotating elements, nearby machinery and noise. For this reason, envelop detection is a commonly used signal processing technique for detecting incipient defects in rolling element bearings. This technique [32-34] involves a high-pass filtering operation to eliminate dominating low frequency components from the original signal. This signal is then rectified, demodulated, and a low-pass filter is finally used to eliminate the carrier high frequency. The processed signal is then displayed in the frequency spectrum showing the isolated bearing defect frequencies.

3.3 Modified Peak Ratio

In the detection of a localized bearing defect, it is essential to determine the presence and the severity of the defect. Enveloping technique or HFRT has proven to be an efficient method of displaying bearing defect frequencies by isolating other unwanted frequencies. However, for automatic diagnosis of bearing defect it is necessary to extract a symptom of failure without any human involvement. Shiroishi [32] suggested a peak ratio (PR) as an indicator to identifying the presence of bearing faults in the spectrum. PR is defined as the sum of the peak values of the defect frequency and harmonics over the average value of the spectrum and is shown in Eq. (1).

$$PR = \frac{N\sum_{j=1}^{n} P_j}{\sum_{k=1}^{N} S_k} \tag{1}$$

Where, P_j is the amplitude value of the peak located at the defect frequency harmonic, S_k is the amplitude at any frequency, N is the number of points in the spectrum, and n is the number of harmonics in the spectrum.

A *modified PR* is proposed in this study in order to make it more effective in showing the severity of the defects. The modified PR is defined in the following equation using the differences between the peak defect frequencies and the average value of the spectrum over the average of the spectrum.

$$mPR_O = 20\log_{10}\frac{\sum_{j=1}^{n}(P_j - A_s)}{A_s} \quad \text{(dB)} \tag{2}$$

$$mPR_I = 20\log_{10}\frac{\sum_{j=1}^{n}(P_j - A_s) + \sum_{i=1}^{l}(Ps_i - A_s)}{A_s} \quad \text{(dB)} \tag{3}$$

$$A_S = \frac{\sum_{k=a}^{b} S_k}{(b-a)}$$

Where, A_s is an average spectrum amplitude in the frequency band from a to b. By using a frequency band instead of whole spectrum band, PR can be a reliable indicator for earlier defect detection. In the case of an incipient bearing defect the amplitude of defect frequencies are often smaller than other peak frequencies.

4 EXPERIMENTS

The test rig used in this study is shown in Figure 1. The shaft is supported by two bearings and connected with an induction motor with a flange-bolt-rubber coupling. The shaft speed can be controlled by an inverter from 30 rpm to 6000 rpm. The bearings used in this test were cylindrical roller bearing (SKF, NJ2204) which has a removable inner ring. The localized defect was obtained by a minute scratch on the inner race. Previous studies have also involved seeded defects induced by using acid etching, spark erosion, scratching or mechanical indentation. Relatively small defects with a width of 1mm and average depth of 20 μm were used to assess the detection capability of incipient failures. It is well known that inner race defects are more difficult to detect than outer race defects due to the relative motion of the ring and the rolling elements. The bearing characteristic frequency for inner race fault (BPFI) is calculated to 6.713 times the shaft speed (Hz). The equipment involved in the collection of vibration and ultrasound data is shown in Fig. 1. It consists of an accelerometer (IMI 608A11), an ultrasound detector (UE Systems ultraprobe 9000), a signal conditioner (PCB 482A20), an analog filter (Krohn-Hite 3202), a DAQ Card (National Instruments 6062E) and a laptop computer with LABVIEW 7.1 (National Instruments).

Vibration and ultrasound data were collected at speeds ranging from 30 rpm to 1200 rpm. The data was analysed using statistical methods in the time domain and envelop spectra in the frequency domain. The vibration signal was sampled at 40 kHz with a cut-off frequency of 10 kHz. Ultrasound was sampled at 140 kHz with a cut-off frequency of 50 kHz. The time duration for each data set was 10 sec for the accelerometer and 4.5 sec for the ultrasound probe. The signal processing and analysis was achieved with the use of MATLAB 7.0 for feature extraction and enveloping.

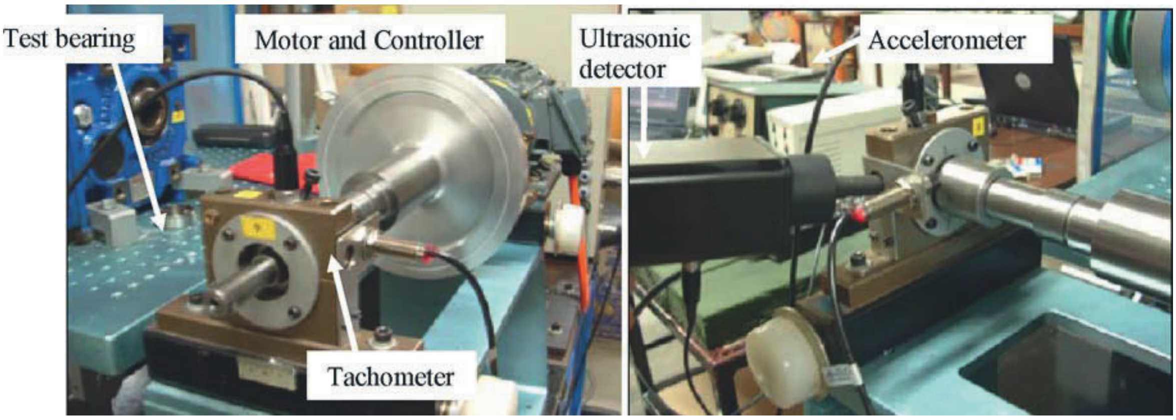

Figure 1. Experimental rig.

5 RESULTS

The signals measured in this experiment were vibration and the heterodyned ultrasound from a normal bearing and the bearing with the inner-race defect, bearing with a range of shaft speeds from 30 rpm to 1200 rpm. The objectives of this test and analysis were to gauge the effectiveness of the ultrasonic techniques by comparing it with vibration signals. The experimental tests are used to uncover the best statistical parameter for fault detection and to introduce an efficient frequency domain indicator for condition monitoring of low speed bearings.

5.1 Time wave form

Figure 2 shows the time wave forms of vibration acceleration signals from a normal and a defective bearing operating at low (150 rpm) and high speeds (1200 rpm). It was noted that at the low speed, there is no significant difference in the characteristics of signals from the normal bearing and from the defective bearing. The two signals can be easily distinguished at high speeds. This implies a potential limitation of the acceleration signal for fault detection of low speed bearing defects. Figure 3 shows ultrasound signal with a heterodyne frequency of 30 kHz under the same conditions. There are significant differences between a normal and a defective bearing in terms of magnitude and shape of the signal. Furthermore, the signals are much clearer at low speeds and display a number of impulses which are generated by the localized defects in bearings. By comparing these two figures, it can be concluded that ultrasound signals are more sensitive at detecting localized defects in bearings than acceleration signals.

5.2 Time Domain Parameters

In this paper, RMS, skewness, kurtosis and crest factor were used to compare their effectiveness for condition monitoring of low speed bearings on the basis that they are commonly used parameters for condition monitoring of bearings. For quantitative comparisons, all parameters are presented in decibel scale with reference of 1mV for each parameter. Figure 4 shows the comparisons of statistical parameters of vibration acceleration signals from a normal bearing with those from a defective bearing at different shaft speeds. RMS and skewness increased as the shaft speed decreased, while the kurtosis and crest factor decreased slightly. The relative amplitudes of parameters are shown in Figure 5. It is importantly noted that all the statistical parameters from vibration acceleration signals have smaller relative amplitudes as the shaft speed decreased, which indicates the vibration signal is not appropriate for condition monitoring of low speed bearings. The skewness and kurtosis values provided good detection at high speeds. Their detection abilities decreased sharply as speed decreased.

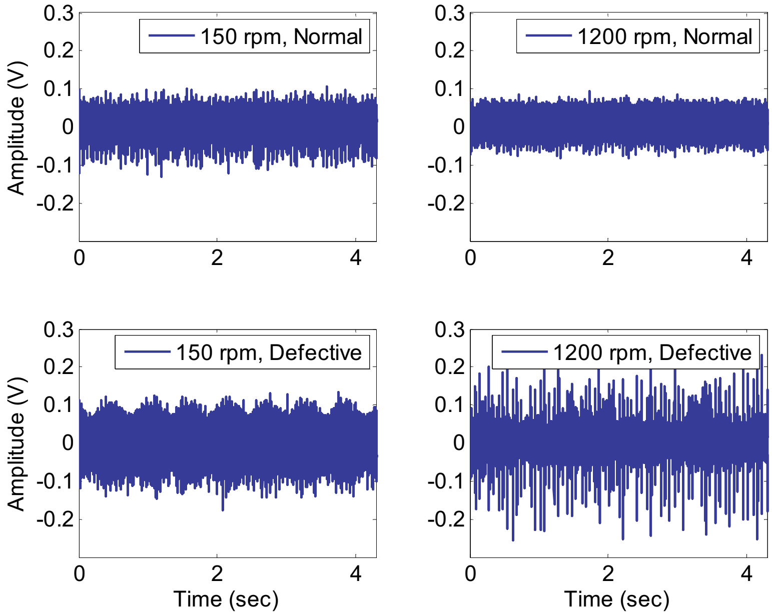

Figure 2. Time wave forms of acceleration signal from a normal and a defective bearing at 150 rpm and 1200 rpm.

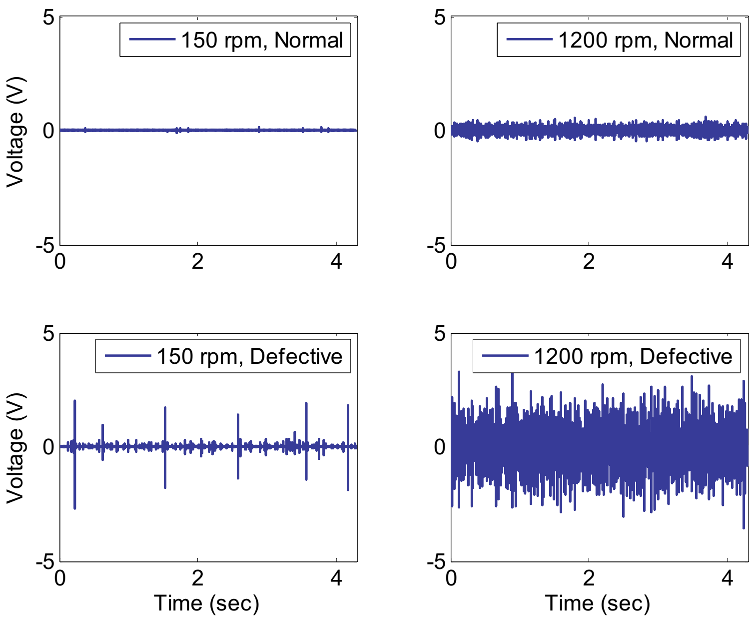

Figure 3. Time wave forms of ultrasound signals from a normal and a defective bearing at 150 rpm and 1200 rpm.

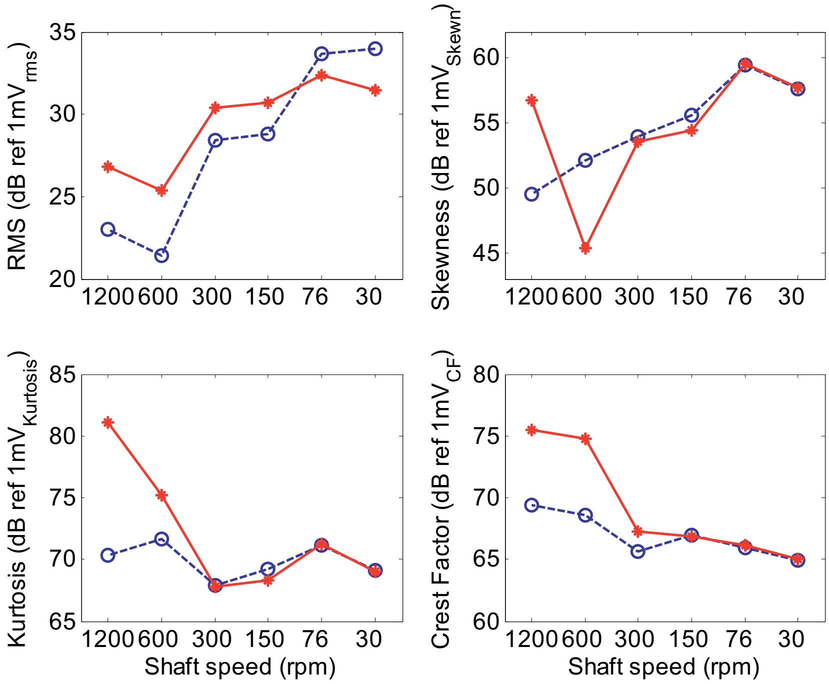

Figure 4. Comparison of statistical parameters from vibration (--o--:normal, —*—:defective).

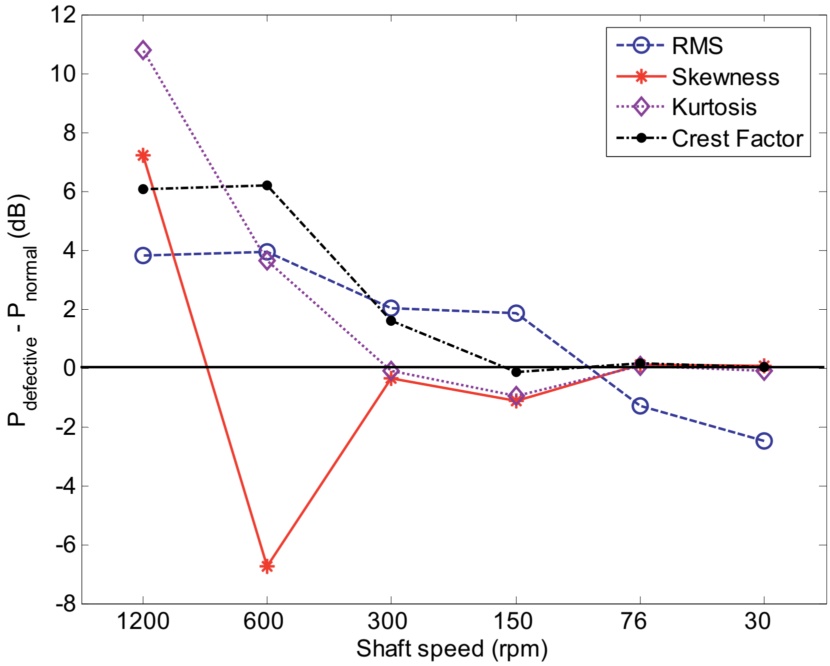

Figure 5. Relative amplitude of statistical parameters from vibration acceleration measurements.

Likewise comparisons of those parameters from ultrasound signals are presented in Figures 6 and 7. The RMS values almost linearly decreased according to a decrease in shaft speed with similar relative amplitudes at all speeds. This means that the RMS value is a good indicator for condition monitoring of bearings for the range of shaft speeds. This result reveals the reason why most ultrasound detector manufacturers use RMS as an indicator for condition monitoring. Skewness didn't show a clear trend for the range of speeds. In contrast, crest factor and kurtosis showed interesting results. Their values from a defective bearing were smaller than those from a normal bearing at high speeds. However, when shaft speeds were less than 300 rpm their relative values increased dramatically. This clearly indicates its significant potential for condition monitoring of slow speed bearings.

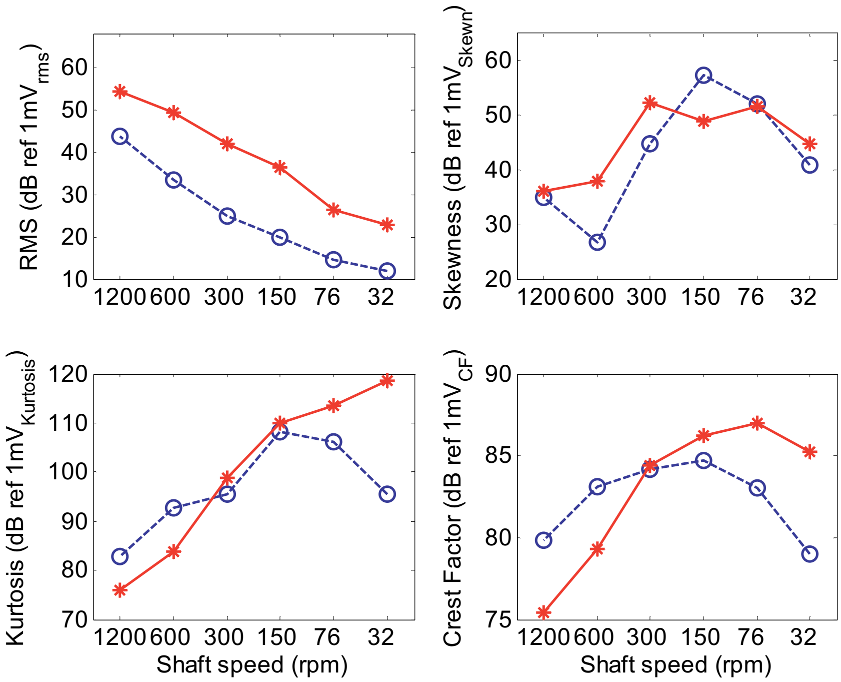

Figure 6. Comparison of statistical parameters from the ultrasound signal (--o--:normal, —*—:defective).

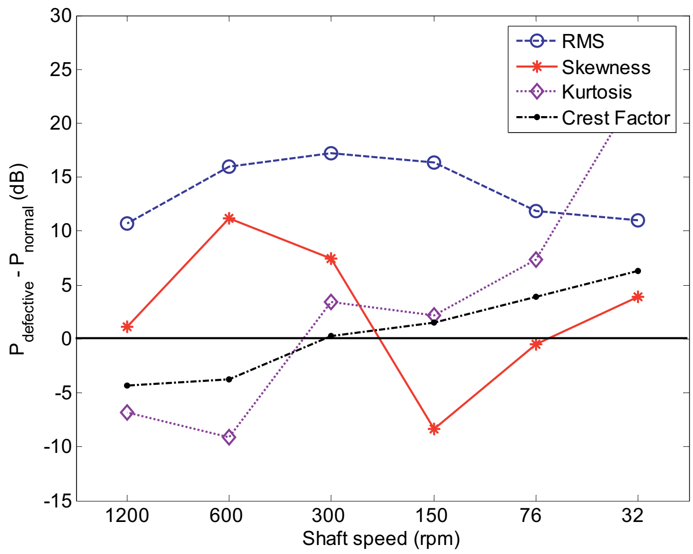

Figure 7. Comparison of differences of statistical parameters from the ultrasound signal.

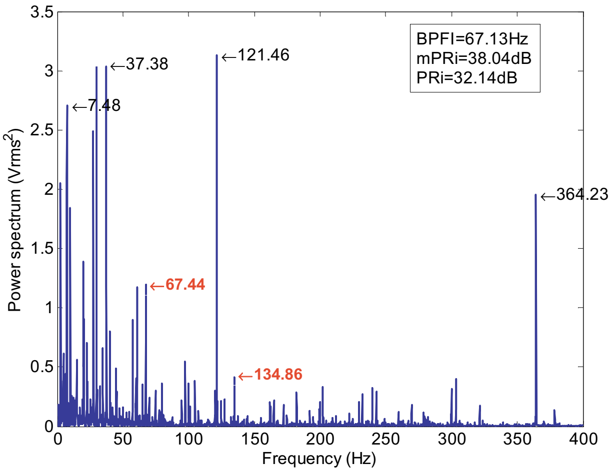
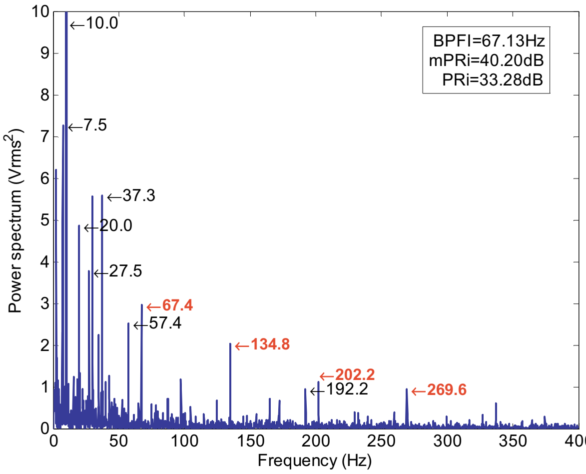
It is worth noting that RMS of the ultrasound signals is a very reliable indicator at most speeds showing relatively constant amplitudes larger than 10dB. The kurtosis value of ultrasound signals is potentially the best parameter at very slow speeds (less than 50 rpm), followed by crest factor. By comparing the results from ultrasound signals in Figure 7 with those from acceleration signals in Figure 5, it is evident that the ultrasound technique is superior to vibration measurements at low speeds.

5.3 Frequency Domain Parameters

As explained in the previous section, the modified Peak Ratio is introduced in this paper to improve the reliability of identifying the presence of bearing defect characteristic frequencies in the frequency spectrum. Figure 8 shows the enveloped power spectrums of vibration acceleration signals and ultrasound signals at 600 rpm of a defective bearing. The defect frequency (BPFI=67.13 Hz) and its harmonics are clearly evident in both spectra. However, they are more significant in the ultrasound spectrum with relevant side bands of the shaft speed. It is also noted that the modified Peak Ratio for the inner-race fault frequency (*mPRi*) which is proposed in this study, has a much higher value (6-7dB) than the original Peak Ratio proposed by Shiroishi [32], implying that *mPRi* can be an effective indicator for the detection of bearing defect frequencies in frequency spectra.



(a) vibration



(b) ultrasound

Figure 8. Enveloped power spectrum from defective bearing at 600 rpm.

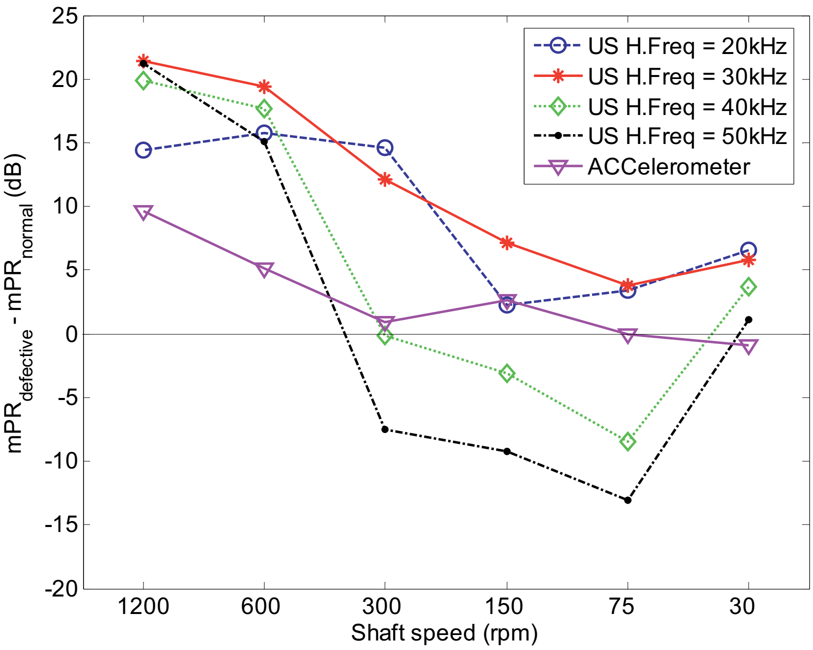


Figure 9. Relative modified Peak Ratio from ultrasound and acceleration.

Finally, the effectiveness of the *mPR* from ultrasound signals was compared with those from vibration signals and the results are shown in Fig. 9. In this study four different heterodyne frequencies in the ultrasound detector were examined for comparison. The 30 kHz heterodyne frequency gives the best result at most speeds and followed by 20 kHz. It is also clear from this study that the vibration acceleration measurements are inferior to the ultrasound technique in terms of detectability of fault in the frequency domain at all shaft speeds.

6 CONCLUSIONS

A number of experiments have been carried out to investigate the effectiveness of the ultrasonic techniques for condition monitoring of low speed bearings. A defective bearing which a simulated defect on the inner race was used in conjunction with a healthy bearing at different shaft speeds ranging from 1200 rpm to 30 rpm. The vibration signals obtained from an accelerometer were also measured and analysed for comparative purposes. The time-domain statistical parameters and frequency-domain modified Peak Ratio were calculated and compared. This study revealed that ultrasound technique is demonstrably superior to vibration acceleration measurements for detecting incipient defects in low speed bearings. The RMS of ultrasound signals provided the best parameter at almost all speeds. However, at very low speeds (less than 50 rpm), the kurtosis and crest factors performed best. In the frequency domain, a modified Peak Ratio was proposed and was proven to a better indicator than the original Peak Ratio. A setting of 30 kHz for the heterodyne frequency on the ultrasound detector gave the best result. Again, detection of fault from ultrasound signals was superior when comparisons were made in the frequency domain. The work is progressing in getting more samples from both the laboratory and the field and these results will be presented in due course.

DEVELOPMENT OF TESTING FACILITIES FOR VERIFICATION OF MACHINE CONDITION MONITORING METHODS FOR LOW SPEED MACHINERY

V Kosse & A Tan

School of Engineering Systems, Queensland University of Technology
2 George St., GPO Box 2434, Brisbane, Qld 4001, Australia

Abstract: Machine condition monitoring (MCM) of low speed machinery is highly challenging task. Methods of MCM of machinery operating at a speed of 500 to 3000 rpm are well-developed including wear debris and vibration monitoring (both instrumentation and signal processing). Machinery operating at a speed below 500 rpm is usually grease lubricated and wear debris analysis cannot be effectively used. Monitoring of vibrations at such speed is very difficult because conventional accelerometers give very week signal especially at a speed below 100 rpm. There is a vital need to develop new approaches to monitoring fault development on low speed machinery, which include new sensors and alternative methods such as sound emission and ultrasonic emission. Essential part of this process is development of testing facilities that enable modeling of different combinations of loading conditions that take place on low speed machinery and verify new MCM methods. For this purpose a design study has been conducted to develop methods of modeling of different combinations of loads on bearings and gears operating at low speed. This study resulted in the development of a unique highly versatile test rig presented in this paper. It enables modeling of different types of bearings operating at a speed of 30 to 600 rpm under a combination of different loading conditions, in particular, steady load, impact load, swinging load, axial load and rumble. It also enables modeling of transitional processes in shaft-mounted, flange-mounted and foot-mounted gear drives under different loading conditions (start up, coast down, increase or decrease of speed). Special instrumentation enables monitoring of the supply frequency, phase current, power consumed and taking these parameters for recording.

Key Words: Machine condition monitoring

1 INTRODUCTION

Low speed machinery is widely used in industry. The speed is considered low if the machine operates at a speed below 600 r.p.m. Some examples are: metallurgical converters and mixers, cement furnaces, kilns, crushers, etc. To drive such machines multi-stage gear drives are used with DC or frequency-controlled AC motors. Such machines quite often experience shock loading, frequent star and stop. Open gear sets may entrap lamps of hard dirt and crushing it induces rumble (vibrations) in the drive train. The dynamic factor on such machinery quite often exceeds two especially during transitional processes. An accidental failure on such machinery may have disastrous consequences both in terms of down time, lost production and environmental impact. Large safety factors and over designing the machinery helps to a certain degree but contributes to increased cost of equipment.

Machine Condition Monitoring (MCM) methods for high speed machinery are well developed. They include vibration monitoring, wear-debris analysis, thermography, sound emission and ultrasonic diagnostic methods. MCM methods for low speed machinery remain “undigged field” as a result of challenges discussed in the next section. Development of MCM methods for low speed machinery is one “burning” issue. Another problem is that at this point in time there are no experimental facilities that enable investigation of different mechanical faults development at low speed and verification of MCM methods for such faults.

In this paper approaches to experimental investigation of different mechanical faults development at low speed are discussed and a concept of a low speed test rig is presented.

2 CHALLENGERS TO MACHINE CONDITION MONITORING OF LOW SPEED MACHINERY

Mechanical drives for low speed machinery are usually three or four stage gearboxes. If a lubricant is selected for an intermediate stage, high speed input stage and low speed output stage of the gearbox will be inadequately lubricated. In long term it makes the gearbox vulnerable to excessive wear and gear fault development. Gear drives for mixers processing powdered products quite often have a reciprocating mechanism built in the gearbox, which causes shock loading. Many intermediate shafts have bearing supports inaccessible for sensors and suppliers of drives would not allow to drill holes in the gearbox to take cables out.

Drives on mixers and crushers are typically shaft mounted or cradle mounted and there is a torque arm that holds the reactive torque. During transition mode (start up, coast down or load variations) knocking signal is generated in the torque arm joints, which is superimposed on harmonics generated by the machine itself.

If vibrations are used for MCM purpose, energy of signals coming from high speed stages and shock loading of the operating unit is high, and it masks low energy signal coming from low speed stages. Background noise makes situation even worse. There is a theoretical possibility to extract a low energy useful signal using signal processing methods, but in reality it is problematic.

The use of wear debris analysis is very difficult because low speed units usually are geese lubricated. In multi-stage gearboxes inadequate lubrication causes uneven wear, which is difficult to predict and monitor.

The use of thermography is problematic because the heat energy dissipation rate is comparable with the heat generation rate in the area of fault development and it is very difficult to detect notable temperature rise.

Main components of low speed drives that require attention from the standpoint of MCM are bearings and gears. Occasionally other components fail (e.g. shafts or mixing screws). Rolling elements bearings on low speed heavy machinery usually have cylindrical or taped rollers as rolling elements. Often double-raw rolling bearings are used, which makes the vibrational signature even more complex. With modelling of bearing faults in laboratory environment contradictory requirements have to be satisfied. In particular, real bearings on heavy machinery are quite large (300mm and bigger); on the contrary, to keep the cost of testing facilities down smaller bearings should be used. In general, to transfer results from a model to a real scale object “cauchi condition” can be used to determine multiplier coefficients for different parameters to satisfy conditions of dynamic modelling. However, fidelity of the modelling remains questionable if too small bearings are used on a model.

In industrial environment different combinations of loading on bearings may take place:

- Steady radial and / or axial load when the load does not vary in time.
- Impact (shock) loading.
- Cyclic loading.
- Rumble when radial or torsional vibrations are imposed on the shaft and transferred to the bearings.

When low speed bearing endurance test is conducted, the test rig has to be run continuously for days or even weeks. Maintaining the consistence of the load becomes a highly challenging task. In the case of a steady load the use of hydraulic devices is questionable because they are expensive, not suitable for long continuous use, and finally, it is almost impossible to maintain the value of the load within a narrow range (say ±2%). The use of weights is possible if the load required is measured in dozens or hundreds of Newtons. The use of larger weights becomes highly unpractical and even dangerous.

Impact or cyclic loading can be applied to the shaft using hammering mechanism. The challenge is how to make sure that the specific bearing is subjected to the shock load but not all bearing on the shaft of the test rig.

For modelling of rumble loading there are no any suggestions in research publications. The use of “saw tooth” disks with spring loaded ratchets is possible, but a challenge is how to control shock impulses in the radial and tangential directions.

On heavy machinery bearing rings may rotate continuously, may perform swinging motion, or one of the rings may remain stationary. The challenge is how to reproduce in the laboratory environment all these kinds of motion under a combination of steady and shock loading.

A real challenge is how to initiate a controlled fault development. There are three possibilities:

- Bearing overloading. This approach is relatively easy to implement, but difficult to pick the moment of the fault development.
- Contaminated lubricant. This method has been suggested by B.Kuhnell [1, 2]. It is easy to implement, but difficult to control.
- Introduced fault. The most common method is the spark erosion. It enables to make a notch of a known size, which is approximately about 0.5mm in width. It is however, too large compared to real faults developing on bearing race surface.

Simulation of gear faults development in laboratory environment requires the satisfaction of the following conditions:

- Provision for shaft-, flange- and foot-mounted gearboxes.
- Possibility of visual monitoring of the fault development.
- Possibility to reconfigure the test rig from gearbox test to bearing test.
- Accessibility of housing surfaces for sensor mounting.

These requirements could be relatively easy satisfied by proper selection of gearboxes. The main challenge is how to load the gearbox with a measured torque. If a single gearbox is used with large reduction ratio (e.g. 100:1) the output torque will be 100 times the input torque. To apply that large torque magnetic particle brakes or eddy current brakes can be used. The magnetic particle brakes can maintain the loading torque for a long period of times (days is necessary). The main limitation is very high cost. The eddy current brakes are not suitable for prolonged use. As a consequence of heat released in the brake the loading torque decreases by 20-25%.

A solution to overcome this problem was suggested by V.Kosse [3]. Two gearboxes can be connected back-to-back with low speed shafts. In this case both the input and the output shafts rotate at high speed and relatively small torque is required to load the drive train. The following methods can be used to apply a loading torque at high speed:

Connect the drive train to a DC motor / generator. It is relatively simple. The main challenges are how to control the loading torque and how to dissipate significant amount of heat generated.

Connecting the drive train to a water pump (e.g. centrifugal pump). In this case very difficult to control the loading torque, a large water tank and the pipeline are required.

Disk brakes. Such brakes are widely used on large four-wheel drive vehicles (e.g. Toyota Land Cruiser). The disks are placed in a housing filled with oil. Such brakes can be used only for a short period of time, and the loading torque is difficult to control.

Rheological couplings. They are filled with a rheological fluid that offers different resistance to a disk rotation when the strength of a magnetic field generated by an electric magnet is changing. The strength of the magnetic field and the loading torque are easy to control and theoretically they can be used for a long period of time, but practically the rheological fluid quickly degrades (especially when heat is generated) and has to be frequently replaced, which on most rheological coupling is difficult to implement.

The technological problems discussed in this section show that the development of testing facilities for low speed machinery is a real scientific and technological challenge. In the next section possible approaches to simulation of the fault development in bearings and gear drives operating at low speed will be discussed.

3 SIMULATION OF DIFFERENT MECHANICAL FAULTS ON LOW SPEED MACHINERY IN LABORATORY ENVIRONMENT

Spectra Quest Incorporation (USA) developed a demonstrational rig for medium to high speeds. It is used manly for educational purpose and enables demonstration of most mechanical faults. It is table-mounted and has an AC frequency controlled motor driving through a coupling a shaft with two disks. The shaft rests on two bearing supports that can be shifted in the lateral direction. A small reciprocating mechanism can be attached to the shaft through a belt dive. The rig enables demonstration of the following faults: imbalance, shaft and coupling misalignment, rolling bearings faults, “cocked” rotor, resonance and critical speed study, sleeve bearing study, belt drive performance studies, mechanical rub, gearbox faults, reciprocating mechanism study, foundation effect study. The Spectra Quest demo rig is depicted in Figure 1. Attempts to use it at low speed are unsuccessful because the frequency control does not allow to maintain speed less than 100 r.p.m. Then, components of the rig are so tiny that make it impossible to apply loading conditions typical for low speed machinery.

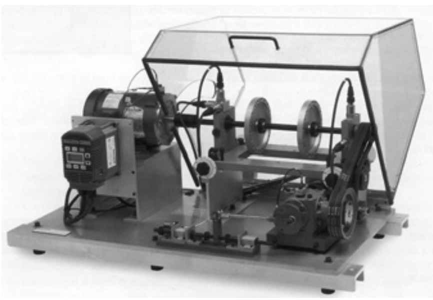

Fig. 1. The machinery fault simulator from Spectra Quest Incorporation (USA)

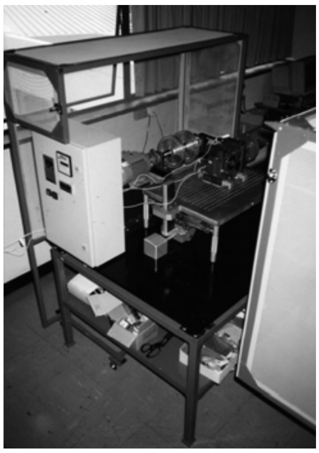

Fig. 2. QUT Fig. 1. The machinery fault simulator from Spectra Quest Incorporation (USA).

At Queensland University of Technology (QUT) V.Kosse developed a much bigger machinery fault simulator (MFS) [3] shown in Figure 2, that utilizes similar concept. The main difference is that it has a tilt table that can be moved parallel to the shaft and tilted in the lateral direction. This enables installation of different gearboxes and loading devices and simulation of belt misalignment faults. As a loading device a disk brake from Toyota Land Cruise is used. This MFS enables modeling of all typical mechanical faults at a speed from 60 to 1400 r.p.m. However, it cannot be effectively used for modeling of mechanical faults at low speed because the frequency controlled AC motor at low speed has such a small power output that any load applied to the shaft stops it. This proves that for simulation of mechanical faults at low speed a specialized test rig has to be developed.

3.1 Simulation of bearing faults

The most feasible concept for simulation of bearing faults at low speed is to use a shaft on two supports. At the driving end the shaft is attached to a gear motor through a coupling that can be quickly disconnected (e.g. chain coupling). The bearing support at the driving end has to be over-designed to ensure it will not fail under the test loading. The bearing support at the opposite end of the shaft (driven end) has to have a provision for installation of a single bearing or two bearings (e.g. two taper roller bearings in X-pattern). These bearings can be of different kinds but with the same bore and outer diameters.

The radial load can be applied close to the driven end support where the test bearings are installed through a rod preloaded with Belleville springs. The value of the loading radial force can be measured by a load cell. This will enable to maintain a constant loading force for a long period of time (days and weeks if necessary). The axial loading force can be applied if two taper roller bearings are installed in X-pattern through Belleville springs preloaded with the nuts. The value of the axial loading force can be monitored through the deflection of Belleville springs. Impact loading can be applied to the shaft through the hammering pivoted arm loaded with weights and cyclically moved with a cam mechanism.

Continuous rotation can be provided through a frequency-controlled gear motor with large reduction ratio. This will enable to maintain a low speed of the shaft rotation within the range of 30 to 600 r.p.m. without sacrificing the power output. Speed can be measured by means of a tachometer. Swinging motion of the shaft can be maintained by a crank mechanism driven by a small electric motor. The value of the swing angle can be controlled by varying the length of the crank arm.

The shaft assembly with the drive and loading devices can be mounted on a robust frame.

For the purpose of gearbox fault development monitoring at the driven end of the shaft another gearbox can be installed. This gearbox has to have a hollow low speed shaft and a flange. This will enable mounting of this gearbox with different configurations when the driving shaft is plugged in the low speed shaft of the gearbox:

- Flange (foot)-mounted when the flange is bolted to the frame.
- Shaft-mounted with the torque arm attached to the frame.

High speed shaft of this gearbox can be attached to a loading device. The gearbox will step up the speed and enable the loading of the whole drive train with a relatively low torque.

Analysis of possible methods of loading conducted above shows that the main problem is how to maintain the torque if experiment has to be conducted for several days of weeks continuously. Most loading devices are suitable for use only during sort period of time. At QUT a new loading device has been developed that utilizes a gear pump attached to the driven end of the transmission that pumps oil through a hydraulic station (see Figure 3). The loading torque can be easily adjusted by means of a throttling device. Large amount of oil (60 liters) enables the use of the loading device for at least of half an hour without a danger of overheating the oil. If the loading device has to be used for a long period of time, the heat exchanges can be used with flowing water that maintain the oil temperature within required range. The pump capacity is selected to match the power output of the driving gearbox and enables the overloading of the driven gearbox if necessary. The power consumed can be measures by means of a multi-functional meter attached to the AC motor, which also enables measurement of the phase voltage and current, the supply frequency and these parameters can also be taken to the recording device.

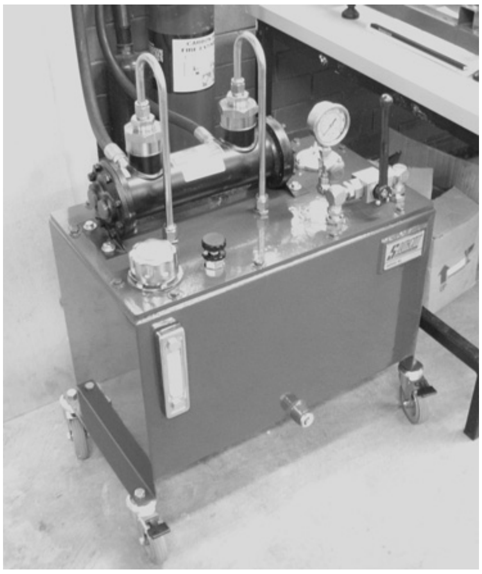

Fig. 3. Hydraulic station of the loading device (heat exchanger is seen on the top).

The approaches for simulation of different bearing and gear faults discussed above can be utilized on a test rig for low speed machinery. Such a test rig has been developed at QUT and is presented in the next section.

4 THE CONCEPT OF THE TEST RIG

A unique test rig for low speed machinery developed at QUT is shown in Figure 4. It has a robust frame on which major components and assemblies are mounted. The control box is not shown to enable clear view of all systems and components. The drive and the shaft assembly on two bearing supports are at the right hand side of the picture.

The hammering mechanism for modelling of impact loads is seen at the top. The rumble mechanism is represented with a profiled disk and spring-loaded roller. The shaft-mounted gearbox at the driven end is shown without loading device. The availability of a driving gearbox with large reduction ratio and frequency control enables to maintain steady power output at any speed from a fraction of revolution per second to 600 r.p.m. This test rig will enable simulation of typical mechanical faults at low speed and verification of different condition monitoring methods.

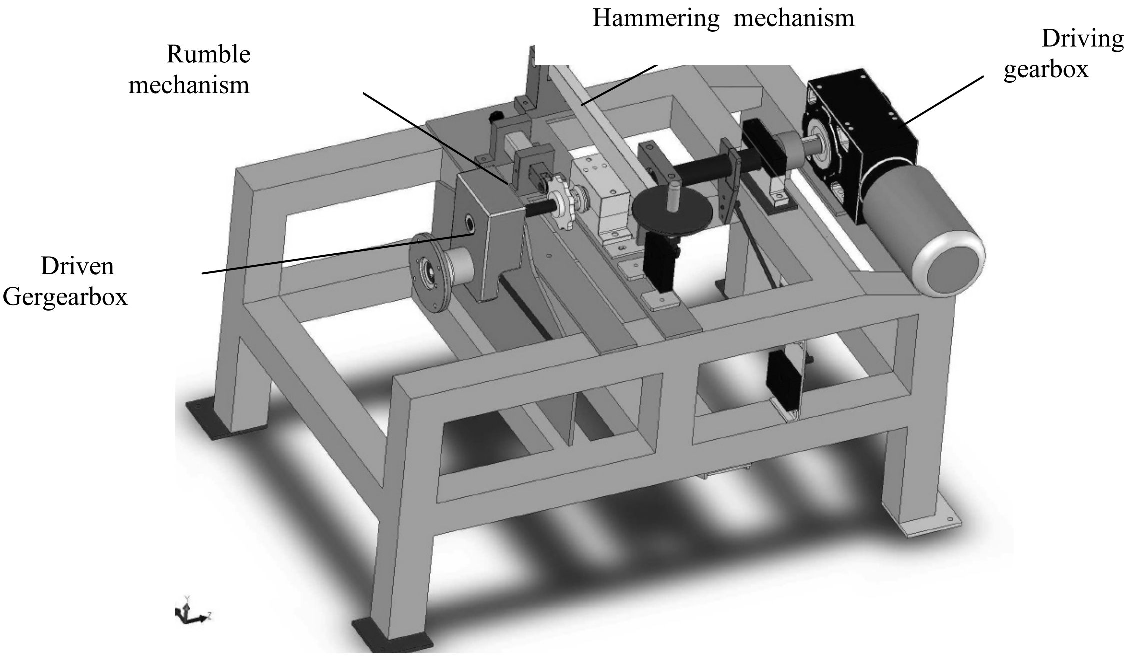

Fig. 4. Test rig for physical simulation of mechanical faults at low speed (30 to 600 r.p.m.).

5 CONCLUSIONS

In this paper approaches to experimental investigation of typical mechanical fault development have been discussed.

It is shown that simulation of typical loading conditions present on low speed machinery is highly challenging task both from scientific and technological standpoints.

Conceptual approaches to physical simulation of bearing and gear faults development on low speed machinery have been discussed.

A unique test rig developed at QUT for physical simulation of fault development on low speed machinery is presented.

This test rig will enable a systematic research on the development of machine condition monitoring methods for early fault detection on low speed machinery.

6 ACKNOWLEDGEMENT

The authors would like to acknowledge that the development of the testing facilities for low speed machinery has become possible with the support of the Cooperative Research Centre for Integrated Engineering Asset Maintenance (CIEAM) and Comalco Australia Ltd. through a project ID202.

Abstract: Detection of an incipient internal defect from a measurement point on the surface of a machine is often made difficult due to the corruption of the source signal by background noise usually through the transmission path. In order to detect or recover the source signal, it is essential to suppress or remove this background noise. With the advancement of digital signal processing techniques, this removal can be achieved using fixed or adaptive filters. The main problem with the application of filtering techniques is that one has to know the characteristics of the noise in advance or may require more than two channels of data if using an adaptive filter. This paper reports on the application of Blind Deconvolution method to recover fault information from the measured (observed) signals of a damaged bearing through the transmission channel and which was also corrupted by noise.. The Blind Deconvolution method manages to recover the fault signal by estimating the inverse of the transmission (channel transfer function) path using the eigenvector algorithm (EVA). Modified crest factor (MCF) and Arithmetic Mean (AM) algorithms were used to optimise the equalizer parameters. Computer simulation and experimental studies were used to verify the applicability of the technique.

Key Words: Blind Deconvolution, Bearings, Condition Monitoring, Signal Processing, Vibration

1 INTRODUCTION

Rolling element bearings from one of the major components in rotating machinery and facilitates rotating motion by usually carrying heavy load over a small surface area. Although the life of rolling element bearings can be estimated based on the load and the rotating speed, catastrophic failure of these bearings can occur prematurely due to unpredictable loading or duty or even vibration transmitted from other machine components. Other factors which can influence the life of a bearing are lubricant film, static and dynamic load, geometry of the housing, shaft and bearing, pre-load and maintenance personnel [1]. One alternative to preventing catastrophic failure is to replace the bearings after a certain period of operation through planned maintenance.

Numerous techniques are now available to detect rolling element bearing failures but the suitability of the techniques varies from system to system. Detection of internal malfunction via vibration analysis is widely used. Some of the techniques commonly used in condition monitoring of rolling element bearings include shock pulse, statistical analysis (crest factor, kurtosis and RMS level) and frequency based detection techniques [2-4]. Unfortunately, vibration analysis based on frequency and time domain analysis can only be effectively applied when the signal-to-noise ratio is relatively high. Although these techniques are widely used, they are now mainly used at the final stage of the analysis process after an improvement in the signal-to-noise ratio is achieved.

In situations where the vibration signal is corrupted by background vibration (referred to as noise) conventional analysis techniques may fail to detect an incipient failure. At this stage the bearing signal is generally small and its detection would require the noise component in the overall vibration signal to be severely attenuated with a consequential improvement to the signal to noise ratio. One of the earliest methods to suppress noise is the application of adaptive filtering techniques, such as adaptive noise cancellation (ANC)[5,6]. This technique is also used in a number of applications, namely, the suppression of unwanted noise and detection of tool wear acoustic emission signals. Other applications of adaptive signal processing include identifying rotating machine faults as described in [7] and the detection of tool wear[8]. Adaptive signal processing for detecting bearing signal corrupted by severe background noise, such as adaptive noise cancellation (ANC), has been shown to have potential but requires two inputs.

Recently other signal processing techniques to enhance an internal defect have been introduced, such as auto-regressive techniques [9,10] and application of higher order moment spectral analysis [11,12]. Although auto-regressive techniques have the potential for early detection of component defects, the complexity of these techniques impedes their implementation. The authors in [10] concluded that they should not replace conventional methods but supplement them.

Blind deconvolution (equalization) is a technique used to recover the desired signal from a single received channel without any *a priory* knowledge about the unknown channel. The technique has been widely used in network communication since the 1980s [13]. In the past 20 years numerous techniques have been proposed to enhance signals based on single inputs. However, an improved Blind Deconvolution technique has been used in in a variety of applications [14-16]. A major advantage of blind deconvolution is that it does not require a training stage, which is essential in conventional equalization [17,18]. Recently the authors have successfully applied the technique to recover fault information from corrupted bearing signals [18a, 18b].

In this paper higher order solutions to blind deconvolution using the EVA algorithm developed in [19] was applied to enhance bearing signals corrupted by a variety of periodic noise. The work presented in [20,21] was use to analyse the gain response of the equalizer. Both the Modified Crest Factor (MCF) and the Arithmetic Mean (AM) in conjunction with a neural network was used to optimise filter length of the equaliser. The results show that the technique was successful in enhancing the defective bearing signal corrupted by periodic noise and the MCF and AM can be used to optimise the filter length.

2 BLIND DECONVOLUTION THEORY

In practical situations, the observed signal $y[n]$ from a measurement is not the original input signal, but is the convolution of the original input signal $x[n]$ with the impulse response system $h[n]$ plus a corrupting noise $s[n]$ as shown schematically in Fig 1. The original input signal is inaccessible and the impulse response system is unknown.

Deconvolution refers to the determination of the impulse response of the system $h[n]$ or determination of the input signal $x[n]$ where the output of the system $y[n]$ is typically accessible and the knowledge of the input signal $x[n]$ is unavailable.

The observed signal from measurement is given by:

$$y[n] = h[n] * x[n] + s| \qquad (1)$$

$$y[n] = \sum_{m=-\infty}^{+\infty} h[m]x[n-m] + s[n] \qquad (2)$$

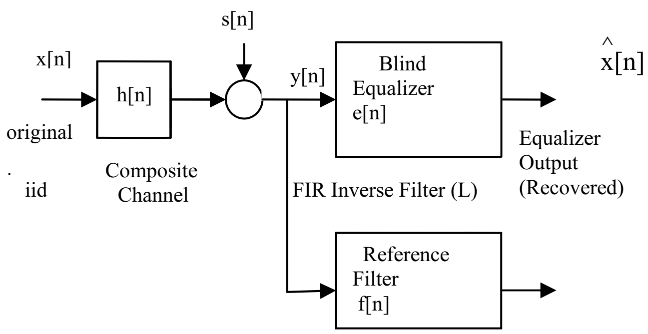

Fig 1. Schematic of observed signal and the Eigenvector Approach (EVA)

In order to reconstruct the original signal, a system that optimally removes the corruption from the unknown channels is needed. This system is known as an equalizer in signal communication. Unlike the ordinary equalizer, the blind equalizer performs without access to the original input or any known training sequence, target or desired signal as in adaptive filtering.

The output of the blind equalizer is denoted by $\hat{x}[n]$:

$$\hat{x}[n] = e[n] * y[n] \qquad (3)$$

$$\hat{x}[n] = \sum_{m=0}^{L} e[m]y[n-m] \qquad (4)$$

The objective is to find the Finite Impulse Response (FIR) of the inverse filter $e[n]$ that will give $\hat{x}[n]$ is as close as possible to the delayed original signal $x[n-k_0]$ in the Mean Square Error (MSE) sense [19] :

$$MSE(e,k_0) \underline{\underline{\Delta}} \sum \{| \hat{x}[n] - x[n-k_0] |\}^2 \tag{5}$$

The eigenvector algorithm (EVA) method used by the Kammyar and Jellonak [19] which is based on the cross kurtosis of two higher order cumulants and maximizes the kurtosis criterion which is applied to determine the impulse response of the equalizer. Using this method, the characteristic of the inverse channel can be estimated directly from a number of samples of the observed signal. Figure 1 shows the schematic of the Eigenvector Approach (EVA). An equalizer, e[n], is introduced to the channel output y[n] to produce an output signal $\hat{x}[n]$. The second inverse filter with the same order is introduced as a reference system filter. The task of the second filter is to generate an implicit sequence of reference data for the iteration process. The impulse response of second filter is denoted by f[n].

The solution to blind deconvolution is based on the maximum *"cross kurtosis"* quality function. Cross kurtosis between $\hat{x}[n]$ and u[n] can be used as a measure of equalization quality. Using the convolution between the equalizer input and output signals, the cross-cumulant of the observed signal y[n] and the reference signal u[n], can be used to maximize the quality function.

$$\text{Maximize } \left| e^* C_4^{uy} e \right| \text{ subject to } e^* R_{yy} e = \sigma_d^2 \tag{6}$$

where C_4^{uy} represents the Hermitian cross cumulant matrix of the output signal u[n] and observed signal y[n]; R_{yy} represents the Toeplitz autocorrelation matrix of the observed signal y[n] and e is the equalizer impulse response. σ_d^2 denotes variance of the signal and " * " denotes the convolution operator.

The qualifying function equation (6) is a quadratic in the equalizer coefficient and can be expressed as follows

$$C_4^{uy} \; e_{EVA} = \lambda \; R_{yy} \; e_{EVA} \tag{7}$$

Equation (7) is known as EVA equation. The coefficient vector e_{EVA} is obtained by choosing the eigenvector of $R_{yy}^{-1} \; C_4^{uy}$ associated with the maximum magnitude eigenvector λ.

3 DETERMINATION OF OPTIMUM FILTER LENGTH

The filter length of the blind equalizer plays a vital role in the deconvolution process due to different operating conditions and types of bearing faults. It is generally know that when a bearing has fatigue crack, the vibration signal will generate a series of periodic impulses. The measurement of energy of the recovered signal can be used to determine the condition of bearing and a high value of RMS above a certain threshold normally indicates the extent of the damage. However, in some cases this criterion has had limited success.

The Crest Factor is defined as a ratio of the maximum peak of the signal over the RMS value and can be used as a feature to identify a bearing fault. In this study a modified Crest Factor, which is the average of peaks over the RMS value, was used to optimise the equaliser length. The modified Crest Factor can be expressed as:

$$\text{Modified Crest Factor} = \frac{\text{Average of Maximum Peaks}}{\text{RMS}} = \frac{\frac{1}{M}\sum_{i=1}^{M} X_{p_j}}{\sqrt{\frac{1}{N}\sum_{i=1}^{N} X_i^2}} \tag{8}$$

where X_{P_j} corresponds to the amplitude of vibration signal exceeding a certain threshold; M is number of sequences exceeding the threshold; x_i stands for the signal amplitude and N is the total number of sequences in a signal.

The overall vibration level of a faulty bearing increases when the fault advances. A simple parameter which can quantify the difference between the spectra is the Arithmetic Mean (AM) and is defined as:

$$AM = 20\mathrm{Log}\left(\frac{\frac{1}{N}\sum_{i=1}^{N} A_i}{10^{-5}}\right) \qquad (9)$$

where A_i are Fourier coefficients of the vibration spectrum. The change in the value of AM with succeeding spectra gives a measure of the change in spectra.

In this paper these two criteria were used to determine the filter length of the equalizer. A neural network (NN) was incorporated to train the behaviour of the system which generates the optimum filter length. Several damaged bearings with outer race defects, inner race defects and ball defects with varying defect sizes were used as target sets for the NN to automatically determine the optimum filter length for the equalizer. A data training set of the neural network was obtained with different defect sizes and by varying the speed of the shaft from 600 RPM to 1800 RPM. Four vibration parameters were considered as the input parameters to the neural network namely; crest factor, kurtosis, arithmetic mean and the Matched filter RMS (Mfrms) of the observed signal [11]. The target of the neural network was to determine the optimum filter length.

4 RESULTS AND DISCUSSION

4.1 Simulation Studies

The robustness of *blind deconvolution* in enhancing the bearing signal was initially demonstrated by corrupting the observed signal with a range simulated deterministic noises. In this test a pre-recorded damaged bearing signal (fig 2(a)) was corrupted by periodic sinusoidal noise to form the observed signal. To simulate a real situation, noise was generated in the laboratory using a deterministic noise generator. The amplitude and the frequency of the generated noise can be varied to produce different signal-to-noise-ratios. The lowest SNR created was -49.68 dB resulting in the bearing signal being totally masked by the noise as shown in Fig 2(b). For higher SNRs, the signal impacts were more prominent and were not considered in this research.

Figure 2(c) shows the output after the BD process and it clearly demonstrates that this technique has the capability of enhancing the bearing signal even with a very low SNR (-49.68 dB). In this test, the filter length was determined using a trial-and-error approach.

To observe the removal of all corrupting noise components, the gain response of the equalizer was plotted as shown in Fig 3. It can be seen that this equalizer acts like a notch filter in removing the corrupting periodic frequencies at 250, 500, 1000, 2000 and 4000 Hz. It can be seen that the BD process removes all periodic components of those frequencies plus all other inherent periodic components.

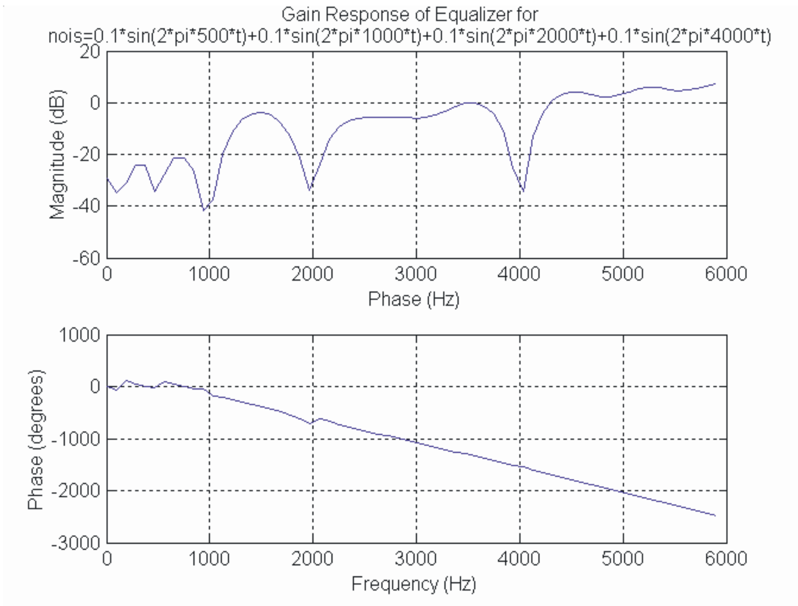

Fig 3. Gain Response and phase plots of an equalizer.

4.2 Optimum filter length

The results above show that BD can remove periodic noise and that the equaliser behaves like a notch filter. In real life applications, the method of trial-and-error approach to determine the optimum filter length for the equalizer is not viable. The above results demonstrated that with different S/N ratios, damaged sizes and operating speeds, different filter lengths were required for a successful application.

The results of optimum filter length trained using a Neural Network with defect sizes of 0.1 to 0.5 mm, and located in different bearing elements with varying speed from 600 RPM to 1800 RPM are shown in Table 1. Only those with a simulated defect on the outer race are presented for discussion.

Table 1. Neural Network trained optimum filter length for the equalizer

	Damage size (mm)	600RPM	1200RPM	1800RPM
Outer race	*0.1*	7.00E+01	4.60E+01	5.60E+01
	0.2	3.60E+01	6.840E+01	5.40E+01
	0.5	6.80E+01	6.800E+01	5.20E+01

From the table it is not possible to establish a consistent trend of equalizer filter length against the operating speeds or defect sizes. However, for high operating speeds, the filter lengths for an outer race defect are between 52 and 56. At lower speeds (600 rpm) the filter lengths fluctuate between 36 and 70. Similar trends were obtained for damage on the inner race and ball.

The optimum filter length was selected based on the modified crest factor and arithmetic mean criterion. Figure 4 shows a typical plot of CF and AM versus filter length for an outer race fault of 0.1 mm defect width with rotational speed of 600 RPM. The algorithm selects the optimum filter length based on the values of CF and AM. It can be observed from the plot that the CF values stabilized at around 70 filter length and remained fairly constant all the way to 240 filter length. In the AM plot it can be seen that the AM amplitudes decrease from -35 dB to -50 dB until 70 filter length. Beyond that value, the AM amplitude remained fairly constant at about -50 dB. The optimum filter length of 70 for this particular case was then input to a data training set for the equalization process.

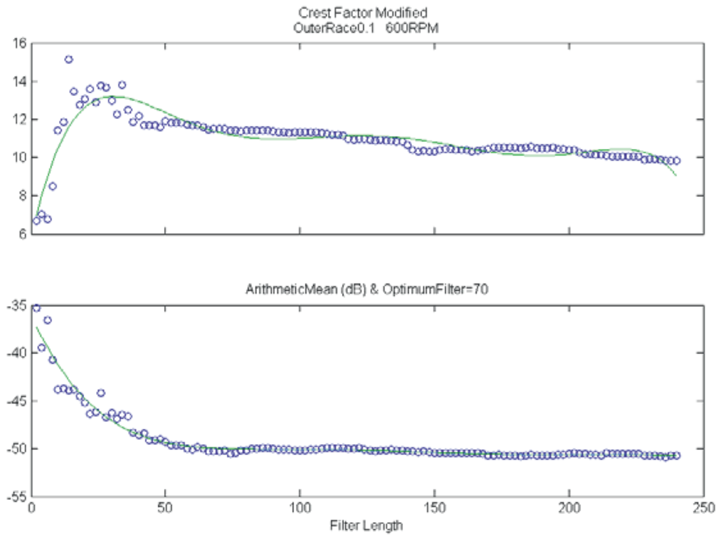

Fig 4. CF and AM plot for Outer Race Defect of 0.1 mm width at 600 RPM

4.3 Removal of corrupting noise

Using the results of optimum filter length, an observed signal with an outer race defect of 0.1 mm operating at 600 rpm was put to the test to see if the NN determined filter length can be used to optimise the blind equalizer. Figures 5(a) and 5(b) show the original observed bearing signal of an outer race defect of 0.1mm and the corrupted bearing signal by a sinusoidal noise of 500Hz, respectively.

It can be seen from Fig 5(b) that the observed signal is totally masked by the corrupting noise. With a filter length of 70, the recovered signal from the BD process is shown in Fig 5(c). It can be seen that blind deconvolution with optimum filter length has enhanced the original bearing signal and has eliminated the background noise. The impulses from the defect on the outer race can be clearly seen and the SNR has been improved.

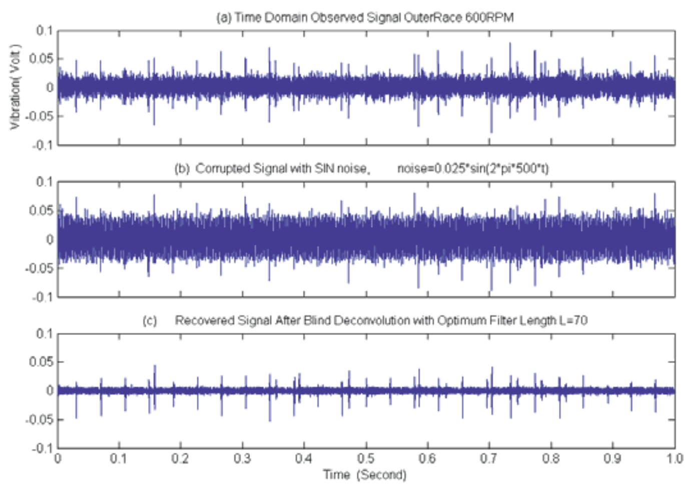

Fig 5. (a) Observed signal at 600 rpm with an outer race defect of 0.1mm; (b) Observed signal corrupted by periodic noise and (c) Recovered signal after the BD algorithm.

The recovered signal shows a consistent impulsive signal of a damaged bearing. The corrupted signal has a kurtosis value of 2.78 which indicates a healthy bearing and can be misleading as the damaged signal is corrupted by high level noise. The recovered signal shows the impulsive nature of a damaged bearing with a kurtosis value of 9.06. The results show that it is impossible to notice a damaged bearing signal from the corrupted signals as the Kurtosis value indicates a good bearing.

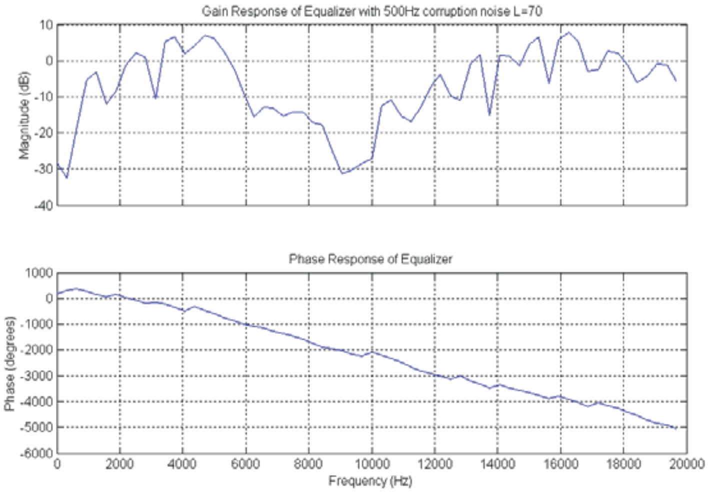

Fig 6. Gain response and phase response of the equalizer of an outer race defect of 0.1mm.

In order to understand the nature of the equalizer in the blind deconvolution algorithm, the gain response of the equalizer was plotted using the computed coefficient of the equalizer e[n]. Figure 6 shows the gain response of the equalizer (filter) which was used in this experiment. It can be seen from the gain response plot that there is a notch at the corrupting frequency of 500 Hz with -34dB and a band of frequencies from 6200 to 11500 Hz. Although there was no prior knowledge of the simulated noise it can be seen that the equalizer has successfully eliminated the sinusoidal noise and a band of high frequency signals. The resonant frequencies of the defective roller bearing were found by performing an impact test on the ball bearing. It was found that one of the excited frequencies of the bearing's structure was around 8000 Hz.

5 CONCLUSIONS

This study has revealed the advantages of blind deconvolution as a technique to recover the original signal of a faulty bearing corrupted by noise and distorted by the transmission path. Since characteristic frequencies contain very little energy, and usually are overwhelmed by noise and higher levels of macro-structure vibration, it is difficult to identify them in the time domain. The procedure to obtain the optimum inverse filter is addressed, considering the influences of input parameters of blind deconvolution. The modified Crest Factor (CF) and Arithmetic Mean (AM) graphs was used successfully to to determine the optimum filter length. It was found that there is a good correlation between both graphs to determine the optimum filter length. Using a slope and finite difference programs, the optimum filter length of the equalizer can be identified and applied to the blind deconvolution algorithm automatically. This study has revealed that blind deconvolution behaves like a notch filter in eliminating periodic noise. The results show that the proposed algorithm works very well with neural networks to determine the optimum filter length.

Smart Engineering Asset Management Laboratory (SEAM),
Department of Manufacturing Engineering & Engineering Management,
City University of Hong Kong, Hong Kong, China

Abstract: Many advanced techniques have been developed for the analysis of mechanical vibrations. It is one of the prerequisites to vibration-based machine fault diagnosis that the vibration signal measured from a machine component must be well isolated from other vibration signals that are generated by adjacent components. Due to the physical constraints of installing sensors in the machine, sometimes only one sensor can be installed. Hence, the sensor will collect an aggregated source of vibrations rather than just the vibration generated from the inspected component. Manufacturing machines are prone to such interference of multiple vibrations. Thus the fault-related vibration must be recovered from the aggregated sources for accurate fault diagnosis. In this paper, the eigenvector algorithm (EVA) of blind equalization (BE) is applied to the recovery of mechanical vibration signals. The conventional EVA can extract only one dominant source from the collected data at a time. In this paper, we propose an enhance EVA that is constructed with the method of channel extension and further post-processing algorithm to recover multiple sources of vibrations. That is, besides the dominant vibration, other less dominant vibrations but relevant to existing faults can also be recovered by using the analyses of correlation and kurtosis. The experiments performed on real vibrations that are generated by industrial machines present the effectiveness of the proposed methods.

Key Words: Blind equalization; Blind deconvolution; Vibration analysis; Machine fault diagnosis

1 INTRODUCTION

Rotational components in machine are often related to the use of bearings and shafts, any faults of which will result in the ineffiecient operation or breakdown of the machine. The additional vibration that is generated by the defects can provide useful information for the fault diagnosis. Currently there are many methods for this aim, but they are ineffective in practical applications if the vibration of interest interferes with other source signals seriously. In the machine with numerous small components closely packed, an inspected source is easily contaminated by vibrations or noises from other adjacent components, which means the signal that is acquired by a sensor is usually the superposition of a number of sources. Hence, the recovery of concerned signals of interest is the prerequisite to apply the vibration-based analysis methods for sucessful fault diagnosis.

A great deal of efforts have been paid for the approaches of vibration recovery in mechanical field recently, which mainly include exact wavelet analysis [1], principal component analysis [2], neural networks [3] and adaptive noise cancellation [4]. However, their effectiveness in extracting fault-related vibration is not always satisfactory, especially when the fault symptom is small whereas the interference or noise is relatively large. Therefore, more efficient methods of vibration recovery are required for an accurate and reliable diagnosis of rotational components. Recently, blind equalization (BE), which was initially used to recover sound signal, has been successfully applied to engineering problems in many other industial fields. The fundamental idea of BE is to derive from the received signal the equalizer characteristic without any prior knowledge of the sources and propagation channels. It can recover the source with one sensor even when time delay is involved in the signal collection. Another advantage of BE is that it does not require a training process, which is necessary in many conventional signal equalization methods. EVA is one of the most popular solutions of BE, and it turns out to be very useful in recovering the fault-related impacts. Jelonnek et al. [5] applied EVA to get the optimum result in the received signal that is an aggregation of data from many unknown transmission channels. However, as a serious limitation for its appliation in machine fault diagnosis, EVA can recover only one dominant source from the mixture that is collected by a single sensor.

In this paper, the eigenvector algorithm (EVA) of blind equalization (BE) is applied to the recovery of mechanical vibration signals. We propose an enhanced EVA that consists of channel extension and a post-processing method to recover multiple sources of vibrations. The post-processing method is based on correlation and kurtosis as the criteria to determine the relation between recovered signals and inpected components. The real vibrations that are generated by industrial machines are used to verify the effectiveness of the proposed methods. The results show the characteristic difference between conventional and enhanced EVA in recovering fault-related vibrations from mixed sources, which indicates that the enhanced EVA can be taken as a promising method for the recovery of vibrations in machine fault diagnosis.

2 CONVENTIONAL EVA SOLUTION TO BLIND EQUALIZATION

One of the solutions for linear blind equalization was found and expressed as the theory related with eigenvector in 1994 [6], namely EVA, and it has been the most popular technique of BE nowadays. The complete model of EVA is introduced in Figure 1. EVA takes over all assumptions from blind equalization theory. Moreover, it applies an additional virtual equalizer *f(k)*, which has the same order as equalizer *e(k)* in conventional BE, to generate an implicit sequence as reference data for estimation of reference output *z(k)* in subsequent iterative process.

$$z(k) = x(k) * f(k) \tag{1}$$

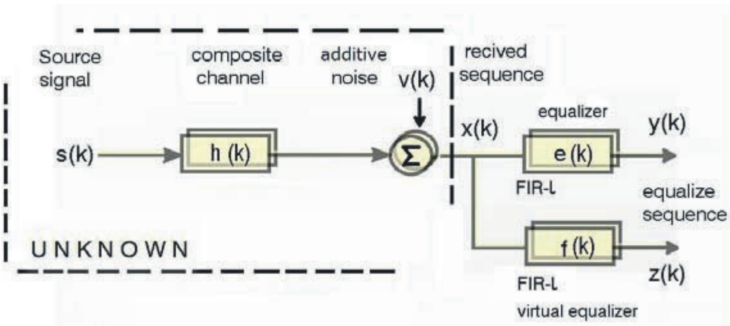

Figure 1. The conventional configuration of EVA.

The EVA requires the two-dimensional fourth order cross-cumulant matrix for equalizer between the samples of the received signal *x(k)* and the reference system output *z(k)*. The cross-cumulant matrix with size $(l+1)\times(l+1)$ is derived as

$$C_4^{zx} = \mathrm{E}\left\{|z(k)|^2 xx^*\right\} - \mathrm{E}\left\{|z(k)|^2\right\}\mathrm{E}\left\{xx^*\right\} - \mathrm{E}\left\{xz(k)\right\}\mathrm{E}\left\{x^*z^*(k)\right\} - \mathrm{E}\left\{xz^*(k)\right\}\mathrm{E}\left\{x^*z(k)\right\} \tag{2}$$

where x and x^* denote the vectors $[x^*(k), x^*(k\text{-}1), \ldots, x^*(k\text{-}l)]^T$ and $[x(k), x(k\text{-}1), \ldots, x(k\text{-}l)]$.

Using the autocorrelation matrix of received data *x(k)* and the vector of the equalizer impulse response, we finally get $\left|e^* C_4^{zx} e\right|$ as the criterion. The proper adjustment of equalizer coefficients could be achieved by maximizing it on the condition that

$$E(x^*x) = E\{[(v^*e)^*](v^*e)\} = E(e^*vv^*e) = e^*E(vv^*)e = e^*Re, \quad \text{so } |e^*R_{xx}e| = \sigma^2 = const. \tag{3}$$

The EVA technique was discussed as a promising tool for mechanical fault diagnosis in many literatures (see [7, 8]). Some researches have proved that the EVA as a solution of BE is effective in recovering the periodic or impulsive type of signal, which appears mostly in faulty machines, from interferences and noises with only one sensor. However, there are still many shortcomings that are associated with the application of EVA in mechanical applications. The signals in manufacturing machines are always very complex and prone to the interference from various adjacent components and noises. It means that the signal that is collected with one sensor is definitely a mixture of numerous sources. Although the conventional EVA can recover the dominant source of the aggregated signal that has the highest amplitude, other fault-related sources with the lower amplitudes may not be able to be recovered.

3 THE ENHANCEMENT OF EVA FOR THE RECOVERY OF MECHANICAL VIBRATIONS

Enhancement of the conventional EVA is proposed to facilitate the recovery of multiple mechanical vibrations, which may not only include the primary source but also some other subdominant sources in the collected signal. The practice of proposed method in this stage of research mainly involves bearing diagnosis. Our enhanced EVA is constructed by the methods of channel extension and post-processing algorithm. Fractional Tap Spacing (FTS) equalizer is also considered to improve the performance of proposed EVA method. The advantages of FTS have been discussed in some literatures (see [9]), and detailed description about FTS equalizer can refer to the work of Jelonnek et al. [5].

According to the concept of FTS equalizer, the multirate baseband model of BE with spaced equalizer can be decomposed and extended to multiple channels that are showed in Figure 2. That is, the EVA can be applied to $x_1(k)\ldots x_M(k)$, where M denotes the factor of up-sampling or down-sampling in FTS [5]. Compared to the model of conventional EVA, such an enhanced EVA possesses more than one parallel channels, e.g. $h^o(n)$ … $h^e(n)$, which refer to different propagation paths and correspond to the source signals that are generated in the inspected machine. In order to recover original signals, the equalizer and reference system must be consequently divided into the same number of channels [10]: $e^o(n)$... $e^e(n)$ and $f^o(n)$... $f^e(n)$, each of which is characterized by specific order of filter l_j. Total number of equalizer coefficients will be finally adjusted by EVA amounts

$$\tilde{l}+1=\sum_{i=1}^{M}(l_i+1)=M+\sum_{i} l_{i.} \tag{4}$$

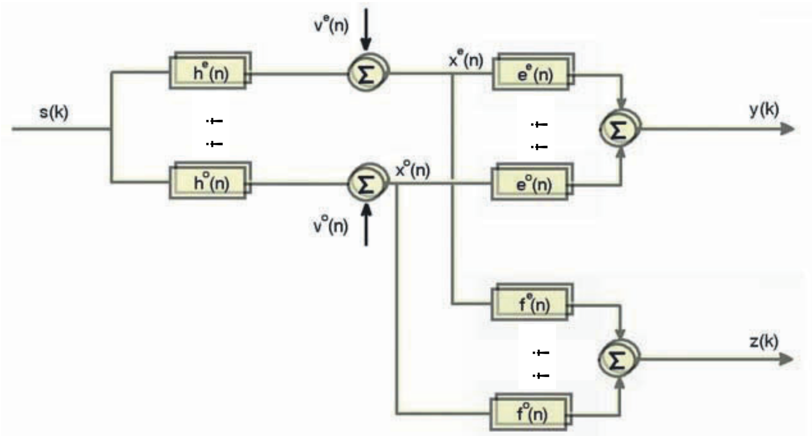

Figure 2. The enhanced EVA for multirate baseband model with multiple transmission channels.

In order to obtain an effective solution for the enhanced EVA, $q(k)$ and $r(k)$ are defined as the overall system where the input is $s(k)$ and the outputs are $y(k)$ and $z(k)$. The criterion based on fourth order cumulants between $y(k)$ and $z(k)$ is used to identify the quality of equalization [11]. Output $y(k)$ can be expressed as a sum of input sequences $x(k)$ of the equalizers

$$y(k)=\sum_{i=1}^{M} x_i(n) * e_i(n)=\tilde{x}_n^{*}\,\tilde{e}\,, \tag{5}$$

where the vectors $\tilde{x}_n$ and $\tilde{e}$ with a length of l+1 are composed of M subvectors.

$$\tilde{x}_n^{*} = \left[x^{*}_{n,1}, x^{*}_{n,2}, \ldots, x^{*}_{n,M}\right]^T \quad \text{where} \quad x^{*}_{n,i}=\left[x_i(n)\ldots,x_i(n-l_i)\right] \tag{6}$$

$$\tilde{e}=\left[e_1^T, e_2^T, \ldots, e_M^T\right]^T \quad \text{where} \quad e_i=\left[e_i(0),\ldots,e_i(l_i)\right]^T \tag{7}$$

Then quality criterion of cross kurtosis is applied to $y(k)$ that is obtained in equation (5),

$$\tilde{C}_4^{zx} = \mathrm{E}\left\{|z(k)|^2\,\tilde{x}_n\,\tilde{x}_n^{*}\right\} - \mathrm{E}\left\{|z(k)|^2\right\}\mathrm{E}\left\{\tilde{x}_n\,\tilde{x}_n^{*}\right\} - \mathrm{E}\left\{\tilde{x}_n\,z(k)\right\}\mathrm{E}\left\{\tilde{x}_n^{*}\,z^{*}(k)\right\} - \mathrm{E}\left\{\tilde{x}_n\,z^{*}(k)\right\}\mathrm{E}\left\{\tilde{x}_n^{*}\,z(k)\right\}, \tag{8}$$

$$\text{maximize } |\tilde{e}^{*}\,\tilde{C}_4^{zx}\,\tilde{e}|, \qquad \text{subject to } |\tilde{e}^{*}\,\tilde{R}_{xx}\,\tilde{e}|=\sigma^2=const., \text{ where } \tilde{R}_{xx}=E\{\tilde{x}_n\,\tilde{x}_n^{*}\} \tag{9}$$

The optimization of this equation leads to the generalized eigenvector problem ($C_4^{zx}e_{EVA}=\lambda R_{xx}e_{EVA}$). Its solution is obtained by choosing the eigenvector with the largest eigenvalue. In this way coefficient vector $\tilde{e}_{EVA}=\left[e_{EVA,i}^T,\ldots,e_{EVA,M}^T\right]^T$ is acquired and applied to blind equalization in FTS configuration with two channels. There is different sequence of filter coefficients $e_{EVA,i}=\left[e_{EVA,i}(0),\ldots,e_{EVA,M}(l_i)\right]^T$ (i=1,…, M) for each channel. In the enhanced EVA solution, the impulse response of equalizer $\tilde{e}(n)=e(k)$ is constructed by interleaving the $e_{EVA,\,i}$ components.

To obtain multiple outputs in the equalization process, different sets of filter coefficients are proposed. The filters in proposed method are set with different lengths. In the example of this paper, the enhanced EVA will adjust the number of coefficients to 4, 8, 16, 32, 64 for $L=2^i$ (i=2, 3…6), so that five different characteristic of blind equalizers are obtained. After applying these filters to inspected signals

$$x(k) * e_i(k) = y_i(k), \tag{10}$$

the results of the equalized signals $y_i(k)$ are obtained, each of which may relate to a different vibration component in the aggregated raw input signal.

After obtaining the multiple equalized signals based on the conventional EVA, first, our post-processing method will calculate the correlation coefficients (*cc*) between the collected raw vibration signal x(t) and each of the obtained equalized signals yi(k). The signal with the largest value of *cc* in existing equalized results is found for an identification process, and then it will be converted to its frequency domain. From its frequency spectrum, we will verify the existence of bearing characteristic frequencies (BCFs) to confirm whether this signal is generated from a bearing. If it is belonged to the desired bearing vibration and the sensor is mounted on the bearing's housing, then the process is halted. If not, then it is necessary to search the bearing vibration from the rest of the equalized signals. Second, to avoid sequential searching just based on *cc* that is time intensive, a fast searching approach is introduced here by using Kurtosis. Kurtosis is a statistical indicator to evaluate the distribution of impulsive characteristic of a vibration signal, and it is particularly suited to monitor bearing's faults as most of them will exhibit impulsive characteristic in its vibration signal if the bearing is defective. The value of kurtosis for each remained equalized signals will be calculated. The equalized signal that has the largest kurtosis will then be identified. If the signal belongs to one of the BCFs, then the process is halted, whereas a further step will be processed. The identification process will continue if the last step has failed to identify the bearing vibration. The remained equalized signals will be ranked again according to their *cc* or kurtosis and taken the verification of BCFs. If it is the bearing vibration, the searching process is halted; if not, then the process will be repeated until the bearing vibration can be identified or all of the equalized signals are investigated. Note that if an equalized signal that may have a large kurtosis value but a low *cc* value, and cannot be verified as one of the BCFs, is probably noise. With the help of the enhanced EVA, both the dominant vibration and the interested bearing vibration that has been overwhelmed by other larger vibrations can be recovered. Some useful signals relevant to the components of the inspected machine can also be extracted in this process for further identification. A real case of recovering such overwhelmed vibration using the enhanced EVA is presented in the following section.

4 RECOVERY RESULTS OF REAL SIGNAL IN INDUSTRIAL MACHINE

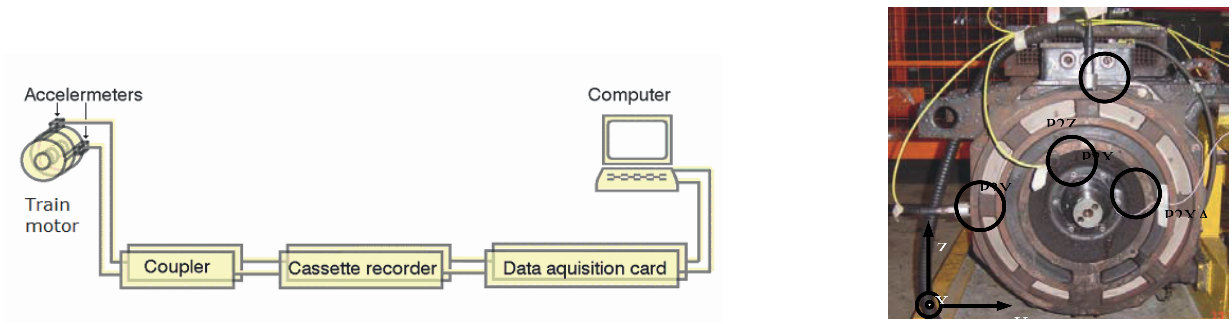

Figure 3. The schema of the testing system, and the position of four accelerometers in the traction motor.

In our previous work [4], two fault-related vibrations that were generated by two faulty components of a traction motor were obtained from the data collections of multiple sensors using the method of adaptive noise cancellation (ANC). The diagnosis of the two faulty components was confirmed by the maintenance staff after an overhaul had been done on the traction motor. To investigate the effectiveness of the conventional EVA and the enhanced EVA in the recovery of vibration signals, the experiments were conducted on the same traction motor using the same collected signals for comparison purpose.

The real vibration signals from a traction motor in a subway train were simultaneously collected for fault diagnosis to validate the proposed method. The engine was uncoupled from the gearbox for the experiments. The motor consisted of a 250 kg rotor that was supported by two rolling element bearings, one of which was located on the drive end and the other on the non-drive end of the motor. The vibrations in three orthogonal directions of each bearing were respectively monitored by three accelerometers at the positions P2X, P2Y and P2Z. An additional sensor labeled as P2XA was also mounted at the axial direction, but much closer to the bearing house of the motor than the other sensors. The experiment schema with all components that were involved in the testing is shown in Figure 3. The signals from the sensors were amplified by a coupler (Kistler 5134), and a digital cassette recorder (Sony PC204Ax) was used to acquire the signal simultaneously at the sampling rate of 48k Hz for each of channels. The record length of data was approximately 1.5 minutes. Then the signals were transmitted to PC with a data acquisition card for further processing. The sampling rate of data acquisition was 32.8k Hz.

The conventional EVA and the enhanced EVA in this research were respectively applied to the testing of the motor. Both accelerometers P2XA and P2X could acquire the vibrations from the motor and the bearing. However, the sensor P2XA was mounted closer to the bearing house, and so it would capture more vibration that was generated by the bearing than the sensor P2X. Therefore, the vibration that was obtained at the position of P2XA was analyzed to recover the overwhelmed bearing vibration from all of motor signals. Figure 4 shows the raw vibration from P2XA and the result after the application of the conventional EVA.

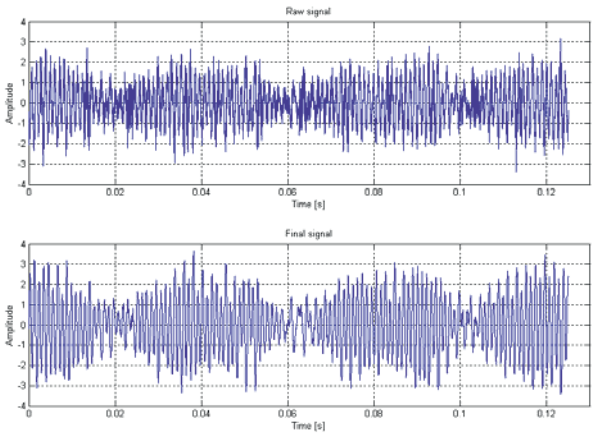

Figure 4. Raw signal and recovered signal after implementation of the conventional EVA.

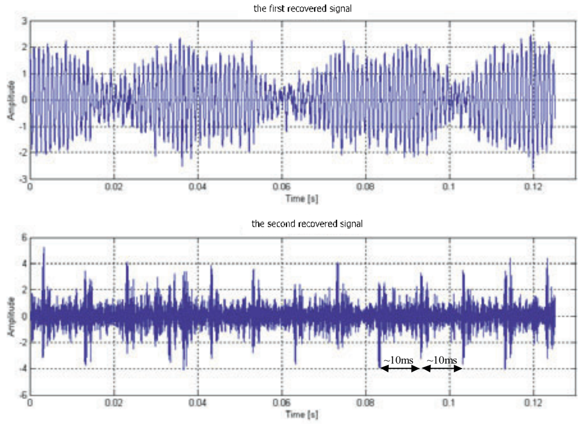

Figure 5. Two recovered signals after implementation of the enhanced EVA.

There were two faults existing in the tested motor, one of which was a motor eccentric problem due to poor workmanship on the clearance between the rotor and the stator. The second fault was an outer-race defect occurred in the inspected bearing. The raw signal collected in the top diagram contains the fault-related vibrations that were generated by both the bearing and the motor. The bearing signal is difficult to be identified because it was overwhelmed by the dominant vibrations from the faulty motor. The conventional EVA adjusted the equalizer length to 8 to recover the motor vibration because of its dominant status, which is shown in the bottom diagram of Figure 4. However, the bearing vibration still remained ambiguous. The proposed enhanced EVA shows more efficient ability than the conventional EVA in the recovery of mechanical vibrations. The results of this method are presented in Figure 5. As proposed in section 3, the motor vibration was firstly recovered as a dominant component of the collected mixture as shown in the top diagram of Figure 5. A filter with the length of 8 was used in the experiment to obtain this result. The recovered vibration signal had a correlation coefficient of approximately 0.8, which was the largest value in all equalized results. Besides the motor vibration that can also be recovered by the method of conventional EVA, the enhanced EVA enables the recovery of the second signal component, which is shown in the bottom diagram of Figure 5. The signal recovered by the equalizer with a length of 32 has a largest kurtosis in all equalized results, and was marked as the second dominant signal. In addition, its impulsive characteristics further proved that the second recovered vibration is come from the faulty bearing. With the sampling rate of 32.77k Hz, the period of the impacts can be roughly estimated through dividing the time length of the signal by the number of periods in it. The result showed that impacts occurred at a time interval of around 10 ms. Based on the knowledge about the diagnosed bearing (SKF 6215) and its rotation speed (25 Hz), it has calculated that the characteristics frequency of the defected outer race is 113.6 Hz or a time interval of 8.8 ms. This value matched closely with interval of 10 ms shown by the impacts in the bottom diagram of Figure 5. Hence, the impacts are confirmed to be generated by the defective bearing. These conclusions also correspond to the experimental results that were generated by the ANC method done on the same test (see [4]). From the above results, it shows that the enhanced EVA is effective in the recovery of multiple vibration sources. Even when the vibrations generated from various mechanical components are captured as a mixture of vibration by one sensor, it is still possible to extract the diagnostically useful signals. With the help of this method, machines that have physical limitations on installing more than one sensor at a time can use such method to recover aggregated signals.

5 DISCUSSIONS AND CONCLUSIONS

It has been mentioned in the previous sections that the signal collected from the machine with one sensor is always the mixture of numerous sources, and conventional EVA cannot meets the need of recovering multiple faulty vibrations from a machine. The results of the conducted experiments show our proposed method has great potential for complex machine fault diagnosis. Based on the algorithm of our enhanced EVA, a new model of monitoring system and its schema can be proposed here. The general model of mechanical system of analysis is presented in Figure 6 with multiple sources and the data of a single sensor is in consideration. Each source signal $s_i(k)$ that represents the signal generated from a different component of machine has its own propagation channel with an additive noise. Therefore, the signal that is collected by a single sensor will be a composition of various sources and noises with different time delays. Only when all other signal components are small enough to keep the dominance level of vibration in received signal, the conventional EVA can achieve successful result. Otherwise it is difficult to recover any overwhelmed signal of interest. This is the main predicament that must be concerned before applying the conventional EVA. Our proposed method can enhance the effectiveness of conventional EVA in machine fault diagnosis through the construction of a single sensor input and multiple recovery outputs. The suggest schema is illustrated in Figure 7. Only one sensor is used to collect the mixed signals, minimizing the requirement for numbers of sensor in many practical applications. The equalizers are respectively used to eliminate the distortion that is introduced in each propagation path between the source signal $s_i(k)$ and the sensor signal $x(k)$. The recovery of multiple sources based on this proposed structure will be very useful for practical machine fault diagnosis.

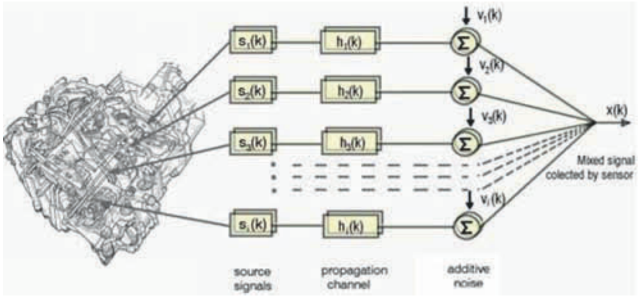

Figure 6. Multiple vibrations generation in a machine.

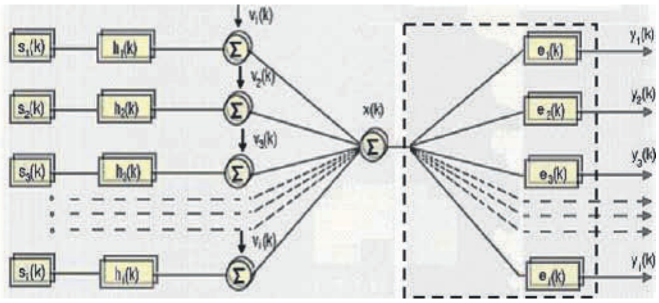

Figure 7. The schema of proposed recovery method.

Compared with the conventional EVA, the enhanced EVA in this research shows to have more prospects for complicated vibration recovery. It provides the possibility to recover more than one source signal even only using a single sensor. Such kind of multiple recoveries is impossible in conventional EVA except using Blind Source Separation with many sensors. However, there are still some problems to be overcome in its efficient application, such as the stability of signals in the presence of a high level noise, and the amplitude/scale indetermination before and after the recovery process. Further researches on EVA are required to enhance the recovery of useful vibrations for machine fault diagnosis.

DEFECTIVE EVALUATION OF CONCRETE STRUCTURE WITH RISK-BASED MAINTENANCE

K Toda T Nishido & Y Moroyama

Ishikawajima-Harima Heavy Industries Co., Ltd, Structure & Strength Department Research Laboratory, 1 Shin-Nakahara-cho Isogo-ku, Yokohama 235-8501 Japan

Abstract: Effective maintenance for concrete structures is important and urgent tasks. Maintenance cost depends on its start time. Conventional inspection for structural defects consist of non-destructive tests, e.g. Schmidt hammer test, and destructive tests, e.g. cored samples. Defective degrees are decided by total ratings with the tests, but the tests cannot consider the importance of the structures. A concrete slab in a bridge in an urban area is more important than it in a rural area, because the destruction of the concrete slab in the urban area greatly influences on users. The size and kind of damage on the destruction are different according to the roles of the structures. The risk-based maintenance (RBM) is used for the defective evaluation of the concrete structures. If a disaster occurs, the damage can be kept minimum with the RBM. The risk evaluation is expressed a matrix, in which a vertical axial is likelihood for the destruction and a horizontal one is consequences for the damage. The conventional inspection is used only the likelihood that is classified at four levels, e.g. Safety, usefulness, influences for users and aesthetics are evaluated numerically as the consequences. By using the RBM, the effective maintenance is possible and repair cost is cheaper than with the conventional plans.

Key Words: Risk-based maintenance, Concrete structures, Defective evaluation

1 INTRODUCTION

The size and kind of damage are evaluated according to the social roles of concrete structures. The concrete structures that are located in or near sea are especially damaged by salt attack. Chloride ions from the surfaces penetrate the insides and cause steel bars to corrode. The steel bar corrosion is serious problem for reinforced concrete (RC). Once the corrosion occurs in the RC, it causes cracks and chloride ions to penetrate easily. Moreover, the heavy steel bar corrosion causes covers to come off and durability to decrease. Engineers must consider the damage and the influences on the destruction.

Risk-Based Inspection (RBI) and Risk-Based Maintenance (RBM) enable the engineers to reduce risk by considering safety and cost. The methods have been used for the maintenance of boilers, cement plants, LPG plants and other large-scale structures. The RBM is a useful tool for the operation of plants [1] especially. In recent years, administrators have considered life-cycle cost (LCC) and asset management for the concrete structures. Japan Concrete Institute (JCI) proposes the guideline of the asset management for the concrete structures [2]. The authors have applied the RBM to the concrete structures like a bridge, a shipyard dock and a plant foundation and confirmed its effectiveness in the study.

2 RBM

The RBM method has been generated to optimise inspection and maintenance plans. Risk is commonly defined as the likelihood of failure multiplied with the consequence of failure. Fuji and Kihara have suggested that if the administrators use the RBM methods for plants and other structures, cost and risk are reduced [3]. There are some approaches to the evaluate risk in the RBM (i.e. qualitative, semi-quantitative and quantitative). The fundamental differences among these approaches are the amount and the detail of input, calculations and output. Expert judgements are used to assign rating on the likelihood and the consequences of failure in the qualitative (or semi-quantitative) RBM. The expert judgements may be powerful methods and important factors to evaluate the risk, because unknown factors to assess the likelihood and the consequence of failures are included in their experiences. Figure 1 shows the procedure of the RBM approach, which may also be similar to a generic representation of a risk analysis. The steps of the procedure are summarised below [4].

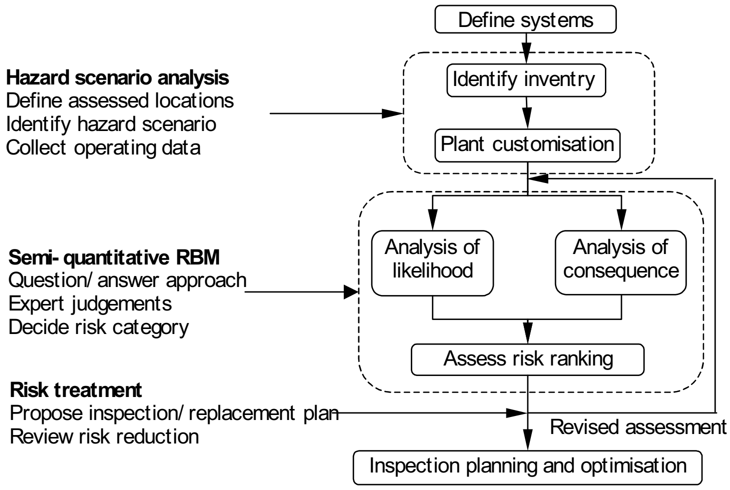

Figure 1. Flow of Risk-Based Maintenance approach

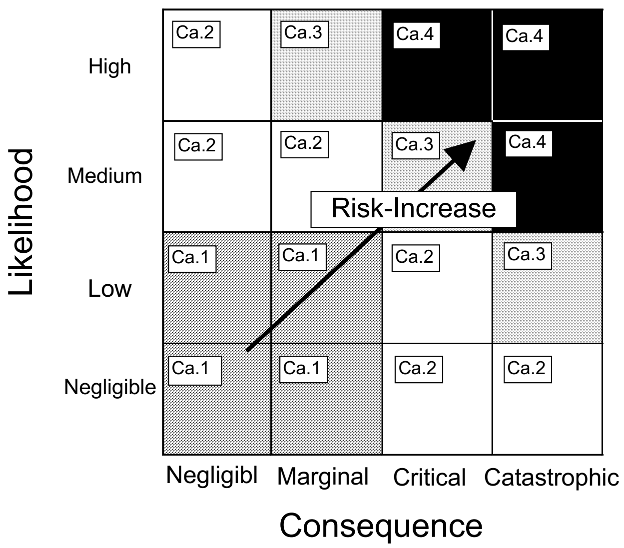


Risk Rank	Required actions
Category 1: Acceptable	No inspection or other actions required within timeframe considered unless to satisfy national legislative requirements
Category 2: Acceptable with controls	Take appropriate inspection or other actions to keep operating
Category 3: Undesirable	Mitigate to risk ranking 1 or 2 within timeframe of next inspection
Category 4: Unacceptable	Mitigate to risk ranking 1 or 2 immediately

Figure 2. Matrix of risk ranking and categories

Step 1 : Making hazard scenario analyses at assessed locations, we identify hazard scenarios and collect operating data. For the concrete structures, the worst scenarios are falling bridges and fatal or serious accidents by them.

Step 2 : The next step is question and answer approach by the expert judgements and decided the risk categories. For the decision of the likelihood degrees, quantitative and semi-quantitative data are gathered by visual and detail inspection. For the decision of the consequence degrees, we assume the risk for human and cost. Once the likelihood and the consequences are classified for a matrix as shown in Figure 2, the highest risk conditions are clear.

Step. 3 : If evaluated risk rating for a location is high (i.e. category 3 or 4 in Figure 2), the risk reduction is required. In order to reduce the risk, detail inspection and a replacement plan can be proposed. If the reduction can be confirmed, proposed methods are applied to the optimised maintenance plan. However if some plans are proposed and their revised risk ratings are same categories, the quantitative analyses may be needed to identify the optimised plan.

3 LIKELIHOOD FOR CONCRETE STRUCTURES

Assessment is needed to classify the damage on the likelihood for the concrete structures. The first step is to check design books, which include situations, locations, construction years, design strength, water-cement ratios, sorts of aggregates and so on. The information in the design books is useful for the classification. The second step is inspection for the concrete structures. Diagnosis items are shown at Table 1. The classification is mainly done by the visual inspection [5]. Although non-destructive tests contain unknown factors, they are often useful. If cracks found by the visual inspection on the concrete structures have large width (0.2mm), chloride ions and carbon dioxide can easily cause steel bar corrosion. If the compressive strength measured by the Schmidt hammer test is low, the likelihood is judged as high.

Destructive tests are done for the detail inspection. If sampling time and place are permitted, cored simple tests, which indicate objective compressive strength and Young' module, is the best method for the diagnosis. The cored sample tests are also needed repairs because the tests damage the concrete structures.

Table 1 Diagnosis tems

Classifications	Items	Methods
Non-destructive tests	Inspection for degree of damaged	Visual Inspection
	Compressive strength	Schmidt hammer test
	Crack depth, Space between concrete and steel bar	Ultrasonic method
	Carbonate degree at exposure point	Phenolphthalein method
Destructive test (Cored sample)	Compressive strength	Compressive strength test
	Carbonate depth	Phenolphthalein method
	Amount of chloride ion	Potential difference titration
	Alkaline aggregate reaction	Microscope inspection

Table 2 Damage states and grades of visual inspection for salt attack and carbonate

Damaged grades	Salt attack	Carbonate
Negligible	Damage is not detected by visual inspection. Amount of chloride ions is less than corrosive occurrence amount.	Damage is not detected by visual inspection. Depth of carbonate is below cover.
Low	Damage is not detected by visual inspection. Amount of chloride ions is more than corrosion occurrence amount.	Some cracks and rust water can be seen. Depth of carbonate is near cover.
Medium	Some cracks occur by steel bar corrosion. Rust water can be seen.	Many cracks and rust water can be seen. Depth of carbonate is near steel bars.
High	Many and wide cracks occur. Loss of covers can be seen.	Many and wide cracks occur. Loss of covers can be seen. Depth of carbonate is over steel bars.

4 CONSEQENCES FOR CONCRETE STRUCTURES

The consequences differ on situations, the types of the concrete structures and damage mechanisms, so the definitions of the consequences are important for the RBM. There are three examples, a bridge, a shipyard dock and a LPG plant foundation.

4.1 Bridges

Concrete slabs in bridges are heavily damaged by fatigue, water and chloride ions in marine environment and with snow melting medicine. Once cracks occur at the surfaces of the slabs, corrosion factors like water and salt penetrate the concrete and cause steel bars to corrode. Stewart has studies chloride-induced corrosion models for bridges [6]. The risk on the consequences is considered as following. The items are objectively evaluated.

a) The loss of covers by the steel bar corrosion and disaster for users.

b) The cost of repair

c) The amount of traffic

d) The importance of road (national or local road)

e) The existence of another bridge under the bridge

4.2 Shipyard Docks

Shipyard docks are often damaged by the salt-attack, because of dry and wet repeat on sea conditions. Cracks can easily occur by dry shrinkage, even though the covers is thick. Then chloride ions can diffuse easily the cracks. If cement-water ratio is more than 50%, the cracks occur regardless of the steel bar corrosion. The risks on consequences are considered as following.

a) The loss of covers and the disaster for workers at shipyard dock bottoms

b) The cost of repair increases because areas are wide and high generally. If repair locations are high, scaffolds or ladder trucks are needed.

4.3 Plant Foundations

Concrete foundations at plants are constructed based on the designed compressive strength of the concrete. If actual compressive strength is lower than designed one, wide and deep cracks occur on their surfaces. If thermal stress is over allowable tensile stress, wide and deep cracks also appear on their surfaces. Chloride ions, carbon dioxide and other corrosion factors diffuse the concrete insides thorough the cracks. Therefore low compressive strength and excessive thermal stress weaken their durability. Plants have many equipments on their concrete foundations, so the risk on consequences as following [7].

a) The amount of flammable solution

b) Heights

c) Boiling solution

d) Driving pressure

e) Rotation numbers

5 APPLICATION TO RBM FOR CONCRETE WALLS IN SHIPYARD DOCK

The authors have investigated the large concrete walls of a shipyard dock that was built in 1972. It has three concrete walls and is stored seawater by a steel gate. The concrete walls are repeated on dry and wet conditions for almost 30 years. A large amount of chloride ions diffuses the concrete wall insides. The designed cover thickness is over 50mm, but serious steel bar corrosion occurs and the covers come off at some places. Repair and replacement have been done according to the damage without thinking of the risk for the repair and workers. The authors apply the RBM to reduce the risk and decide the orders of the repair on the walls.

5.1 Design Books and Document Data

The authors have checked the design books and the document data on the dock. The results are as following.

a) Construction year: 1972

b) Cement type: Portland-blast furnace cement

c) Design cover thickness: Over 50mm

d) Type of aggregate: Blast-furnace slag coarse aggregate

e) Water-cement ratio: 62.5%

f) Design compressive strength: 24N/mm2

5.2 Visual Inspection for Likelihood

The northern and the southern walls are divided in 4×25=100 and 4×22=88 blocks, and the eastern wall in 5×4=20 blocks respectively to reduce operations for diagnosis.

The visual inspection is the best and simple method to investigate the degree of damage considering the size and the area of the dock. The damaged states and grades with the visual inspection are evaluated by using JCI (Japan Concrete Institute). There are many cracks and loss of covers by the steel bar corrosion (Figure 3). The square blocks are ranked by using Table 2.

a) Medium ranked stage

b) High ranked stage

Figure 3. Damage by salt attack.

5.3 Risk for Workers at Bottoms

If the loss of covers by the steel bar corrosion, The workers received serious damages (injured or dead). The risk on the consequences for workers is

$$R_{tp}= S_d \times H_d \times P_{tp} \quad (1)$$

where R_{tp} is the risk for workers, S_d is the damage of one concrete block, H_d is the height of damaged area and P_{tp} is the number of the workers in a day. If the workers at the bottom are near stairs, the risk for them increases. All the blocks near the stairs are ranked as four.

5.4 Risk for Repair

The area of the dock is so large. If all the blocks are repaired, the cost increases. The RBM may be valuable for the economical maintenance of the dock. Main repair for the area, in where there are the loss of covers and spaces among the concrete and the steel bars, is to replace damaged concrete with new one. The risk on the consequences for the repair is

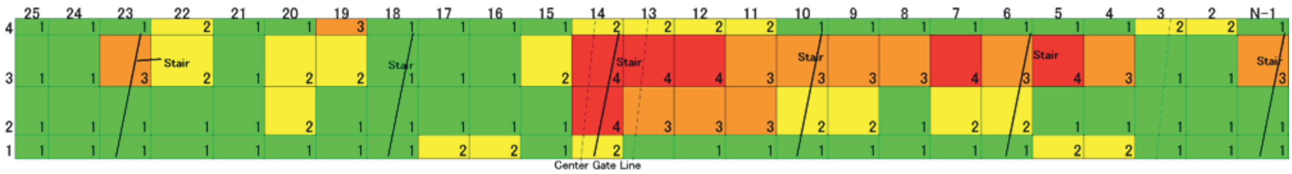
$$R_{rp}=S_d \times C_{rp}+H_d \times C_{sc} \quad (2)$$

where R_{rp} is the risk of the repair, C_{rp} is the cost of the repair and C_{sc} is the cost of the scaffolds or ladder trucks. The cost of the repair is containing materials and persons. It is very important for administrators to choose proper repair methods. If partial repair for the steel bar surfaces is needed, corrosion protect admixtures like nitrite on the surfaces is better. Damage will occur again due to careless repair. Therefore the cost may rise up than the evaluated one.

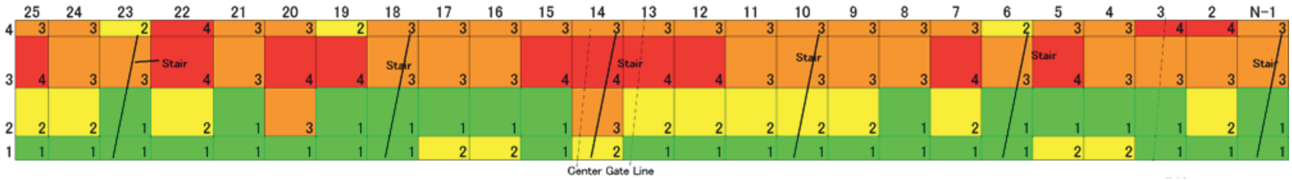
5.5 Results of RBM

Figure 4 shows the results of the RBM at the southern and the northern walls. Numbers are calculated by using the likelihood and the consequences. The numbers mean 1: acceptable, 2: acceptable with controls, 3: undesirable and 4: unacceptable, respectively. The numbers also show the orders of priority for the repair on the walls. The blocks near the stairs and the heights are evaluated high ratings considering danger for the workers. Figure 5 shows the summarised risk matrixes of the RBM. The ways to reduce the risk ratings of the matrixes is partially repaired the blocks that are heavily damaged.

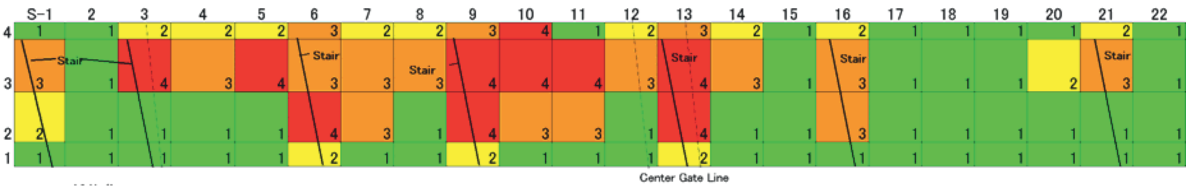
Desalinate is one of better electrochemical repair methods, but it needs large area. Therefore it must be only used for the highest risk ratings. The ratings can be reduced to keep the workers out the stairs during repairing or repair first at the heavily damaged blocks. The results of the RBM may be helpful for administrators to properly choice the ways to reduce the risk.



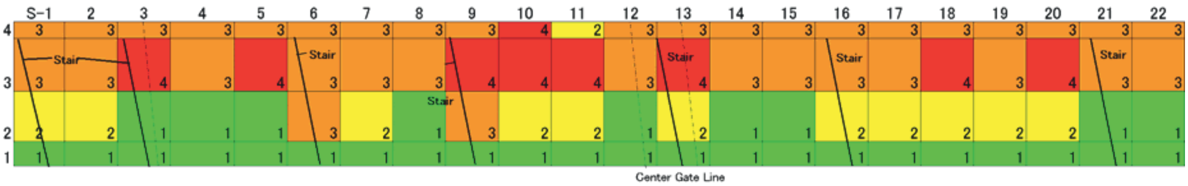
a) Risk for workers at northern wall bottom



b) Risk for repair at northern wall



c) Risk for workers at southern wall bottom



d) Risl for repair at souther wall

Figure 4. Results of RBM application for northern and southern shipyard dock walls

6 APPLICATION TO RBM FOR CONCRETE STRUCTURES IN BRIDGES

The damage of bridges influences not only repair cost but also economical activities. Therefore the bridges are one of the most important concrete structures. If inspection is carried out, traffic regulations may be needed and the flows of cars may go bad. Administrators must avoid the risk during the inspection. Non-destructive tests are useful methods [8] for the diagnosis of the concrete structures compared to destructive tests like cored samples because traffic regulations are minimum.

7 NON-DESTRUCTIVE TESTS FOR CONCRETE STRUCTURES IN BRIDGES

Non-destructive tests for the concrete have been improved and have various methods. Places and methods are shown in Figure 6 when they are applied to a bridge.

7.1 Detail Inspection for Bridges

If chloride ions penetrate the concrete insides and till steel bar surfaces and the amount of the chloride ions more than 1.2kg/m^3 on the surfaces, the steel bars corrode. Cracks due to the corrosion occur; the chloride ions penetrate from there easily. The authors have investigated a steel bridge with a concrete slab, which was constructed 40 years ago. The bridge is situated at a mountain area, so calcium chloride has been sprinkled for melting ice and snow on the slab. The chloride ions in the curb on the slab are shown in Table 3.

Table 3 Amount of chloride ions and calculated-diffusion coefficient.

Sampling position from surface	Mass per unit volume	Amount of chloride ions	Diffusion coefficient of chloride ion	Chloride ion concentration on surface
(mm)	(kg/m^3)	(kg/m^3)	(cm^2/year)	(kg/m^3)
10 – 20	2254	4.40	1.452	5.40
30 – 40		2.46		
50 - 60		2.05		

The diffusion of the chloride ions in concrete is said to follow Fick's second diffusion equation, as expressed with Eq.(3)

$$C(x,t) = C_0\left(1 - erf\,\frac{x}{2\sqrt{D \cdot t}}\right) \tag{3}$$

where C(x,t) is the concentration of the chloride ion (kg/m^3) at depth x (cm) and in period t (year), C_0 is the chloride ion concentration (kg/m^3) on surface, erf is the error coefficient and D is the diffusion coefficient of the chloride ion (cm^2/year). If cover thickness from a steel bars is known, the amount of the chloride ions can be calculated by Eq.(3). The start year of corrosion and the life of a bridge are predicted.

The cover of thickness in the curb, which was reconstructed 10 years ago, is 60mm. The maximum crack width on the surface is 0.5mm. Calculated chloride ion by Eq.(3) on the steel bars is $1.9kg/m^3$, so corrosion started about 4.7 years ago. The heavily corrosion cannot be seen at the surfaces of the steel bars actually, but corrosion will continue and let the cracks to occur from the locations where the chloride ions are calculated.

7.2 Diagnosis for Bridges

If the results are needed high accuracy, Schmidt hammer and cored sample tests are useful for the quantitative. Specialists decide the degrees of the likelihood with their results. The consequences differ at situations where bridges are located as explained in 4.1. The RBM method is applied to various bridges for its accuracy and reliability, as the results of the RBM are omitted here.

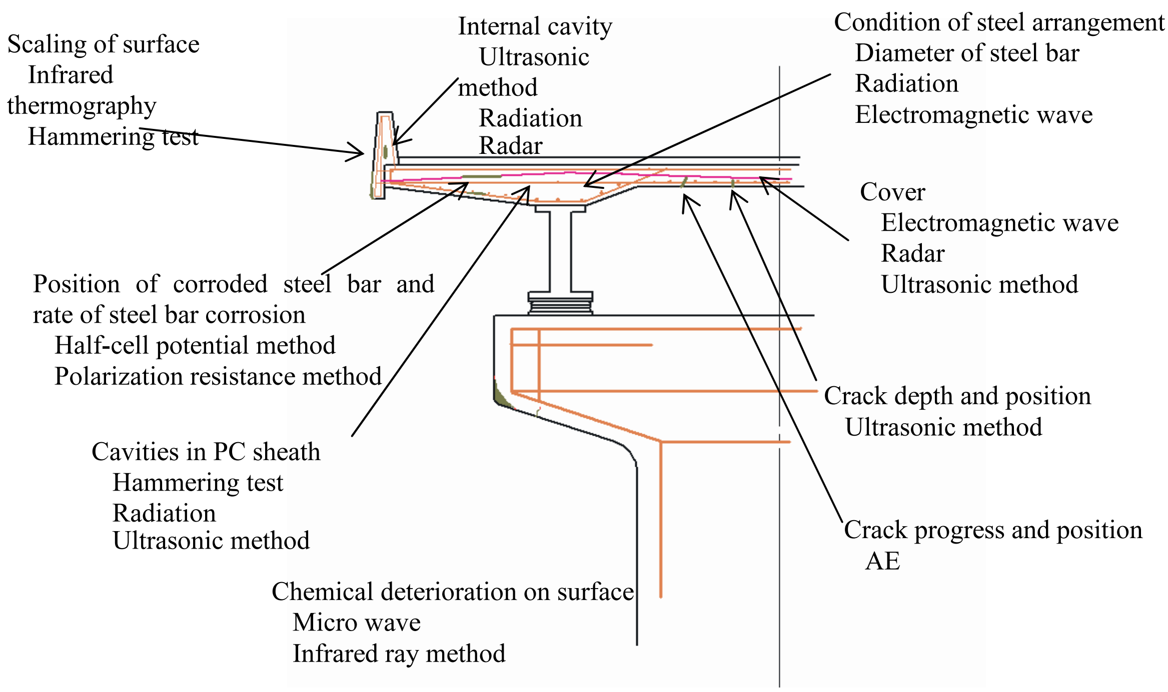

Figure 6. Non-destructive tests for bridge

8 CONCLUSIONS

Although the concrete structures have been said maintenance free, there are many damaged concrete structures. JCI has suggested the standard judgements of diagnosis for defective structures. If the RBM method is used for the concrete structures, the highest risk ratings are clearly assessed by using the risk matrixes. Therefore administrators can propose where is first selected and repaired. Namely they can decide some repair methods to reduce the risk rankings at the shipyard dock.

The detail inspection by the cored samples is the best method for the diagnosis, but cost, time and fixing the cores are needed. Speedy inspection is needed for the bridges to reduce traffic regulations. The diagnosis may be done only by the visual inspection. As the consequences differ at the locations of the bridges and are especially complicated, a guideline for them must be made. Further study on the RBM is needed for more accurate defective evaluation of the concrete structures.

Abstract: It is important to develop an efficient maintenance strategy for existing infrastructures. In this study, a new sensor was developed to establish a new concept of health monitoring of existing bridges. Bridges always show 3 dimensional dynamic behaviours with deflection or torsion by external turbulences such as traffic, winds, and earthquakes. Temperature is also an important factor that governs bridge motions. In order to detect and analyse damage and conditions of bridges, it is essential to monitor these 3 dimensional dynamic responses of bridges. Especially, dynamic torsional behaviours of bridges have not been discussed on so far, but it is expected that they give much information on damage and conditions of bridges. In this study, a new fiber optic sensor, that is, an fiber optic inclinometer was proposed for a new bridge monitoring strategy based on torsional behaviours. Through the tests on dynamic characteristics and temperature effects, the new sensor was developed and verified.

Key Words: inclinometers, bridge, monitoring

1 INTRODUCTION

Lately, the demand for the maintenance of existing infrastructures has been increasing all over the world. It is about time most of existing infrastructures need to be maintained. However, it needs enormous costs and time to maintain so many infrastructures. Therefore, it is important to develop an efficient maintenance strategy for existing infrastructures.

In Japan, the fiber-optic communications net has been connected along the national highways to maintain infrastructures. It will be extended to 300,000 km by 2010. Miki et el (1) monitored an instrumented bridge with the fiber-optic communications net (2001). They constructed the remote monitoring system that can forward the real-time data to the monitoring station. Kobayashi et el (2) attempted to develop a Weigh- In-Motion system utilizing Fiber Bragg Grating (FBG) sensor (2003). Because FBG sensors have capability of dynamic measurements and high durability, it can be considered as promising sensors suitable for bridge monitoring. Recently, new vibration sensors using FBG sensors have been proposed by Mita et el (4) (2003). Furthermore, Miki et el (3) observed a bridge with a monitoring system all by fiber optic system utilizing FBG sensors (2005). These intensive surveys gave the results that the "fiber-optic" monitoring system established by the combination of FBG sensors and the fiber-optic communications network could realize long-term maintenance-free. It should be emphasized that the fiber-optic monitoring system doesn't need to set up power supply in the field, so it can avoid troubles with thunderbolts, electromagnetic noises and dust.

The already-proposed monitoring systems need many sensors to grasp behavior of bridges, because sensors basically measure strain at a point in the target. This makes the cost of the monitoring system considerable. Therefore, in order to expand the applicability of monitoring systems by reduction of the number of sensors, a new concept of bridge monitoring must be established. In this study, focusing on 3 dimensional dynamic responses, fiber optic inclinometers are proposed as a new sensor. The proposed sensors by the authors can monitor 3 dimensional behaviors of bridges, especially torsional behaviors of bridges. It can be expected that 3 dimensional behaviors can give more information to find deterioration of existing bridges than strain gauge and that. the number of sensors will reduce compared with the systems using strain gauges.

With these sensors, measurements at few points make it possible to detect the dynamic responses because of the performance of inclinometer. And the sensor can be set up easily without scaffold. And this system has multiplexing capability. It can monitor plural bridges remotely at once by a set of the system. These factors would realize cost reduction. When it comes to the accuracy, the positions to set up sensors can be changed easily at any time it is needed because of the flexibility in placing.

In this study, the dynamic response characteristics of the proposed sensor were investigated to evaluate application of the Optical Fiber Inclinometer to monitor existing bridges. In addition, because fiber optic is extremely influenced by temperature, temperature compensation of the sensor was inspected.

2 DEVELOPED INCLINOMETERS

Fiber Bragg Grating (FBG) is adopted for this sensor because of the characteristic like durability, simplicity and multiplexing capability (Moreover it doesn't need power supply in the field.) (5).

In this sensor (Showed on Fig.1), the shift of the Bragg wavelengths indicates inclination.

The mechanism of the inclinometer is showed on Fig 2. The swing arm swings as to the pendulum movement, then a strain is happened to the FBG sensor by a stress at the plate string. The direction of pendulum swing is measurable direction of the sensor.

Figure 3. displays the relation between Bragg wavelength shifts and inclination of this sensor. The transform coefficient from wavelength [nm] to inclination [degree] in certain temperature (22.3 degrees of Celsius) is 2.674 [degrees/nm]. The relation can be showed this linear equation below.

Inclination[degree]
= 2.674 [degree/nm] ×wavelength shift [nm]

Figure 1 FBG Inclinometer

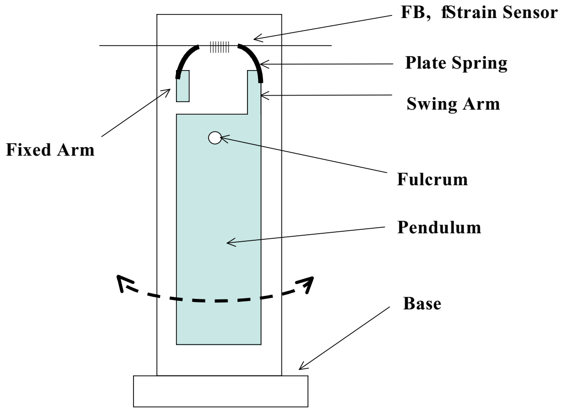

Figure 2. FBG Inclinometer Structure @

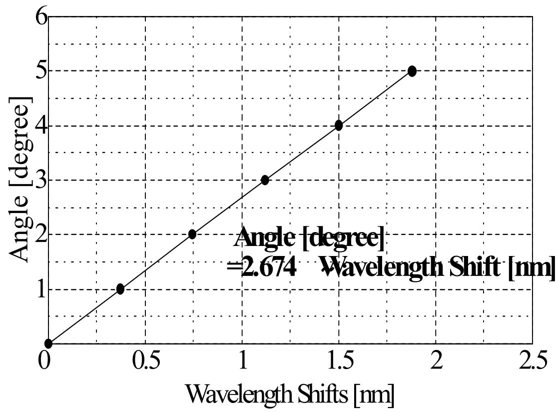

Figure 3 Wavelength Shifts and Inclination

3 TEMPERATURE CHARACTERISTICS

Generally, FBG is extremely influenced by temperature. The error by temperature makes virtual inclination. Therefore, we need to inspect the effect of temperature on the measurement to compensate for temperature.

In this test, the sensor was put into the high temperature chamber. And the temperature was changed by 10 degree of Celsius [ ] from –14 to 64 . Wavelengths were measured on each temperature.

From the results of wavelength on each temperature without inclination, Fig.4 shows relative wavelengths (wavelength shifts) to 1534.642 nm which is at 22.3 as a standard. Wavelength lengthens almost in proportion to temperature. From the result (Fig.4) and the relation between wavelength shifts and inclination (Fig.3), it can be read off that the error is from –0.14 degree to +0.28 degree between –14 and 60 (Fig.5). These wavelength shifts made virtual inclination.

4 DYNAMIC RESPONSE CHARACTERISTICS

The dynamic response characteristic of this sensor has to be investigated to grasp dynamic torsional behaviors of actual bridges. To grasp dynamic characteristics of bridges gives some information like deterioration in a girder and bearing etc. We focused on the response of inclination vibration characteristic but we also detected vertical vibration characteristic, because the sensor is expected to distinguish inclination vibration from other vibration.

Therefore, a vibration simulator was made to simulate torsional vibration of bridges (Fig.6). Two linear actuators were used for the vibration simulator. It can simulate torsional behaviour with control these actuators out of phase. And it can also simulate vertical vibration in phase with each actuator.

4.1 TEST CONDITIONS

The new software was developed to monitor the sensor's responses. Figure 7 shows the system of the dynamic responses characteristic tests.

In these tests, frequency of the vibration table was changed from 2Hz to 5Hz on each behaviors (vertical vibration and inclination vibration) according to actual bridges characteristic (5).

In the vertical vibration tests, the amplitude of acceleration of the table was controlled around 0.1[G].

In the inclination vibration tests, the angular acceleration of the table was compared with the response of FBG inclinometer.

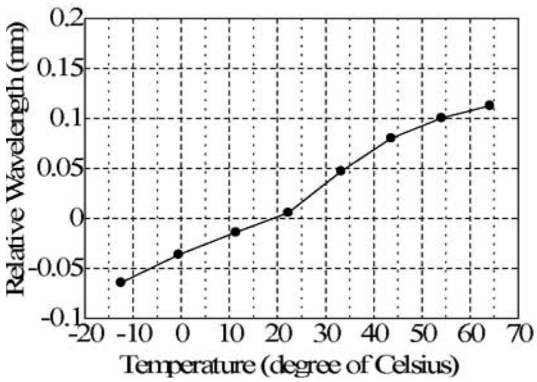

Figure 4 Temperature and Relative Wavelength

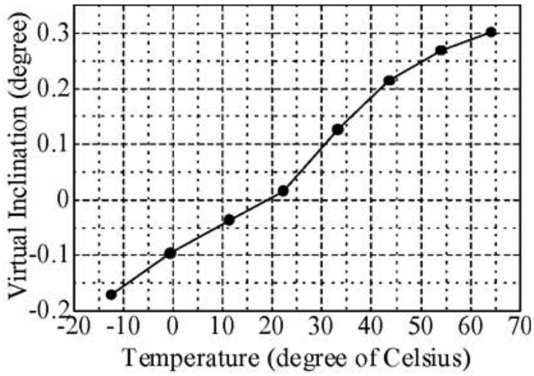

Figure 5 Temperature and Virtual Inclination

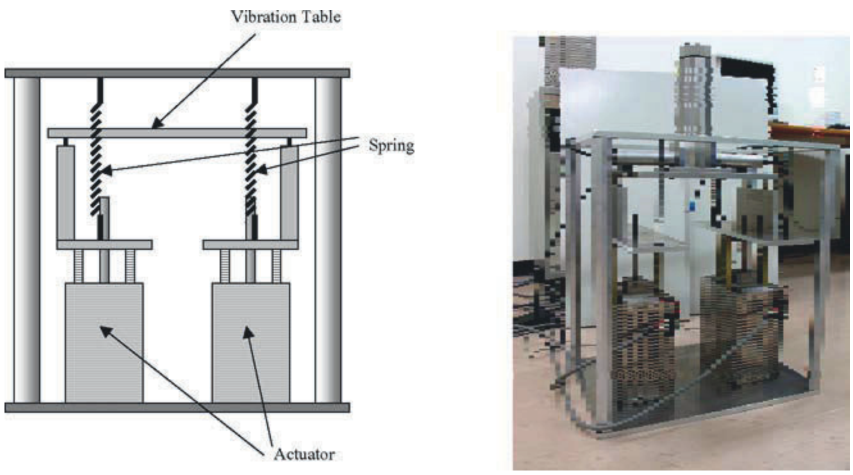

Figure 6 Vibration Simulator

4.2 TEST RESULTS

Figure 8. to Figure 13. show results of tests on dynamic response characteristics. The response of the FBG inclinometer in 2Hz and 3Hz vertical vibration (Fig.8) was extremely small compared with the case in inclination vibration (Fig.11). In addition, the result of FFT analysis in 2Hz vertical vibration (Fig.9) indicates that the small vibration seemed to come from the FBG inclinometer's own characteristic frequency (6Hz). This sensor is expected to indicate minute responses in vertical vibration. On the other hand, this sensor responded bigger in more rapid vertical vibration like 4Hz and 5Hz (Fig.8). From the results of FFT analysis (Fig.9), it can be found that the sensor grasped this table's vertical vibration frequency in 4Hz and 5Hz. Although this sensor responds in vertical vibration that is not measurable direction because the pendulum of this sensor (Fig.2) is not properly symmetry, it is possible to separate kinds of vibration by FFT analysis.

By comparison, in inclination vibration tests, instability of the vibration table's motion reflects the results especially in 2Hz and 3Hz, but from the results of FFT analysis (Fig.12 and 13) and the number of waves in Fig.10 and 11, FBG inclinometer's responses apparently corresponded to the frequency of the vibration table motion. Beside the results of frequency, compared with each angular acceleration measured by accelerometer, each inclination measured by FBG inclinometer also corresponded to actual inclination to some extent.

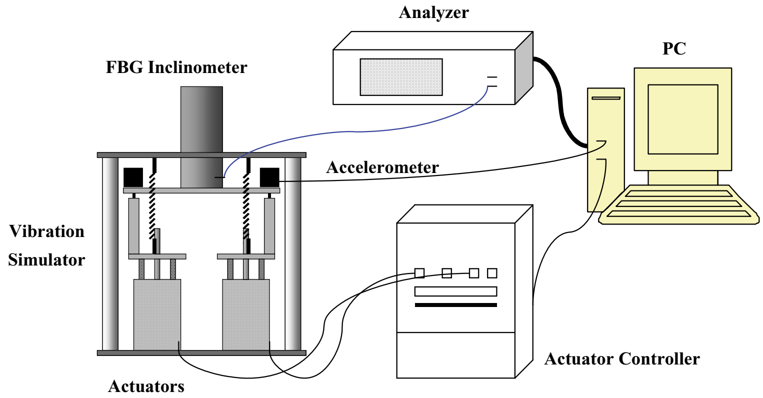

Figure 7 System of dynamic responses characteristic tests

5 CONCLUSIONS

This paper proposed the FBG Inclinometer to establish a new concept of health monitoring system for existing infrastructures. Therefore, the temperature characteristic and dynamic responses of this sensor were investigated to evaluate application of the sensor. From the results of these tests, the following facts were appeared as the characteristic of the sensor.

a) Temperature characteristic of this sensor is linear relation to wavelength shift. It is possible to compensate temperature influence of this sensor.

b) In vertical vibration, this sensor responds small in slow vibration like 2Hz and 3Hz as expectation. Although this sensor grasps vibration frequency in rapid vibration like 4Hz and 5Hz, these waves can be classified with FFT analysis.
c) In inclination vibration, this sensor grasps vibration frequency well.

The FBG Inclinometer was developed and is going to be applied to monitor an actual bridge next.

OPTIMISING ASSET MANAGEMENT DECISION MAKING AND BUDGETING USING RISK MANAGEMENT TECHNIQUES

Adam Aspinall and Peter Trueman

Evans & Peck Pty Ltd, Suite 5, 165 Moggill Road, Taringa, Queensland 4068, Australia

Abstract: The management, maintenance and operation of major infrastructure assets involves long (whole-of-life), complex processes in which there is always a considerable uncertainty for the manager of those assets. The level of uncertainty of asset performance, cost of operation and market competitiveness depends on risk management measures that are put in place (whether or not they are recognised as risk management measures). However, it is rare that risk management measures fully remove these risks. For a long time now, sophisticated levels of quantitative risk analysis have been adopted as tools to both improve management and make financial decisions in other business realms, particularly in the finance and insurance industries and more recently in major engineering capital works projects with considerable success. Quantitative residual risk analysis is now considerably more accessible in the broader engineering context as a result of readily available, easy-to-use computer programs and a growing body of knowledge of the use of modelling techniques. In asset management, the potential for more use of these tools should be higher because of the availability of the relevant statistical data on asset performance. This paper presents a more robust risk management process, including use of both formal qualitative risk management planning and quantitative residual risk analysis techniques, which has considerable potential to be used to improve asset performance, decision-making, budget management and timing for major asset management programs.

Key Words: Asset Management, Risk Management, Budget, Maintenance, Forecasting, Stochastic, Correlation

1 INTRODUCTION

The management of a major infrastructure asset such as a power station, smelter or refinery involves understanding and planning for long-term, complex issues as well as market interactions and transactions in which there is always considerable uncertainty in the outcomes. In this paper we define asset management as the 'whole-of-life' operation and maintenance (including major capital refits) of plant and equipment which together form an asset or group of assets.

The traditional approach to asset management is deterministic, that is, operation and maintenance decisions are traditionally based on the forecast of a single particular outcome or operating regime. In reality the level of uncertainty of particular operational events, plant performance, market performance, procurement outcomes etc will vary considerably from forecast results, that is, they are stochastic in nature. Outcomes can be significantly influenced by the prior experience of the asset manager with the plant, the current position in the life cycle of the plant and many other external influences. The major influencers of the level of uncertainty are the risk management or mitigation measures that have been put in place by plant owners, operators or maintainers.

Many effective asset owners consciously and subconsciously adopt a significant level of risk management measures. However, it is not always easy to recognise all the risk management measures that have been put in place. Additionally, it is rare that risk management measures fully remove the risks. For example, risk transfer mechanisms rarely reduce residual risk likelihood or consequence to zero. Asset management teams often have a limited understanding of the residual risk that they carry and conversely, parties such as insurers, financiers, even corporate management teams and/or Boards tend to not fully take into consideration the risk management measures that are in place in determining and making provision for the risk that they carry. This is potentially to the detriment of their success in the markets in which they operate.

Quantitative residual risk analysis is now considerably more accessible as a result of readily available, easy-to-use computer programs and a growing body of knowledge of the use of computer modelling techniques in the asset management context. Quantitative risk analysis has been adopted to a very high level of sophistication in other business realms for a considerable period of time, particularly in the finance and insurance sectors. Useful quantitative analysis must properly account for the qualitative risk management measures that are in place.

Use of a more robust risk management process as part of the asset management process, including use of both formal qualitative risk management planning and quantitative residual risk analysis has considerable potential to improve the outcomes and decision-making in asset management and operational budget preparation. This paper explores this hypothesis and presents some potential tools for use by the asset manager.

2 TYPICAL STRATEGIC PLANNING AND BUDGET PREPARATION PROCESSES

The typical approach to organisational strategic planning and, as part of that process, asset management and budget preparation like all processes that are in need of an overhaul, has evolved over many years and has been driven by the processes and tools employed. The more recent recognition of the priority that the process of asset management needs to be given in the early stages of plant development has begun this overhaul. The next stage of the overhaul of the traditional approach needs to focus on the process of developing or reviewing the annual strategic plans and budgets for the organisation. Typically, this part of the process begins as asset owners and asset managers are approaching the new financial year in response to the requirement to prepare a plan in order to get approvals for activities and financial provisioning for that next year.

Asset managers who are going through this process often have at their disposal an Asset Management Strategy document (hopefully developed during the very early stages of asset life) that is likely to set out technical details of the plant, market position of the company's assets (which allows the plant to quantify production requirements of the plant) and a high-level assessment of market and operating risks. Additionally, an Asset Management Strategy will set out an operating and maintenance regime, which in turn is supported by plant strategies that have been developed and refined using what are regarded today as common maintenance planning tools such as Reliability Centered Maintenance, Root Cause Analysis etc.

The strategic planning and budgeting process is likely to commence with a review of the Asset Management Strategy for changes in external factors such as market conditions or internal factors such as plant condition. This review process is also used to provide a detailed breakdown of activities that need to occur over the period of the strategic plan and budget (often looking little more than one or two years out).

The next stage of the process is the development and costing of a budget that is structured to match activities identified in this latter part of the process. This budget development sometimes utilises a "zero based" approach, which relies on be estimating skills of plant managers and supervisors or, more often than not, is based on last year's spend with some adjustment for the larger activities. It is a very rare that strategic plans or budgets will be adjusted by referring back to the high-level risk assessment in the Asset Management Strategy document or that further risk analysis will be carried out on the budget itself.

A strategic plan and budget thus produced then tends to go through a structured series of reviews and consolidations in preparation for a final approval by senior management or a Board.

The types of less than desirable issues that the approach described above normally leads to are as follows:

- the resultant activities and budget are difficult for senior management to challenge as there is little or no ability to quantify or qualify outcomes if the robustness of the plan is tested and activities are eliminated or budgets reduced. This normally results in adoption of practices where the budget review process becomes a negotiation between asset managers and senior management (normally to the detriment of the asset manager' s position);
- the approved budget becomes both the target for the asset manager to strive for and the financial provision that the organisation makes in its annual funding requirements. This in turn results in poor incentive arrangements for the asset manager, inaccurate reporting of the actual financial position and an inability to effectively fund appropriate operations and maintenance activities following unplanned plant breakdowns, project cost overruns or unforeseen market events;
- the process does not provide any mechanism for optimising asset performance, maintenance spend, risk mitigation strategies or residual risk levels prior to implementation of the plan or during the plan period in response to actual outcomes; and
- the process normally utilises a single market forecast, even though the market forecast itself might have recognised the stochastic nature of market outcomes, as an input to derive a single profitability forecast. This is ineffective use of data since there is no recognition that asset management can, and should, be tailored to match market outcomes.

The utilisation of strategic planning, budget preparation and Asset Management Strategy review processes that incorporate a more thorough qualitative risk analysis and quantitative residual risk modelling have the potential to address each of these issues. Section 3 below describes the terms qualitative risk analysis and quantitative residual risk modelling.

3 RISK MANAGEMENT AND RESIDUAL RISK ANALYSIS

The long duration, unpredictability of plant performance, complex market interaction and exposure of asset management activities to external influences means that at any point in time up until market outcomes have been realised or all costs have been realised, the forecast financial position for an asset will be a range rather than a single number. The uncertainty of the outcome within this range is directly related to the risk profile of an asset and the risk profile in turn is related to the way that asset risks are managed.

In statistical terms, the future financial position of an asset is stochastic in nature, not deterministic. To understand this, it is not difficult for any relatively experienced operations or maintenance personnel to be able to produce an outline probability distribution for the financial outcome of a small maintenance project (say undertaking the overhaul of a major fan or pump) at the end of the project period, by:

- Identifying the extreme best, expected and worst case financial outcomes;
- Dividing the range between best and worst into a number of equal ranges; and
- Estimating the probability of achieving a financial outcome within each of the ranges.

A typical distribution that might be generated in this way is shown in Figure 1.

In Figure 1, point "B" shows the net estimate of $1 million, point "A" the best possible outcome of $930 thousand and point "C" the worst possible case of $1.35 million. There is a 50 per cent probability that the financial position at a particular time will be between 1 million and 1.05 million, a 20 per cent probability that the cost will be between 1.05 and 1.1 million and so on.

The shape of this distribution is a direct reflection of the residual risk and opportunity in a project. The shape will change depending on the risk management measures that are put in place, as well as the procurement methodologies, project delivery methods adopted and other decisions that are reflected directly in the estimate. The same process can be applied to many other asset management activities such as procurement of spares, market impact of maintenance scheduling, market revenues etc.

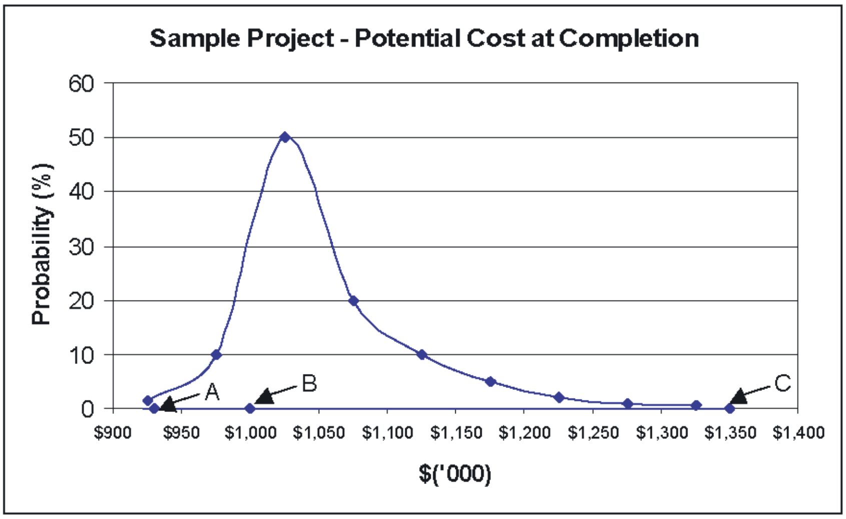

Figure 1 – Distribution of the Forecast Cost at Completion for a Simple Project

3.1 Qualitative Risk Management and Assessment

The risk profile for an asset will depend upon the measures that are put in place to manage risks, including optimising the ability to capitalise on opportunities. Therefore, to measure the potential overall financial outcome for an asset at a particular time, it is necessary to understand:

- all of the potential risks and opportunities;
- how these are being managed;
- whether, after management, there remains some potential likelihood of financial exposure (ie residual risk); and
- if there is residual risk, what potential cost implications it may have.

For example, on a small maintenance project such as the one described above, there will be risks associated with spare parts procurement including both price levels and availability, additional manpower due to difficulties during disassembly or reassembly, or longer term impact due to changes in workplace health and safety requirements each of which can manifest itself in the potential for market losses due to delays. Generally such risks can be mitigated by measures such as a clear delineation of risk under procurement contracts, insurance policies, use of proven maintenance procedures, utilising appropriately skilled and experienced tradespersons and other measures. Notwithstanding these measures, the asset manager can for example be subject to insurance excesses, contract limitations or exclusions or the tradesperson could err in assembly of components. That is, there remains some potential for cost consequences or "residual risk".

The first step in quantifying the cost impact is therefore to assess the risks and risk management measures that exist on such a maintenance project. This is called qualitative risk assessment. There are many ways of undertaking the qualitative assessment including those adopted under international standards and codes of practice.

The basic process involves identifying the risks and opportunities, assessing them generally in terms of likelihood and consequence, identifying the treatment measures that are in place for the risks and opportunities and, where necessary, developing and implementing appropriate, additional risk treatment measures. The process is described in detail for example in AS4360.

Developing comprehensive qualitative risk assessments and optimal management plans is very challenging. Key issues that require to be addressed include:

- establishing a complete picture of all of the risks and opportunities;
- eliminating duplication and overlap;
- recognising the relationships between risks and opportunities, their various sources and root causes; and
- properly recognising all of the treatment measures that are in place including for example generic risk treatment measures (such as appropriately resourced management teams) and measures that offset the effects of risks (such as realising savings elsewhere on a project in response to the manifestation of a risk).

This is a process that most experienced asset managers are familiar with, at least at the high level, as it is the process normally utilised development of an organisation's Risk Register, for the qualification of high level risks in preparing Asset Management Plans or in response to modern Workplace Health & Safety legislative requirements in assessing workplace hazards.

The process is however rarely utilised at lower levels for reviewing projects such as the one used in the example above, for managing the impact of unplanned plant downtime or even for assessing the cost of and prioritising responses to market related event such as abnormally high electricity prices in the electricity market.

This qualitative analysis, which is commonly practiced by asset managers in developing corporate risk registers, is however only the first part of the process we are advocating since it does not entirely eliminate all risks. The second part of the process, and the part that results in the development of several additional useful tools, is the quantitative residual risk analysis.

3.2 Quantitative Residual Risk Analysis and Measurement

The relationship between the qualitative process and the quantitative analysis is illustrated below. As can be seen the outputs of the qualitative process become the inputs to the quantitative process.

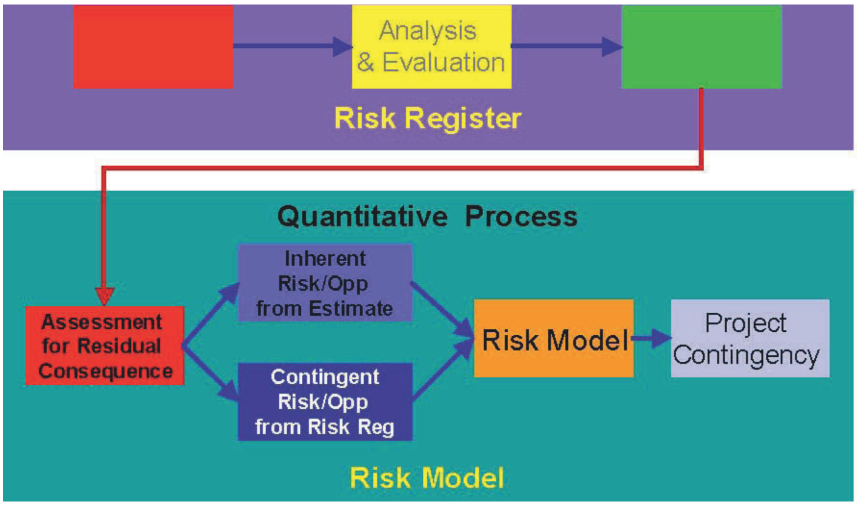

Figure 2 – Relationship Between Qualitative and Quantitative Risk Assessment

Figure 2 shows how the output from the familiar qualitative risk process feeds into the quantitative process which identifies two types of potential sources of residual risk. Inherent risk is the uncertainty in the pricing of the known scope of work, accepting that the asset management strategy is implemented as is contemplated at the time of the assessment; and contingent risks are risk events that may occur during the life of the plan that differ from what has been assumed in the original pricing.

The analysis of the risk profile to develop a quantitative model for potential costs involves using statistical techniques and computer power. The most effective, well recognised of these techniques in this context is Monte Carlo simulation whereby the computer samples very large numbers of potential combinations of risk and opportunity outcomes based on likelihood and consequence parameters provided for each of these (generally in the form of outcome probability distributions for each of these). Subject to proper use, the Monte Carlo modelling and simulation technique is robust, intuitive and widely adopted throughout many spheres of business, particularly in the insurance and finance industries. In developing an asset management strategy and budget (both capital and operating), it would involve:

1. including the potential range of costs for each item of known scope ("inherent risk") usually using a summary of a cost plan or estimate;
2. including the probability of occurrence of each identified risk event and the probable range of costs ("contingent risks"); and
3. simulating potential combinations of the costs of all of these to develop a sufficiently large set of sample total project costs such that, if a completely new set of samples was prepared, the distribution would match the model distribution.

To be accurate, a quantitative risk analysis must obey four rules:

1. It must be complete;
2. The likelihoods and potential cost effects of risks must be valid, meaningful estimates;
3. It must contain no duplication; and
4. The relationships between risks must be reflected in the model, ie independencies and inter-dependencies must be accurately modelled.

The assessment of the potential cost consequence stochastic for each risk may be based on relevant statistics, results on samples of previous annual outcomes or the judgement of asset managers, project teams and/or experts in this type of work.

The likelihood of occurrence of risks must also be assessed and accounted for. Distribution shapes that are commonly used include triangular, uniform, normal, skewed normal, discrete and actual distributions from statistical records.

By examining the potential consequences of each risk, a more detailed view of what might happen on a project overall can be formed.

In undertaking the Monte Carlo simulation, the computer selects a random outcome for each of the risk events and adds these to form a complete scenario. This process is repeated enough times that all possible combinations of events are explored. The density of the total cost outcomes of all of the risk functions then determines the overall forecast cost probability distribution.

Figure 3 below illustrates a forecast budget outcome probability distribution for a sample group of assets.

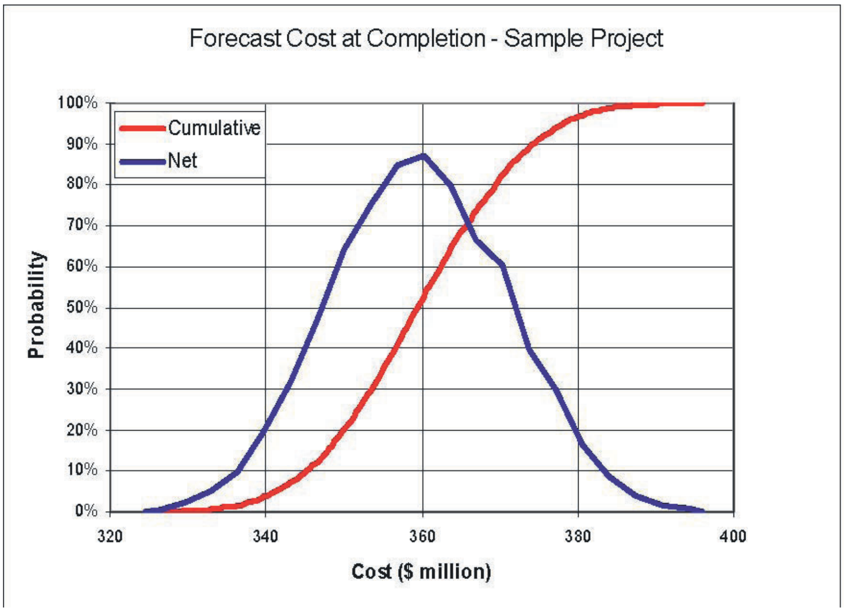

Figure 3 – Cumulative and Net Probability Distributions for a Sample Group of Assets.

This distribution indicates that the forecast budget for the sample assets will be between $327 million and $394 million, that there is a 20 per cent probability that the budget will come in at no more than $350 million (the "P20" figure), a 40 per cent probability that it will come in at no more than $357 million ("P40"), a 60 per cent probability that it will come in at no more than $363 million ("P60") and an 80 per cent probability that it will come in at no more than $370 million ("P80"). It also indicates that the most likely budget outcome is $360 million and that there is a 60 per cent probability that the outcome will be between$350 million and $370 million.

Because the shape of the distribution is a reflection of the risk profile of an asset, the analysis tool can also be used to drive further optimisation of the risk management of the asset. For example, a better managed or scheduled maintenance activity may have a far higher chance of finishing within budget than a less well managed activity. Sensitivity analysis can also be undertaken so that the risks that are having the most potential effect on the project can be identified.

It is a relatively simple conceptual step to recognise that if the same process is utilised for identifying the range and probabilities of market outcomes for the same period that these two analyses can be combined to produce a profitability distribution for the asset. This final step has the potential to produce a most invaluable tool that allows testing and therefore optimisation of operations and maintenance activities to match the variability of anticipated market outcomes.

4 USES FOR RISK ANALYSIS OUTCOMES IN DECISION-MAKING

Assuming that the qualitative risk management work was thoroughly undertaken and the residual risk was accurately assessed, the recognition of the stochastic nature of the potential financial outcomes and an understanding of the various parameters that can affect those outcomes can mean that these models can be useful tools for optimising decision-making and in guiding asset management activities.

4.1 Difficulties in accurate modelling for decision making

The assumption that the risk models are accurate are sweeping and can be found wanting. The key issues in preparing accurate risk models include:

1. Failure to account for the ability of teams to overcome risks in ways not fully understood when the model is built. For example, a risk cost may be offset by cutting a cost or undertaking different work on an entirely un-related component of the project;
2. Incomplete models;
3. Failure to recognise correlation, between components of projects and/or between different projects within a portfolio;
4. The uniqueness of risks and the lack of available data; and/or
5. The over-provision for contingencies at corporate level as a result of a failure to recognise the combined "portfolio" effect of individual project stochastics (discussed below).

Ultimately, risk analysis involves both endeavouring to comprehend what may happen in the future and simplifying what may happen to the point where a model can be prepared in a sensible amount of time. When considering asset management activities, this simplification process is assisted where there are accurate and complete plant history records available which provide a guide to the range of outcomes and risks and data that can assist in building appropriate risk distributions. Such historical data is commonly available for today's asset managers utilising computer maintenance management systems.

Regardless of some of the difficulties faced in preparing accurate risk models, the use of the residual risk stochastic will be of assistance in providing quantitative support for adopting reasonable contingencies, deciding whether to proceed with or modify certain asset maintenance activities or in recognising the potential for maintenance costs to overrun notwithstanding contingencies and so on.

4.2 Portfolio Effects

In making decisions about an individual asset, many business entities will be considering other components of their business, particularly other assets that they have on the books. Portfolio theory in risk analysis is another area that has been very widely explored in the finance industry.

The key outcome of an analysis of portfolios is that the combined levels of risk of all of the assets will be less than the arithmetic sums of the component assets, assuming that there is not perfect correlation between the various assets. For example, the probability of 5 uncorrelated assets all achieving budget outcomes at a P65 cost or greater is $(0.35)^5 = 0.005$, or less than half a per cent.

The corollary of this is that a portfolio manager can have an overall "budget provision" that is smaller than the arithmetic sum of the budget provisions required for the individual assets, whilst effectively having sufficient budget provision for each asset.

An example of this effect in practice would be some of the local Electricity Generation owners who have multiple power station sites operating in different parts of the market requiring quite different operating regimes to be implemented at each. These assets can have quite a low correlation and therefore this portfolio effect can be very useful for allocating appropriate budget provisioning.

5 ASSET MANAGEMENT AND RISK ANALYSIS OUTCOMES

The above discussion focuses on the uses of forecast stochastics in decision-making.

The stochastics also serve to illustrate in an obvious way the differences between targets, forecasts and financial provisions. During the development of an asset budget and strategic plan, it is typically a challenge for management at all levels to filter cost information that is available to understand the potential budget outcomes, accounting for such factors as the optimism of the asset management team, the risks that may yet arise and the potential for costs and/or incomes to change before the plan is complete.

Until the plan is complete and all financial accounts have been settled, there will be some cost and/or price uncertainty. Asset managers are duty-bound to strive for targets (both cost and price, depending on the commercial arrangements). Their regular reports to senior management need to provide accurate information on forecasts – not necessarily the same as the targets. Senior management also needs to be able to ensure that sufficient funds are available in the event of overruns. Figure 4 below illustrates how the cost figures might look at some point through the plan life for the group of assets used in section 3.2 above.

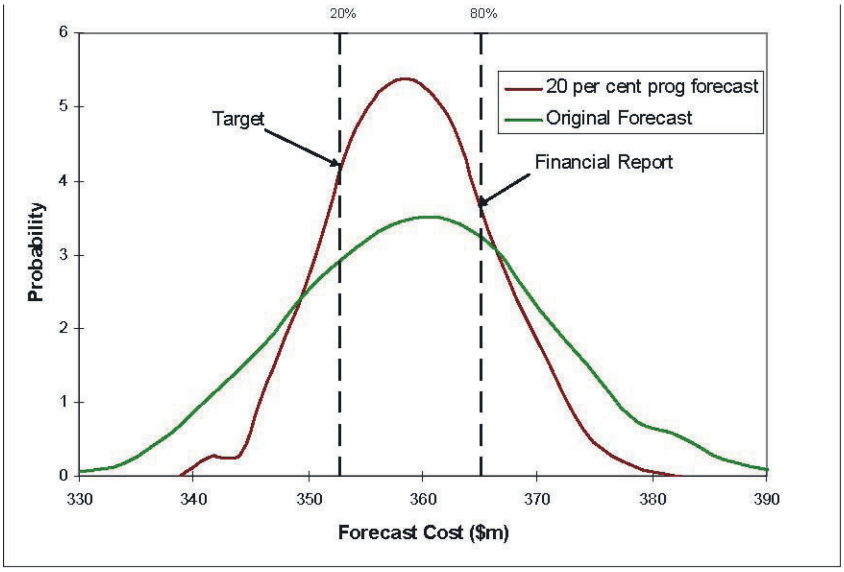

Figure 4 – Forecast Outcome Figures for 35% Complete Budget Plan

In this example, it may be appropriate for senior management to set the target cost at the P20 figure of $353 million. It stands to reason that the forecast expected cost is the "most likely" cost of $358 million. (In most computer-generated Monte Carlo simulation modelling, the use of the most likely figure or mode can be problematic because of the way the models are presented. A more reliable measure should typically be around the median or mean, which are typically close together in asset cost forecast models). The senior manager could make financial budget provisions at the P80 figure of $365 million, although this might need adjustment at portfolio level as discussed in section 4.2 above.

For appropriate targets to be reflected in forecast distributions, it is essential that all opportunities are properly reflected in the qualitative assessment and then as inputs into the quantitative modelling. It is also essential that due account is taken of risk treatment measures including less obvious responses to risks that may arise such as initiatives taken by good asset management teams that are not formally recorded in the qualitative assessment process. Many quantitative models inadequately reflect "upside" cost outcomes as the modelling team tend to concentrate more on the potential downside. Setting stretch targets requires that the better outcomes are given equal attention to the downside outcomes.

A related issue with the overhaul of major assets is the uncertainty in overhaul project durations. For owners and contractors, a considerable proportion of the financial risk will be in the potential for delays resulting in time-related costs. For example, productivity losses due to plant/asset access restrictions. Clearly, the investigation of the uncertainty on the durations of overhaul projects, individual tasks and the relationships between tasks will assist in providing more meaningful, accurate cost forecasts.

As asset management activities progress through the period of the Strategic Plan, the differences between the targets, forecasts and financial provision figures will narrow.

5.1 Budget Issues for Senior Management

Section 2 of this paper addresses a number of issues the Senior Management face during the review of asset strategy plans, corporate strategic plans and associated budgets. The discussion below describes how the authors see the adoption of a quantitative risk modelling approach will assist senior management to address these issues.

The first issue identified was that activities and budget could be difficult for senior management to challenge as there was little or no ability to quantify or qualify outcomes if/when the robustness of the plan is tested and activities are eliminated or budgets reduced. If the asset plan and associated budgets are developed utilising the risk analysis process set out above, the asset manager is provided with an ability to analyse the residual risk if a particular activity is modified or eliminated altogether, and to quantify any argument for the inclusion of particular activities. In other words the outcomes of this process allows the asset manager to demonstrate from a cost or residual risk perspective why particular maintenance levels or projects are being undertaken and allows senior management to understand the risks they must accept if such activities are not undertaken. It also allows both parties to identify and prioritise activities and tasks that should be undertaken if, at any time through the plan period, budget outcomes are forecast to be better than expected.

The second issue was the issue of the traditional approach to developing a budget resulting in budget targets matching financial provisions that are made by the organisation. Section 5.1 above clearly demonstrates the flexibility that the proposed approach yields in relation to both setting stretch targets for asset management and making adequate budget provision to cater for potential risks of cost overrun at the same time.

Adoption of the process obviously leads to the development of a set of tools that allow a significant level of "what if" analysis to facilitate the optimisation of asset performance and maintenance spend.

With the ability to combine the stochastic outputs from both the asset management strategy and the market outcome analysis, the proposed process provides an unparalleled tool for linking asset management decision-making with market priorities. This particular area is one that has traditionally relied upon the expertise and experience of the asset manager who has never been able to rely upon quantifiable analysis to provide assistance in this kind of decision-making.

6 CONCLUSION

Management of major assets involve complex, long life transactions that generally involve considerable degrees of uncertainty. The uncertainty is a function of the risks on the asset and the measures in place to manage that risk. All financial stakeholders will be affected by the uncertainty and therefore these risk management measures. Measures such as risk mitigation or transfer are rarely 100 per cent effective; there is generally some likelihood that the measures will prove ineffective and that some cost can be incurred.

Qualitative risk analysis of high level risks has become a common practice amongst asset owners particularly in relation to development of a corporate risk register. Quantitative risk models, generated by easy-to-use, readily available desktop computer applications are now used to greater or lesser degrees by entities to quantify some of the market risks they face but the same techniques are rarely utilised by asset managers to quantify the risks they face in delivering a strategic plan and budget. Provided these quantitative risk models can be developed to reflect the risk mitigation measures that are in place they can be used to inform decision-making in costing of works and understanding potential financial exposures. They can be used in asset strategies to set targets, separate targets from forecasts and understand the potential for costs to overrun forecasts.

The models can also be used at portfolio level (programme, site or corporate level) to inform decision-making at that level. Portfolio effects, long understood and beneficially used in the finance industry, can also be understood and beneficially used in management and decision-making.

It is difficult to develop accurate models but useful models have been developed and successfully used by Evans & Peck in the management of a number of major infrastructure projects and programs. It is essential to recognise the potential for weaknesses in models and, in making use of them, to subject them to adequate scrutiny and to limit reliance on them consistent with informed judgement of their accuracy. Nevertheless, quantitative models of forecast outcomes, with all their weaknesses, are in widespread use in finance and other areas of industry, and have considerable potential be used with equal benefit in the asset management arena.

E-mails: zhan@me.queensu.ca; chrism@me.queensu.ca

Abstract: A novel technique for detection of gearbox deterioration is proposed in this study. The proposed technique makes use of a time-varying autoregressive model and establishes a compromised autoregressive model based on healthy-state gear motion residual signals under varying load conditions and employs the Kolmogorov-Smirnov goodness-of-fit test statistic as a measure of gear condition. The order of the time-varying autoregressive model is selected by using a proposed fully automatic and highly effective model order selection technique with the aid of hypothesis tests. Validation of the proposed technique is carried out by using both simulated and real entire lifetime gear vibration signals and demonstrates that the proposed technique possesses appealing effectiveness in identifying the optimum autoregressive model order for robust gear condition detection under varying load conditions.

1 INTRODUCTION

A significant surge of research achievements on the condition monitoring of rotating machinery has been reported in the latest two decades. Particular attention should be given to the pioneering work by McFadden [1, 2] who proposed a highly efficient vibration monitoring technique for gearing systems using Hilbert transform based phase modulation (PM) and amplitude modulation (AM). However, this technique involves a strong subjective determination of the dominant meshing frequency and accompanying sidebands. Inappropriate selection of dominant meshing frequency may lead to poor quality detection of the target gear. Such a disadvantage was denoted in some recent research [3, 4].

A recent study by Wang [4] proposed a narrowband structural resonance demodulation based technique which to some extent is able to provide an earlier alert of incipient tooth crack in comparison with the aforementioned PM method by McFadden. Nevertheless, this technique is in need of cautious user provided identification of the frequency band which contains the dominant structural resonance. Such a necessity considerably fetters the real-time application of this technique.

It should also be noted that time-frequency analysis, in particular the wavelet transform, has been an intense research focus in the fault detection and diagnosis of rotating machinery in the latest decade [5−7]. However, the expert based explanation of the resulting time-frequency representations limit the application of these techniques.

There remains a need for an alternative technique in the time-domain which is able to capture the non-stationarity of a signal and show insight into its dynamics, but simultaneously be time-efficient. Kalman filter based time-series analysis is such a candidate technique. It possesses desirable properties but has not yet attracted sufficient attention in the fault detection and diagnosis of rotating machinery. Furthermore, it is worthwhile to note that in recent years the Kolmogorov-Smirnov (K-S) goodness-of-fit (GOF) test has been found to be an extremely powerful tool in the condition monitoring of rotating machinery. Some preceding research using the K-S test has been carried out in the fault detection and diagnosis of gears and bearings and other rotating components [8−10].

Since a desirable detection model must be able to best represent the healthy vibration signals under varying load conditions and be most sensitive to any abnormality caused by a defective condition, the Kalman filter based autoregressive model (Appendix A) is employed in this study to capture the dynamics of healthy vibration signals under varying load conditions, while the K-S GOF test statistic (Appendix B) is used to provide a quantitative indication of the change in the condition of the monitored object. A novel compromised autoregressive (AR) modeling technique with the aid of hypothesis tests will be proposed in this study, which is followed by a simulation analysis using artificially generated full lifetime gear vibration signals and an experimental analysis using real gearbox entire lifetime vibration signals.

The paper is organized as follows. Section 2 presents the theoretical elements of the proposed gear condition detection technique. Section 3 presents a simulation analysis using simulated entire lifetime gear vibration signals. Section 4 presents an experimental analysis using real entire lifetime gear vibration signals. Discussions and conclusions are presented in Section 5.

2 THEORETICAL DEVELOPMENT

2.1 Description of Model

This section proposes a fully automatic condition detection technique for gearbox condition monitoring using a Kalman filter based AR model with the aid of hypothesis tests for the selection of optimum model order to achieve the predominant objective, i.e. consistent normality of the AR model residuals for healthy gear motion residual (GMR) signals under varying load conditions.

In the practical operation of the proposed technique, the GMR signals are divided into two groups: the control group and the treatment group. The control group GMR signals that are collected with the target gear in a healthy condition and under varying load conditions are exclusively used for establishing a compromised AR model fit. It needs to be emphasized that only the healthy condition GMR signals collected under the two extreme load conditions (lower and upper load limits) are needed for establishing a compromised AR model fit. The treatment group GMR signals contain the entire lifetime GMR signals of a gearbox running from new to failure and are used for validation of the established compromised AR modeling technique.

Assume that there are N_1 GMR signals collected under the lower limit load condition and N_2 GMR signals collected under the upper limit load condition available for use. Thus, the control group of GMR signals is of size N_1+N_2. Each GMR signal contains n sample points equally spaced over a complete revolution (0° to 360°) of the target gear. Under a certain AR model order p within the considered order range $[p_s, p_e]$, the adaptive fashion of the Kalman filter yields a set of AR model coefficients a^l_{ijk}, i=1…N_1, j=1…n, k=1…p for the lower limit load condition where the superscript l stands for lower load condition, and another set of AR model coefficients a^u_{ijk}, i=1…N_2, j=1…n, k=1…p for the upper limit load condition where the superscript u stands for upper load condition, where $a^l_{i\bullet\bullet}$ or $a^u_{i\bullet\bullet}$ stands for the AR model coefficient matrix of dimension $p\times n$ over the complete revolution of each GMR signal among N_1 or N_2, and $a^l_{ij\bullet}$ or $a^u_{ij\bullet}$ stands for the AR model coefficient vector of dimension $p\times 1$ at each time instant in each GMR signal among N_1 or N_2.

In the case where phase information is not available, an averaging operation

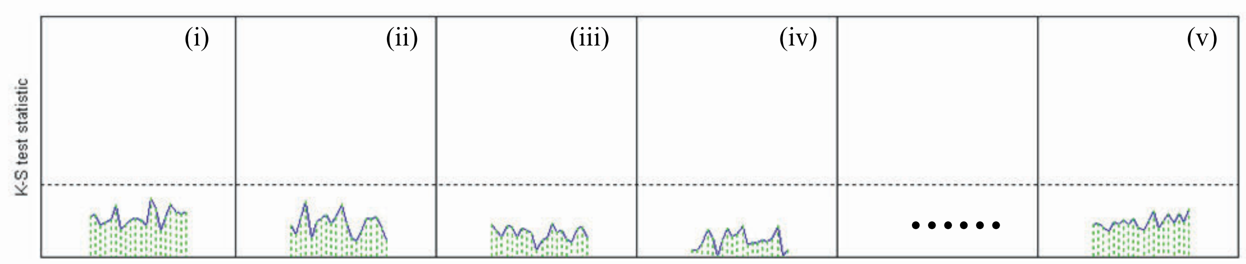
$$\bar{\bar{a}}_{\bullet} = \frac{\sum_{i=1}^{N_1}\sum_{j=1}^{n} a^l_{ij\bullet} + \sum_{i=1}^{N_2}\sum_{j=1}^{n} a^u_{ij\bullet}}{(N_1 + N_2)\times n} \tag{1}$$

is carried out, where $\bar{\bar{a}}_{\bullet} = \bar{\bar{a}}_k$, k=1…p. Note that the proposed $\bar{\bar{a}}_k$ differs from the AR model coefficient vector a_k, k=1…p described by Wang and Wong [11] which is estimated on the assumption of stationarity by the conventional Yule-Walker method. Eq. (1) will be used throughout this study. The obvious reason for using this constant state vector is that the healthy condition GMR signals that were used to construct the compromised AR model may not be in phase with future GMR signals.

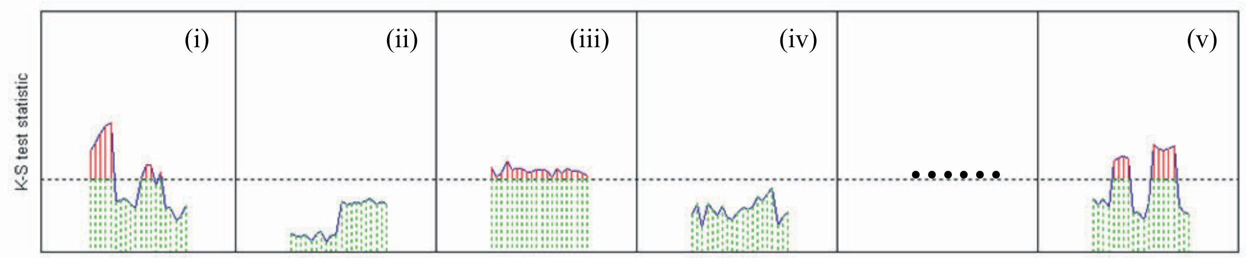
The second signal processing operation is based upon an important previous finding that the AR model order is the decisive control factor which determines whether or not a compromised AR model that is robust with respect to varying load conditions can be established [12]. The K-S test statistic is applied to the AR model residuals of each GMR signal, as a quantitative gear condition indicator. In practical implementations, two types of AR model order within the considered range $[p_s, p_e]$ may be present and are defined as below:

(a1) Type I orders within $[p_s, p_e]$ that enable the compromised AR model fitting procedure to generate normally distributed AR model residuals for all GMR signals in the control group;

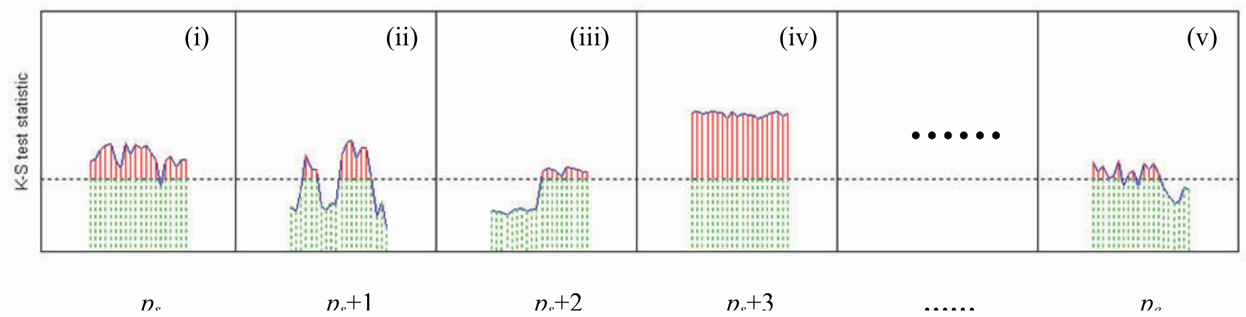
(a2) Type II orders within $[p_s, p_e]$ that enable the compromised AR model fitting procedure to generate normally distributed AR model residuals only for part of the control group GMR signals.



a) The first situation (b1) which all the orders in $[p_s, p_e]$ are Type I



b) The second situation (b2) which the orders in $[p_s, p_e]$ are either Type I or Type II



c) The third situation (b3) which all the orders in $[p_s, p_e]$ are Type II

Figure 1. The three situations that contain the Type I and Type II AR model orders within the considered order range $[p_s, p_e]$. The horizontal dotted line in each subplot denotes the K-S critical value.

Consequently, three possible situations may take place:

(b1) All orders within $[p_s, p_e]$ are Type I, as shown in Figure 1(a);

(b2) Some orders within $[p_s, p_e]$ are Type I, while others are Type II, as shown in Figure 1(b);

(b3) All orders within $[p_s, p_e]$ are Type II, as shown in Figure 1(c).

In terms of our experimental investigation, the first situation (b1) is rare, while the second and the third situations, (b2) and (b3), are often encountered. It is natural to think that priority should be given to the Type I orders when the first or second situation, (b1) or (b2), appears. Under such circumstances, the optimum AR model order should be exclusively chosen from the Type I orders, while the remaining Type II orders will not be considered if the second situation (b2) is encountered. The proposed procedure of selecting the optimum AR model order from Type I orders is summarized below:

(c1) Search for the order p_{lm} which gives the least mean of the K-S test statistics over all control group GMR signals;

(c2) Calculate the variance V_{lm} of the K-S test statistics over all control group GMR signals under the order p_{lm};

(c3) Search for the order p_{lv} which gives the least variance V_{lv} of the K-S test statistics over all control group GMR signals;

(c4) Compare V_{lm} with V_{lv} using the Bartlett's test under the null hypothesis H_0 and the alternative hypothesis H_a:

$$H_0: V_{lm}=V_{lv}$$

$$H_a: V_{lm} \neq V_{lv}$$

at a significance level of 5%;

(c5) If the null hypothesis H_0 is accepted, the optimum AR model order $p_{optimum}$ takes the value of p_{lm}. Otherwise, $p_{optimum}$ takes the value of p_{lv}.

By following this procedure, the order p_{lm} with the least mean of the K-S test statistics is selected if its variance is not statistically different from that of the order p_{lv} with the least variance of the K-S test statistics. Otherwise, the order p_{lv} with the least variance is selected. Therefore, the normality of AR model residuals of the control group GMR signals collected under the two extreme load conditions is always guaranteed by the determined $p_{optimum}$, while in the mean time it possesses the least variance.

On the other hand, when the third situation (b3) occurs, the objective of searching for $p_{optimum}$ is to find an order from Type II orders which gives the least violation against the normality assumption of the AR model residuals of each control group GMR signal in the sense that, over the full control group GMR signals, the K-S test statistics beyond the K-S critical value remain at the least mean level. Therefore, our interest is in the analysis of the K-S test statistics which exceed the critical value under a certain Type II order and thus are termed K-S outliers, whereas other K-S test statistics that are below the critical value, under the present order, are not considered. As such, a different procedure of searching for $p_{optimum}$ from Type II orders for the third situation (b3) is proposed below:

(d1) Search for the order p_{lm} which gives the least mean M_{least} of the K-S outliers;

(d2) Search for all the orders whose means of the K-S outliers are statistically equal to M_{least} using the Satterthwaite's t'-test under the null hypothesis H_0 and the alternative hypothesis H_a:

$$H_0: M_{least} = M_i$$

$$H_a: M_{least} \neq M_i$$

at a significance level of 5%, where M_i is the mean of the K-S outliers of an order p_i in $[p_s, p_e]$;

(d3) Let a set $P=\{p_j, j=1\ldots k\}$ store all the orders found in (d2);

(d4) Calculate the area A_j between the curve of the K-S outliers and the horizontal line of the K-S critical value for each p_j in set P, as shown in the area covered by vertical solid lines in each subplot of Figure 1(c);

(d5) Compare all the A_j's and search for the order p_{la} in the set P which has the least area A_j;

(d6) The optimum AR model order $p_{optimum}$ takes the value of p_{la}.

In the above procedure, the order with the least mean level of K-S outliers and the least area beyond the K-S critical value can be determined, which is optimum in the sense that the violation against the normality assumption of AR model residuals remains at the lowest level. The application of the Satterthwaite's t'-test, in contrast to the conventional t-test, is used in view of a realistic consideration that the homoscedasticity of the K-S outliers under different Type II orders cannot be guaranteed. This is known as the Behrens-Fisher problem, whereas the homoscedasticity is a major assumption for the conventional t-test.

2.2 Some notes

Note that in the second processing, for the situations (b1) and (b2), comparing to other orders within $[p_s, p_e]$ the least variance of the K-S statistics of the selected $p_{optimum}$ is ensured, which implies that the mean M_{N_1} of the K-S statistics of the N_1 control group GMR signals corresponding to the lower limit load condition cannot differ much from the mean M_{N_2} of the N_2 control group GMR signals corresponding to the upper limit load condition. Otherwise, the variance will be increased. Hence, the load-independence can be achieved to the best available extent.

However, the case is somewhat different when the third situation (b3) comes forth since all orders within $[p_s, p_e]$ are Type II. Thus, the primary objective is to search for an order to bring the least violation against the normality assumption of the AR model residuals rather than the equality between the M_{N_1} and M_{N_2}. This is done to avoid the realistic possibility that, for the third situation (b3), the equality between the M_{N_1} and M_{N_2} which takes priority over the normality assumption may result in the selection of an order which strongly violates the most desired normality assumption

Further, when the normality assumption is ensured to the best available extent in the sense that some K-S test statistics of the control group GMR signals only slightly exceed the K-S critical value, the varying load induced difference between the M_{N_1} and M_{N_2} cannot be large in comparison with the fault-induced variations of the K-S test statistic in its future application because the K-S critical value is a small value. Under the same principle, a similar possible case may happen to the second situation (b2), as shown in Figures 1(b-ii) and 1(b-iii), where the order p_s+1 is thus preferred instead of p_s+2.

To ensure the normality of AR model residuals as best as we can during the establishment of the compromised AR model fit using healthy condition GMR signals will reveal the presence of incipient defective gear conditions. This is due to the fact that a gear defect usually gives a slight deviation from normality in the AR model residuals at an early stage of development, although it is sometimes at the expense of deteriorating the equality requirement for the M_{N_1} and M_{N_2}.

2.3 Definition of gear condition indicators

Since our interest in the condition monitoring of gears using the condition detection technique proposed in Section 2.2 is to detect the deviation of AR model residuals from the normality assumption, we modify the conventional K-S test statistic to be

$$MKS = (KS - KS_{cv})I(KS > KS_{cv}) \tag{2}$$

where KS stands for the original K-S test statistic at a significance level of 5%, KS_{cv} stands for the K-S critical value, MKS stands for the modified K-S test statistic, and $I(\bullet)$ is a sign function. By means of the Eq. (3), the deviation from the normality assumption of AR model residuals determined from healthy gear conditions can be detected.

For the kurtosis measure, the normality is achieved only when it is equal to 3, beyond which or below which the distribution is termed leptokurtic or platykurtic, respectively. Thus, the modified kurtosis measure to detect the deviation from normality is

$$MKT = |(KT - 3)| I(KT \neq 3) \tag{3}$$

where KT stands for the original kurtosis value, MKT stands for the modified kurtosis value, and $|\bullet|$ stands for the absolute operation.

3 SIMULATION ANALYSIS

3.1 Signal model

This study proposes more realistic baseline functions of simulated gear vibration signals under healthy and defective conditions, which are given by

$$x(t) = \sum_{m=0}^{M} (1 + c_i^k) X_m^k [1 + a_m(t)] \cos\{2\pi m T f_s t + \phi_m + b_m(t)\} \tag{4}$$

and

$$x(t) = \sum_{m=0}^{M} (1 + c_i^k) X_m^k [1 + \tilde{a}_m(t)] \cos\{2\pi m T f_s t + \phi_m + \tilde{b}_m(t)\} + h_3 z(t) \tag{5}$$

where c_i^k , i=1,…,L is a random coefficient series corresponding to a total of L vibration signals collected at the k-th load condition, $(1 + c_i^k) X_m^k$ is the modified amplitude of the m-th meshing frequency at the k-th load condition. When a localized gear fault occurs, localized impacts may modify the healthy condition modulation functions $a_m(t)$ and $b_m(t)$ expressed by

$$a_m(t) = \sum_{n=1}^{N} A_{mn} \cos(2\pi n f_s t + \alpha_{mn}) \tag{6}$$

and

$$b_m(t) = \sum_{n=1}^{N} B_{mn} \cos(2\pi n f_s t + \beta_{mn}) \tag{7}$$

to be $\tilde{a}_m(t)$ and $\tilde{b}_m(t)$ expressed by

$$\tilde{a}_m(t) = a_m(t) + h_1 d(t) \tag{8}$$

and

$$\tilde{b}_m(t) = b_m(t) + h_2 d(t) \tag{9}$$

where h_1 and h_2 are coefficients which determine the magnitude of the localized impact induced additional amplitude modulation and phase modulation. At the same time, localized impacts may also excite structural resonances. Using the same notation as that used by Wang and Wong [11], we denote the impact-induced resonant vibration in one revolution of the monitored gear by $z(t)$ which is expressed by:

$$z(t) = d(t)\cos(2\pi f_r t + \eta_r) \tag{10}$$

where $d(t)$ is the envelope (modulating) function of the resonant vibration, f_r the resonance frequency (carrier frequency), and η_r the corresponding initial phase. The envelope function $d(t)$ takes the normalized form of a modified log-normal distribution function, which is given by [4]

$$d(t) = d_0(t) / \max |d_0(t)| \tag{11}$$

where $d_0(t)$ is given by

$$d_0(t) = \frac{1}{t\sigma_{impact}\sqrt{2\pi}} e^{-\frac{(\ln t - \mu_{impact})^2}{\sigma_{impact}^2}} \tag{12}$$

where σ_{impact} and μ_{impact} stand for modified log-normal distribution variance and mean which determine the shape of the envelop function of the resonant vibration.

Table 1 shows the basic information of this simulated test. As shown in Table 1, the gear of interest has 27 teeth, a maximum number of considered gear meshing frequencies of 6, a shaft speed of 40 Hz, and a sampling frequency of 40 kHz. Each TSA signal has a length of 1000 sample points and thus each extracted GMR signal.

Table 1

General description of the simulated test

T	27
M	6
f_s (Hz)	40
S	6 (one healthy and five defective)
K	7
L	5
μ_{impact}	-8.5172
σ_{impact}	1
f_r (shaft order)	121
η_r	$-\pi/2$
N	3

Sampling frequency (kHz)	40
Length of each TSA/GMR signal	1000 data points

3.2 Condition detection

This section also proposes some alternative condition indicators and carries out a comprehensive comparison. For convenience, abbreviations MKS_1, MKT_1, MKS_2, and MKT_2 are used, where MKS_1 is the proposed technique in this study, MKT_1 is a kurtosis based alternative indicator to MKS_1, MKS_2 is the modified K-S statistic applied to gear motion residual signal, and MKT_2 is the conventional gear motion residual signal kurtosis based method.

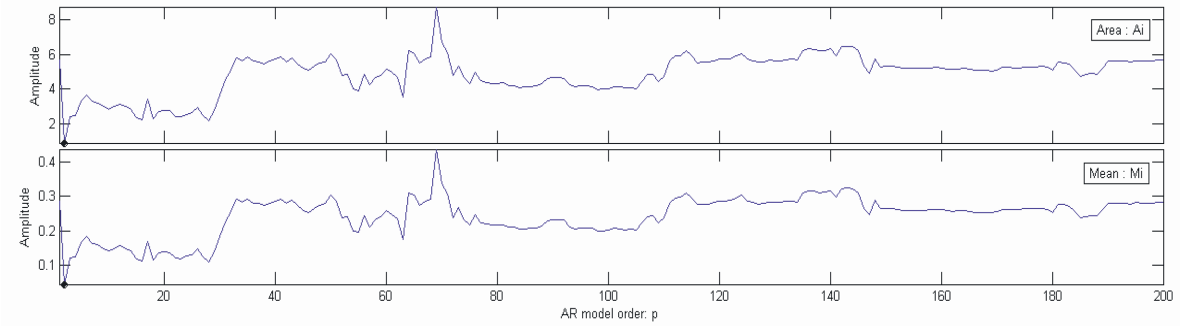
Figure 2 shows the AR model order selection for MKS_1 and MKT_1 using the control group GMR signals, which has 40 GMR signals in total. The optimum orders are selected from Type II orders for both MKS_1 and MKT_1. The selected optimum orders are 2 for MKS_1 and 182 for MKT_1. Note that in each of Figures 2(a) and 2(b), the area curve A_i and the mean curve M_i have identical trace. This is because, at each order, the number of K-S outliers is constant over the AR model order horizon.

As shown in Figure 2(b), the Satterthwaite's t'-test at a significance level of 5% found a few orders for MKT_1 which have statistically equal means of K-S outliers to that of the $p_{optimum}$.

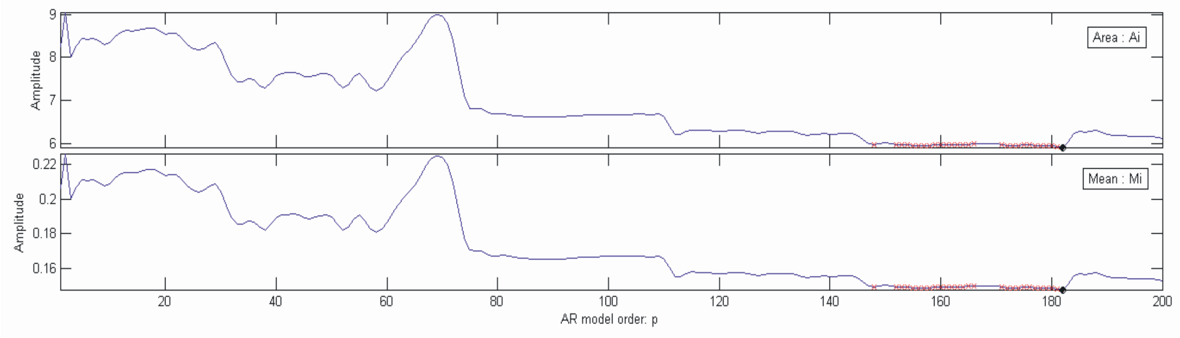
Figures 3(a) and 3(b) show the state detection using the optimum AR model orders of MKS_1 and MKT_1 found in Figure 2. The four gear condition indicators all give the first alarm at the GMR signal #36 when the first defective condition GMR signal is encountered.

Within the healthy condition of the gear, i.e. GMR signal interval [1:35], the proposed MKS_1 presents the least violation against the normality assumption as denoted by the downward arrow mark in Figure 3(a), while the MKS_2 ranks second as denoted by the downward arrow mark in Figure 3(c).

In addition, by comparing the trace of MKS_1, as shown in Figure 3(a), with that of MKT_1, as shown in Figure 3(b), it is found that the kurtosis-based gear condition indicator MKS_1 demonstrate strong varying-load induced fluctuations in contrast with the K-S test statistic-based condition indicator MKT_1. For instance, within the GMR signal interval [71:105], the variability of MKS_1 caused by varying load conditions as denoted by the upward arrow mark in Figure 3(a) is much less than that of MKT_1 as denoted by the upward arrow mark in Figure 3(b). The same comparison and conclusion can be applied to and

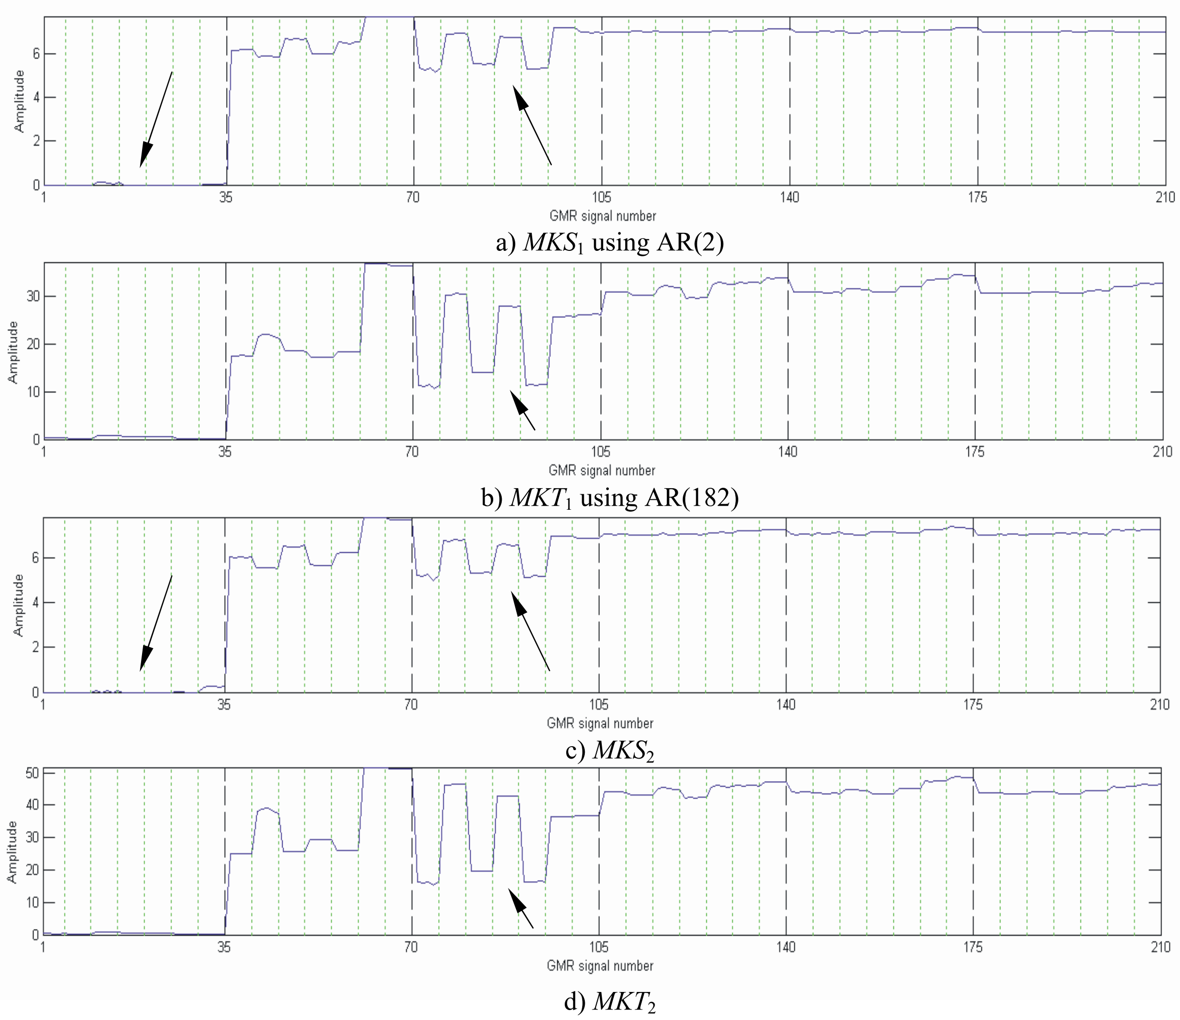


a) $p_{optimum}$=2 for MKS_1, selected from Type II orders



b) $p_{optimum}$=182 for MKT_1, selected from Type II orders, where the orders marked by cross markers are the orders with means of K-S outliers which are statistically equal to that of the $p_{optimum}$ via the Satterthwaite's t'-test at a significance level of 5%

Figure 2. AR model order selection, where the order marked by a dot in each subplot is the selected order $p_{optimum}$.



a) MKS_1 using AR(2)

b) MKT_1 using AR(182)

c) MKS_2

d) MKT_2

Figure 3. Gear condition detection using simulated clean lifetime GMR signals. The dotted lines denote the boundary of each load condition. The dashed lines denote the boundary of each gear condition.

drawn from MKS_2 and MKT_2 as denoted by the upward arrow marks in Figures 3(c) and 3(d).

In general the proposed MKS_1 outperforms other gear condition indicators due to its most significant first alarm for incipient fault, least violation against the normality assumption of AR model residuals within the healthy period of the investigated gear, and the least varying-load induced fluctuations.

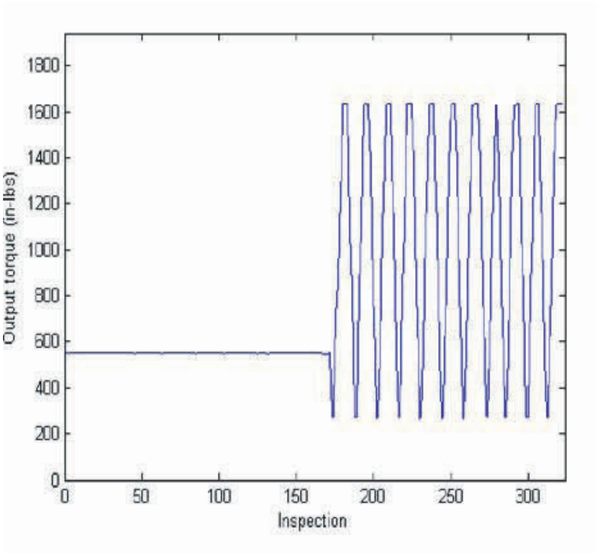
3.3 Optimality checks

To validate the optimality of the $p_{optimum}$ selected by the proposed compromised AR model fitting technique, gear condition detection using MKS_1 and MKT_1 under alternative orders with similar means, M_i's, are carried out. (Note: Not necessarily statistically equal means because, for instance, for MKS_1 as shown in Figure 2(a), the selected order p=2 does not have statistically equal means from other orders).

Table 2 shows a numerical analysis of the mean of K-S outliers expressed by

$$\sum_{i=1}^{35} MKS_{i} I(MKS_{i} > 0) \Big/ \sum_{i=1}^{35} I(MKS_{i} > 0) \tag{13}$$

for the performance of MKS_1 within the healthy GMR signal interval [1:35] under alternative orders 1, 3, 16, 18, 23, and 28, respectively. The minimum is achieved at the selected order p=2, which indicates that the normality assumption of AR model residuals within the healthy gear condition is best achieved by the selected $p_{optimum}$. Therefore, it confirms the optimality of the $p_{optimum}$=2 for the proposed MKS_1.



a) The output torque level switches from a constant 555 in-lbs at the 172nd inspection to a sinusoidal load condition at the 173rd inspection

b) Post drive gear with seven broken teeth

Figure 4. Load condition and the post drive gear of TR#14

A similar numerical analysis was carried out for MKT_1 under alternative Type II orders, which, for simplicity, was not presented here. The result indicates that the selected optimum order p=182 results in the minimum mean of K-S outliers within the healthy period of the gear of interest. Therefore, it confirms again the capability of the proposed compromised AR model fitting technique in the selection of a robust model order under varying load conditions.

Table 2

Comparison between the $p_{optimum}$ and alternative orders in gear condition detection using MKS_1

Order p	Mean of K-S outliers within the healthy gear condition [1:35]
2 ($p_{optimum}$)	6.549E-02
1	1.650E-01
3	7.430E-02
16	9.092E-02
18	8.684E-02
23	8.752E-02
28	7.492E-02

4 EXPERIMENTAL ANALYSIS

4.1 General description of TR#14

Full lifetime data of test-run #14, provided by the Applied Research Laboratory (ARL) at the Pennsylvania State University, will be used in this study. Researchers used various combinations of motors, equipment, and sensors on its

Mechanical Diagnostic Test Bed (MDTB) and ran the MDTB to failure, collecting the resulting data and carefully documenting their observations [13, 14].

There were a total of 323 data files collected during the lifetime of TR#14. The gearbox in TR#14 had a 70:21 tooth ratio and was driven at the 100% nominal output torque level of 555 in-lbs for 95 hours in which 172 data files were collected. Subsequently, during the sinusoidal load condition, which varied between 50% nominal output torque level (277 in-lbs) and 300% nominal output torque level (1665 in-lbs) which lasted 19.3 hours, 151 data files were collected. This run was periodically stopped to allow oil samples and gear photos to be taken. When bringing the run to a stop for these purposes, data was sampled when the load dropped to 250%, 200%, 150%, 100% and 50%.

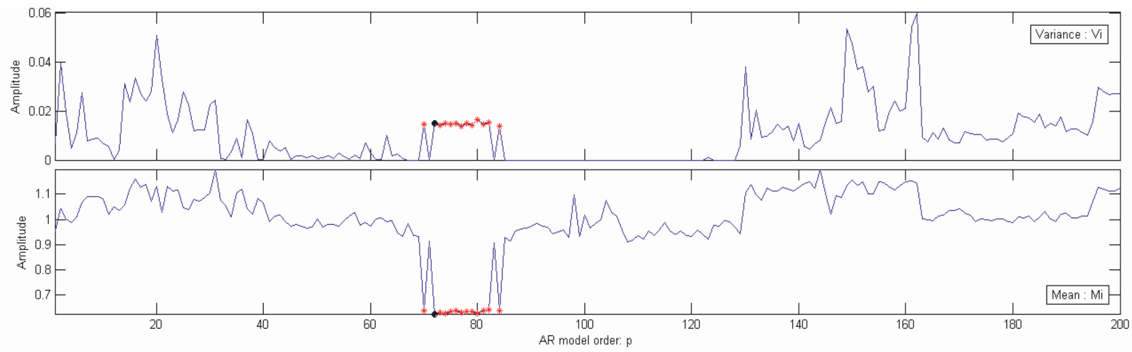
Figure 4(a) shows the load condition of TR#14. The input speed slightly varies between 1750 and 1752 rpm throughout the entire test-run. The gear was driven until there were seven broken teeth on the drive gear, as shown in Figure 4(b). A TSA signal of 2284 data point length at each inspection was obtained after an averaging operation over 87 ensembles. The GMR signals generated in this test-run were obtained by removing 12 sidebands on either side of every meshing frequency from the FFT spectrum of each TSA signal.

4.2 Condition detection

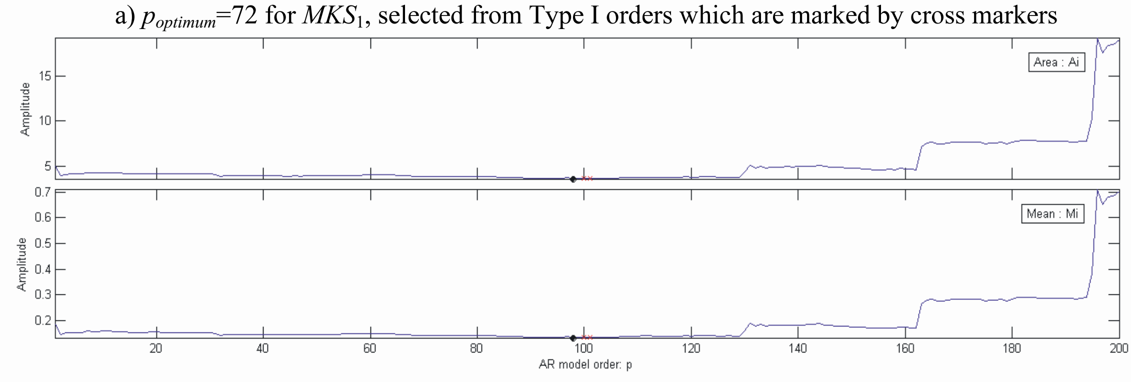
It is noteworthy that two previous studies conducted analysis of the same MDTB data sets and proposed two condition indicators termed the fault growth parameter (FGP) [15] and the modified fault growth parameter (FGP1) [16] for detection of gearbox deterioration, respectively. The comparative analysis will incorporate these two condition indicators.

Twelve GMR signals, i.e. [173, 174, 188, 189, 202, 203, 216, 217, 230, 231, 244, 245], under the 50% nominal output torque level and fifteen GMR signals, i.e. [180, 181, 182, 183, 194, 195, 197, 208, 209, 210, 211, 222, 223, 224, 225], under the 300% nominal output torque level are selected to form the control group GMR signals to establish the compromised AR model fitting on the healthy GMR signals under varying load conditions. Figure 5 shows the AR model order selection for MKS_1 and MKT_1. The selected optimum orders are 72 for MKS_1 and 98 for MKT_1.

Figure 6 shows the gear condition detection using MKS_1 and MKT_1 under the optimum AR model orders found in Figure 5 for as well as FGP and FGP1. Table 3 summarizes the performance evaluation of these four condition indicators for TR#14. It is found from Figures 6(c) and 6(d) that FGP and FGP1 are dependent on the sinusoidal load condition beyond the GMR signal #173. Further inspection indicates that the variations of FGP and FGP1 are opposite to that of load level at a few inspections. For example, the local peaks of FGP and FGP1 appearing at the 173rd, 202nd, and 216th inspections as indicated by circle marks



a) $p_{optimum}$=72 for MKS_1, selected from Type I orders which are marked by cross markers



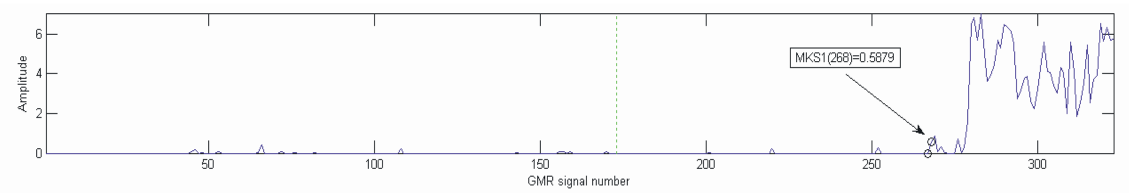
b) $p_{optimum}$=98 for MKT_1, selected from Type II orders, where the orders marked by cross markers are the orders with means of K-S outliers which are statistically equal to that of the $p_{optimum}$ via the Satterthwaite's t'-test at the significance level of 5%

Figure 5. AR model order selection, where the order marked by a dot in each subplot is the selected order $p_{optimum}$

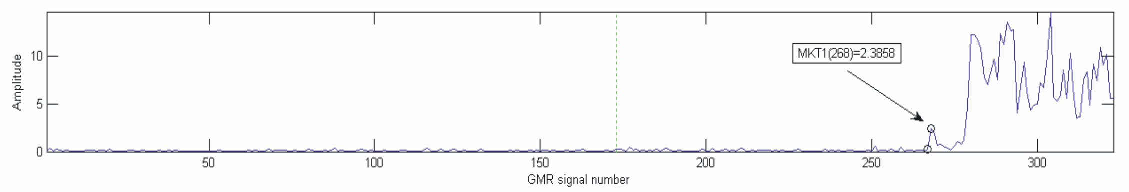
in Figures 6(c) and 6(d) respectively correspond to inspections carried out at 50% nominal output torque level. Such an inverse relationship may be attributed to the fact that, when the gearbox is in a healthy condition, major fluctuations are usually present in lightly loaded conditions, while heavily loaded conditions usually do not exhibit large instantaneous variations. In contrast, the proposed MKS_1 and MKT_1 do not present load-dependent behavior under the sinusoidal load condition as shown in Figures 6(a) and 6(b) respectively, where the normality assumption of AR model residuals is generally guaranteed at most inspections during the healthy period of this test-run.

Based on visual inspection of the traces of the four condition indicators, the occurrence of incipient gear fault may appear at the 268th inspection. For the purpose of reference, the amplitude of each condition indicator at the 267th inspection is also denoted by a circle mark in each subplot of Figure 6. It should be noted that the proposed MKS_1 is against the normality assumption at very few inspections during the healthy period of the investigated gear, i.e. the GMR signal interval [1:267] as shown in Figure 6(a). Due to distinct theoretical basis, the kurtosis based MKT_1 does not possess such a property, where the normality in the healthy condition of the gear cannot be guaranteed at all inspections as shown in Figure 6(b). Although the MKT_1 presents a stable trace within the GMR signal interval [1:267], our extensive tests that are not presented here have shown that MKT_1 is prone to more considerable variability than MKS_1. Such a disadvantage can be evidenced by examining the difference between MKS_1 and MKT_1 in Figures 3(a) and 3(b) or, alternatively, MKS_2 and MKT_2 in Figures 3(c) and 3(d).

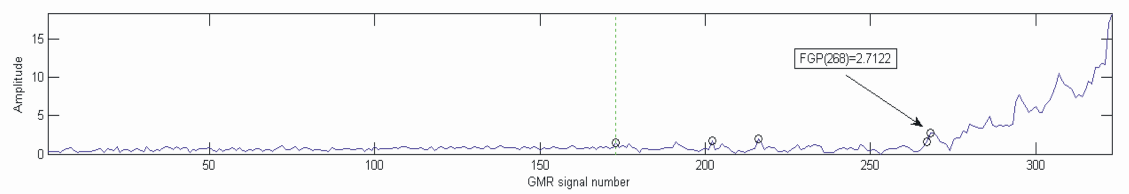
On the other hand, since FGP and FGP1 do not have a critical value to define the healthy condition of a gear, they are in need of a longer period to gain an understanding of around which numerical value FGP or FGP1 corresponds to the healthy condition of the investigated gear, where thus a prompt condition analysis cannot be carried out. It should be emphasized that the strong load-dependence of FGP and FGP1 to a great degree exacerbates such a disadvantage since, at every specific load condition, an individual examination is compulsory to find the numerical value of FGP and FGP1 which corresponds to the healthy condition of the investigated gear. Otherwise, the load induced jump of FGP or FGP1 may extremely possibly result in frequent false alerts and in turn incur maintenance cost in vain.



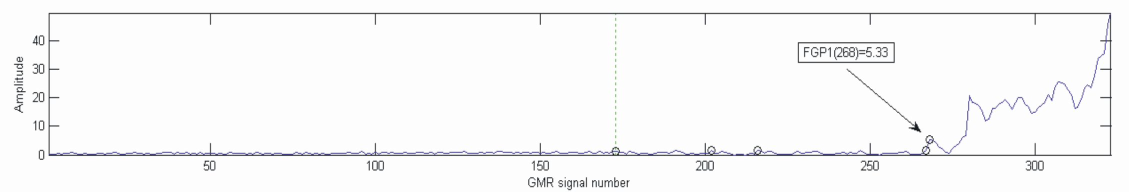
a) MKS_1 using AR(72) where the first alert is generated at the 268th inspection



b) MKT_1 using AR(98) where the first alert is generated at the 268th inspection



c) *FGP* where the first alert is generated at the 268th inspection



d) *FGP*1 where the first alert is generated at the 268th inspection

Figure 6. Gear condition detection of TR#14. Each GMR signal on the abscissa represents an inspection. The dotted line in each subplot denotes the GMR signal #173, i.e. the first inspection carried out under the sinusoidal load condition. The annotated inspections in each subplot correspond to the first alert for incipient fault and the false alerts.

Experimental analysis using alternative MDTB test-runs was also carried out. The proposed MKS_1 constantly demonstrates remarkable performance in comparison to a variety of condition indicators proposed in some recent studies. Therefore, the proposed MKS_1 significantly outperforms its counterparts proposed in relevant studies.

Table 3

Performance assessment of condition indicators for TR#14

Condition indicator	Load-independence	First alert for incipient fault
MKS_1	Yes	268
MKT_1	Yes	268
FGP	No	268
$FGP1$	No	268

5 CONCLUSIONS

In this study, gear vibration signals are divided into two categories: the control group GMR signals and the treatment group GMR signals. The control group consists of healthy condition GMR signals for modeling purposes, while the treatment group consists of regular lifetime GMR signals for validation and detection. This study proposed a novel compromised AR model fitting technique with the aid of hypothesis tests, which establishes a compromised AR model on the control group GMR signals. By compromised, we mean that the AR model of each healthy condition GMR signal in the control group has identical model order and model coefficients.

The model order is classified into two categories, i.e. Type I and Type II, and selected by means of two hypothesis tests, i.e. Bartlett's test and Satterthwaite's t'-test, respectively. The role of the Bartlett's test is to check, within all Type I orders, if the variance of K-S test statistics under the order with the least mean of K-S test statistics is statistically equal to the variance of K-S test statistics under the order whose variance of K-S test statistics is the least. The role of the Satterthwaite's t'-test is to check, within all Type II orders, if the order with the least mean of K-S outliers has alternative orders with statistically equal means of K-S outliers.

The calculation of model coefficients depends on the phase information being available or not. In consideration of the healthy condition GMR signals that were used to construct the compromised AR model not being in phase with the future-state GMR signals, an averaged coefficient vector is used.

Simulation and experimental analyses confirm the remarkable effectiveness of the proposed compromised AR model fitting technique in selecting the optimal order for gear condition detection under varying load conditions. In particular, the proposed K-S statistic based condition indicator MKS_1 demonstrates an appealing robustness to varying load conditions.

Furthermore, it is noteworthy that the gear condition detection technique proposed in this study is completely automatic in both modeling and detection. In particular, the proposed AR model order selection technique can be carried out automatically and is in need of no expert human supervision. In comparison with a previous study by Zhan et al. [12], the AR model order selection is greatly improved.

7.1 APPENDIX A: Time-Varying AR Model Based on a Noise-Adaptive Kalman Filter

An AR process is a discrete-time multivariate linear stochastic process given by

$$y_i = \sum_{k=1}^{p} A_k y_{i-k} + \varepsilon_i \tag{A.1}$$

for i = 1, 2, …, N, where N is the sample size, p the order of VAR model, y_i the ith measurement vector of dimension $d\times1$, A_k the kth $d\times d$ coefficient matrix of the measurement y_{i-k}, and ε_i an $d\times1$ sequence of zero-mean white Gaussian measurement noise. Considering the non-stationary cases, the coefficient matrices of the AR model are assumed time-varying

$$y_i = \sum_{k=1}^{p} A_k(i) y_{i-k} + \varepsilon_i \qquad \text{(A.2)}$$

The time-varying model coefficients are in need of an adaptive estimation algorithm. The Kalman filter is employed here. With the following notation:

$$a_i = vec([A_1(i), A_2(i) \ldots, A_p(i)]^T) \qquad \text{(A.3)}$$

$$Y_i = (y_i^T, y_{i-1}^T, \ldots, y_{i-p+1}^T) \qquad \text{(A.4)}$$

$$C_i = I_d \otimes Y_i^T \qquad \text{(A.5)}$$

where I_d is an $d \times d$ identity matrix, $\otimes$ is the Kronecker product, an appropriate state space representation of the VAR model with stochastic coefficients can be given by

$$a_{i+1} = f_i(a_i) + \nu_i \qquad \text{(A.6)}$$

$$y_i = C_{i-1}^T a_i + \varepsilon_i \qquad \text{(A.7)}$$

where a_i is the $pd^2 \times 1$ state vector, ν_i an $pd^2 \times 1$ sequence of zero-mean white Gaussian state noise, C_{i-1}^T of dimension $d \times pd^2$, and the noise covariance matrices:

$$E\{\nu_k \nu_i^T\} = Q_k \delta_{k-i} \qquad \text{(A.8)}$$

$$E\{\varepsilon_k \varepsilon_i^T\} = R_k \delta_{k-i} \qquad \text{(A.9)}$$

where T denotes transposition, δ denotes the Kronecker delta sequence, Q_k denotes the covariance matrix of ν_i and R_k denotes the covariance matrix of ε_i. Suppose that the evolution law of the state vector a_i is a random walk process which results in a state space representation

$$a_{i+1} = a_i + \nu_i \qquad \text{(A.10)}$$

$$y_i = C_{i-1}^T a_i + \varepsilon_i \qquad \text{(A.11)}$$

Thus, with the aid of a standard Kalman filter the following recursive prediction equations

$$P_{i|i-1} = P_{i-1|i-1} + Q_{i-1} \qquad \text{(A.12)}$$

$$\hat{a}_{i|i-1} = \hat{a}_{i-1} \qquad \text{(A.13)}$$

where $P_{i|i-1}$ is the one-step ahead prediction of the state covariance matrix, $P_{i-1|i-1}$ is the estimate (error) covariance matrix of the state vector, $\hat{a}_{i|i-1}$ is the one-step ahead predication of the state vector, $\hat{a}_{i-1}$ is the optimal filtering estimate of the state vector a_{i-1} and updating equations

$$G_i = P_{i|i-1} C_{i-1} [C_{i-1}^T P_{i|i-1} C_{i-1} + \hat{R}_i]^{-1} \tag{A.14}$$

$$P_{i|i} = [I - G_i C_{i-1}^T] P_{i|i-1} \tag{A.15}$$

$$\begin{aligned} \hat{a}_{i|i} &:= \hat{a}_i \\ &= \hat{a}_{i|i-1} + G_i (y_i - C_{i-1}^T \hat{a}_{i|i-1}) \end{aligned} \tag{A.16}$$

can be obtained for $i = 1, 2, \ldots, N$, where G_i is the Kalman gain and the covariance matrix Q_i of ν_i is assumed to be known *a priori*. The innovations sequence is defined as

$$z_i := y_i - C_{i-1}^T \hat{a}_{i|i-1}, \tag{A.17}$$

which leads to the estimate of R_i, using the i most recent residuals, given by

$$\hat{R}_i = \frac{1}{i-1} \sum_{k=1}^{i} (z_k - \bar{z})(z_k - \bar{z})^T, \tag{A.18}$$

where

$$\bar{z} = \frac{1}{i} \sum_{k=1}^{i} z_k . \tag{A.19}$$

is the mean of the innovations up to the ith time instant. Therefore, an adaptive Kalman filter for estimating the state as well as the noise covariance matrices is termed the noise-adaptive Kalman filter (NAKF).

7.2 APPENDIX B: Kolmogorov-Smirnov Goodness-of-Fit Test

The Kolmogorov-Smirnov (K-S) goodness-of-fit test compares an empirical distribution function with the distribution function of the hypothesized distribution [17]. To define the K-S statistic, we must first define an empirical distribution function. For the K-S test, we define an empirical distribution function $F_n(x)$ from our data $X_1, X_2, \ldots, X_n$ as

$$F_n(x) = (\text{number of } X_i\text{'s} \le x) / n \tag{B.1}$$

for all real numbers x. Thus, $F_n(x)$ is a (right-continuous) step function such that $F_n(x_{(i)}) = i/n$ for $i=1,2,\ldots,n$. If $\hat{F}(x)$ is the fitted distribution function, a natural assessment of goodness of fit is some kind of measure of the closeness between the functions F_n and $\hat{F}$. The K-S test statistic D_n is simply the largest (vertical) distance between $F_n(x)$ and $\hat{F}(x)$ for all values of x and is defined formally by

$$D_n = \sup_x \{|F_n(x) - \hat{F}(x)|\} \tag{B.2}$$

[The 'sup' of a set of numbers A is the smallest value that is greater than or equal to all members of A. The 'sup' is used here instead of the more familiar 'max' since, in some cases, the maximum may not exist. For example, if $A = (0,1)$, there is no maximum but the 'sup' is 1.] D_n can be computed by calculating

$$D_n^+ = \max_{1 \le i \le n} \left\{ \frac{i}{n} - \hat{F}(x_{(i)}) \right\}, \quad D_n^- = \max_{1 \le i \le n} \left\{ \hat{F}(x_{(i)}) - \frac{i-1}{n} \right\} \tag{B.3}$$

and finally letting

$$D_n = \max \left\{ D_n^+, D_n^- \right\} \tag{B.4}$$

Suppose that the hypothesized distribution is N(μ, σ^2) with both μ and σ^2 unknown. We can estimate μ and σ^2 by $\overline{X}(n)$ and $S^2(n)$, respectively, and define the distribution function to be that of the N($\overline{X}(n)$, $S^2(n)$) distribution; i.e., let $\hat{F}(x) = \Phi\left\{ [x - \overline{X}(n)] / \sqrt{S^2(n)} \right\}$, where Φ is the distribution function of the standard normal distribution. Using this $\hat{F}$ (which has estimated parameters), D_n is computed in the same way, but different critical points must be used. An accurate approximation, which obviates the need for large tables, is provided by Law and Kelton [17]; namely, we reject H_o if

$$\left(\sqrt{n} - 0.01 + \frac{0.85}{\sqrt{n}} \right) D_n > c'_{1-\alpha} \tag{B.5}$$

where α is always 0.05 in this study and thus $c'_{1-\alpha}$ takes the value of 0.8950 as shown in the Table 6.14 on page 390 by Law and Kelton [17].

DEVELOPMENT OF AN OPTIMUM VOLTAGE STEP CONTROL STRATEGY FOR A ROBOTIC MANUFACTURING PROCESS

CK Mechefske and C Zheng

Department of Mechanical and Materials Engineering, Queen's University, Kingston, Ontario, Canada K7L 3N6

Abstract: This paper addresses the development of optimum current step settings used at a local manufacturing plant. The step function and the effects on other operation process parameters are obtained through reverse and correlation analysis of Target Parameter C (for confidential concerns, all related information are replaced by close item as required), Parameter B and real one. The Secondary Current for any operation sequence is then obtained based on this control methodology. The correlation between operation order and tip wear value are also determined by modeling the real data. A simulation model for optimum step control for a robotic manufacturing system has been developed. Based on some assumptions, simulations are carried out to control two important indicators within their proper limits. One is the Parameter E consisting of real secondary current and Parameter D, which should be constant or vary only slightly through the whole process. The other is current density. Each step can be adjusted and optimized and the indicator trend curves showing operation sequences per step and expected total operation sequences will be displayed. Results show that the step setting can be optimized to control the operation or step current to get good quality. At the beginning of each cycle, Real Secondary Current can be set very close to the Target one(which is much lower than the existing setting level) , so power is minimized and the tip useful life is extend.

1 INTRODUCTION

Robotic manufacturing process is becoming increasingly important for the modern industry due to its high efficiency, reliability and productivity. It is well known that it is the generated heat (shown in equation 1) that produces the kind of process.

$$\text{Heat} = I^2Rt \tag{1}$$

Where, I is the real secondary current, R is the total resistance and t s the operation cycle.

As the number of operation increase, electrode tip wear and the contact area between the tip and the workpiece becomes larger resulting in lower current density. As the current density gradually decreases there is increased risk of failure. Therefore, a current controller (stepper booster) is required to guarantee that enough heat will be generated during the whole process. This kind of stepper booster (most linearly stepper) is used to regulate the amount of current which is added to the base heat that starts out with new tips. It has the following functions: 1) It automatically steps current to compensate for electrode wear and contamination ensuring better, more consistent operation. 2) It counts the number of operation made.3) increases the same current in each discrete steps. 4) It enables the operation gun to maintain a constant current density or within acceptable control limit[1].

This stepper booster is expected to be fine-tuned to match the actual wear and contact area change that process causes on the tips at all stages. In reality, it is not easy to achieve such an objective because the process mechanism is so complex. The timing of step changes and the amplitude of the current to be used in each step is not well understood.

There is a tradeoff between too much current, resulting in expulsion and too little current, resulting in under-size nugget. Any change in the schedule, such as operation sequence force or heat time, will affect the wear and generated heat on the tips as well. Therefore, many companies and researchers have involved in the research of stepper control. For example: WTC, Atek Corperation, Diamlerchrysler, Toshiba and etc. [2-4] have developed many useful heat control tools for industries and they can be set to use in different applications. Jou Min[5] studied the real time monitoring of this process for the fabrication of sheet metal assemblies, and explored the phenomenon of how signal indicative (electrode displacement) of strength and quality changes due to the input (percentage heat input) for various sheet steels used in industry. I. Komine et.al.[6] studied the heat control of this process in steel pipe production. All these have very successful applications in reality. However, the stepper booster does not track the change in surface area. Even though the current is regulated, the current density is overlooked. Unfortunately, inadequate current density usually produces non intact process. Therefore, it is also crucial to have a proper current density in the area where the process is to be made. This will require an active adjustment of the stepper boost which has become a real and practical problem for some manufacturing plants.

In this paper, the current step control strategy in a robotic manufacturing process will be studied. Our industry partner had invested more than $2M to realize online quality and process control which has built up solid foundation for step optimization. Based on field data models, we use simulation to obtain the optimum operation sequence strategy for each step (the appropriate amount of current increment and when to transfer to the next step). The final aim is not only to get good product every time, but also to extend the tip life as long as possible and minimize the energy usage.

2 FIELD DATA ANALYSIS AND MODELING

The experimental work has been conducted on the robotic manufacturing factory which has significant experience on step optimization in its real production line. Both the 5 step and 3 step methodologies have been used and each of them has its successful application. But there is still room for optimization because the current steps used now mostly come from experience and may not necessarily be the best.

A monitoring system has been employed to realize online quality and process control. Necessary information is automatically collected and input into the PLC, and then transferred and stored in a database. Data of 21 tip shifts from a servo gun of robot LHsub1 between June 1 and June 24 in 2003 have been obtained. Data sample of tip 18 is shown in Table 1. The operation robot performs a tip check and tip wear compensation with no current passing through after operating several sequences, which is good for tip wear compensation and heat dissipation.

Table 1: Data sample for tip 18

Log #	Part #	Operation Sequence #	Tip Wear	Parameter A	Parameter B	Target Parameter C	Parameter D	Parameter E	Stepper	Note
4761	210	1	65519	568	124	12500	67	195	1	
4762	210	2	65519	572	123	12500	69	190	1	
4763	210	3	65519	572	123	12500	67	194	1	
4764	210	4	65519	570	123	12500	69	189	1	
4765	210	24	65519	0	0	0	0	0	1	Tip Check
4766	211	1	65515	575	124	12500	67	194	1	
4767	211	2	65515	574	123	12500	69	188	1	

2.1 Step Setting

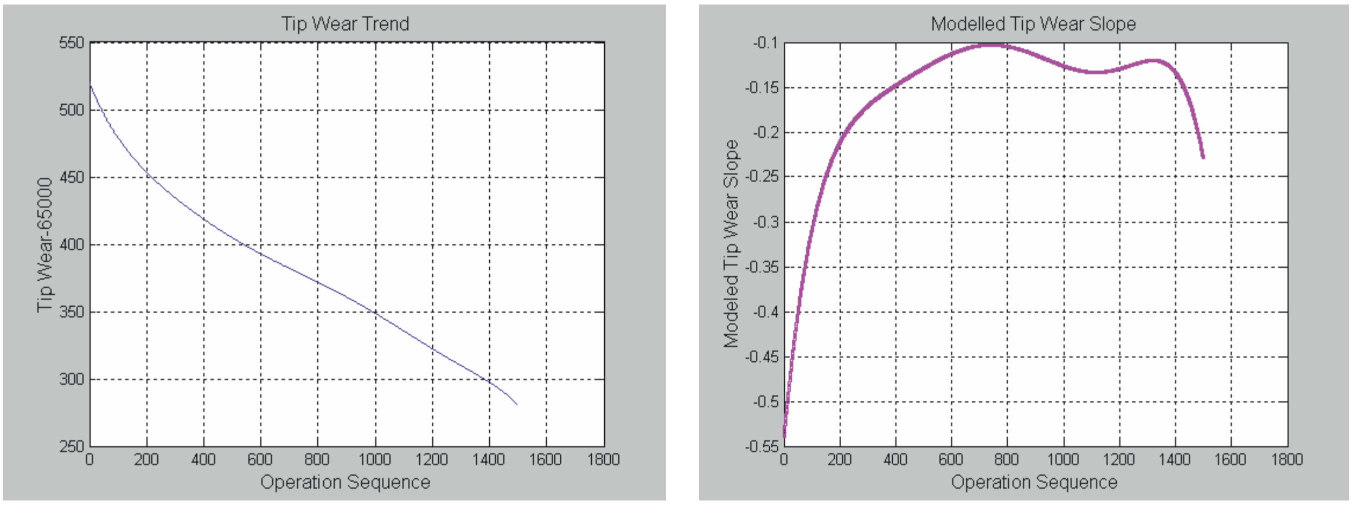
In this experiment, a 3 step methodology is employed. The step setting for some tip shifts is shown in Table 2. This table indicates that step 1 ends around 100 operation sequences, step 2 ends at 400 operation sequences and step 3 is used for the remainder.

Table2: Step Number Distribution

Tip No.	Total Operation number	Step=1	Step=2	Step= 3
4	1448	100	400	948
5	1428	96	400	932
6	1464	100	400	964
11	1444	100	400	944
12	1448	100	400	948

2.2 Tip Wear Data Analysis and Modeling

The repeated use of a set of tips, heat and force tend to increase the effective radius of the tips (mushrooming), and flatten the contact area. The average model and its slope trend are shown in Figure 1[7]. From tip wear results, it is clear that the tip wear decreases sharply before 200 operation sequences. Therefore, if an earlier step setting is adopted, tip life may be extended.



a) Tip wear general model **b) Slope of tip wear model**

Figure 1: Tip wear model and its slope trend

2.3 Parameter D and A Data Analysis and Modeling

Parameter D is the actual % heat fired. It follows a similar increasing trend shown in Figure 2, but drops again at the end of each tip life. The heat must be taken back out (be reset to the 1st stepper level) because new tips will be installed, otherwise it will result in expulsion and tip sticking after a tip change. This Parameter A average of all tips varies slightly, as shown in Figure 3.

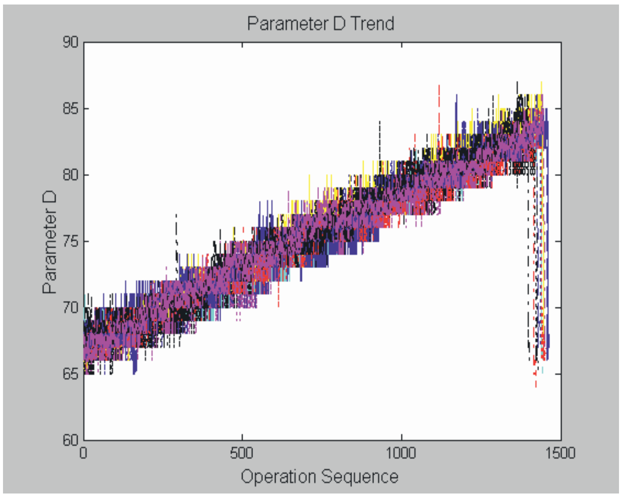


Figure 2: Parameter D trend

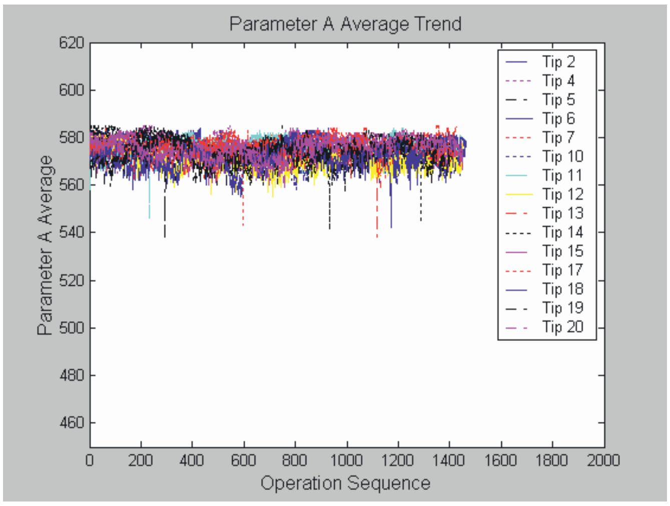

Figure 3 Parameter A Average trend

2.4 Parameter E Data Analysis and Modeling

Measured parameter E.

The Parameter E represents one percent of current increases or equals the secondary current divided by Parameter D. Parameter E should be constant or vary only very slightly through the whole process. The step control can compute the output current and the percentage that it fired after each cycle pulse.

$$E = \frac{I_{\sec}}{D} \tag{2}$$

Where I_{sec} is the real secondary current.

Normalized parameter E.

The above Parameter E equation assumes that the operation bus is constant. However, current flow is not only affected by the resistance of the tools but also by the Parameter A of the bus. As the number of operation increases, Parameter A typically increases while current decreases. Resistance at the workpiece is not constant. So the Normalized Parameter E, based on Parameter A average, is introduced in order to strictly observe the resistance variable and is defined as follows [8]:

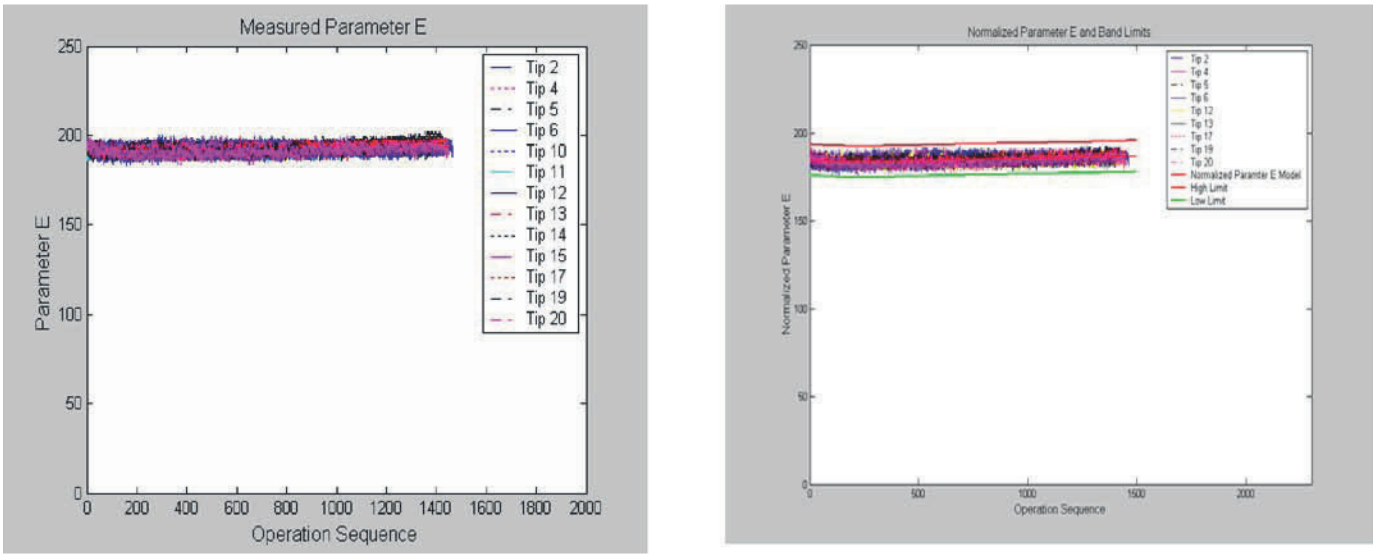
$$E_{normalized} = \frac{E_{absolute} * A_{norminal}}{A_{actual}} \tag{3}$$

The measured and Normalized Parameter E general models representing the trends of all tips are as follows and shown in Figure 4.

$$E(z) = -0.00061791x^3 + 0.031178x^2 - 0.15953x + 191.73 \tag{4}$$

$$\text{Normalized\_E(z)} = -4.4813e-005x^5 + 0.0022658x^4 - 0.042418x^3 + 0.36065x^2 - 1.1194x + 184.69 \tag{5}$$

Where, z=1,2,3,…1500 and x=z/100.



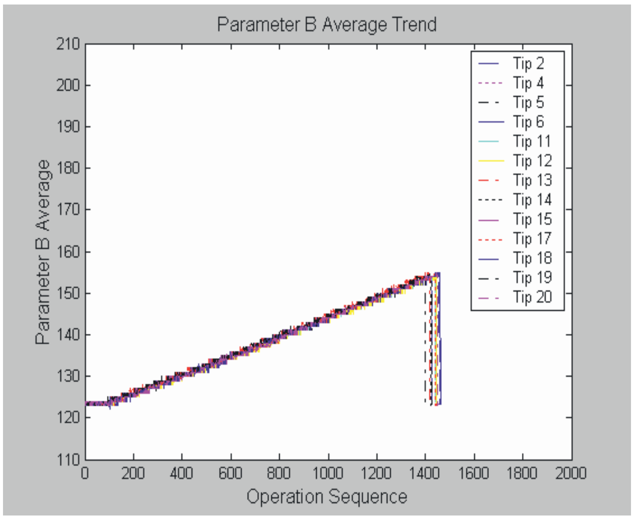
a) Measured Parameter E **b) Normalized Parameter E Model and Band Limits**

Figure 4: Parameter E trend and models

2.5 Parameter Correlation Analysis

Parameter B.

The measured Parameter B includes a measure of the maximum (high), the average (average) and the minimum (low). Because the stepper controller has the ability to control the current very accurately, most of the operation sequences do not vary significantly from the average. Among these three, Parameter B Average of all these tips follows a well behaved gradually increasing trend shown in Figure 5. It is nearly constant at step 1, then increases continuously (almost linearly) during steps 2 and 3.



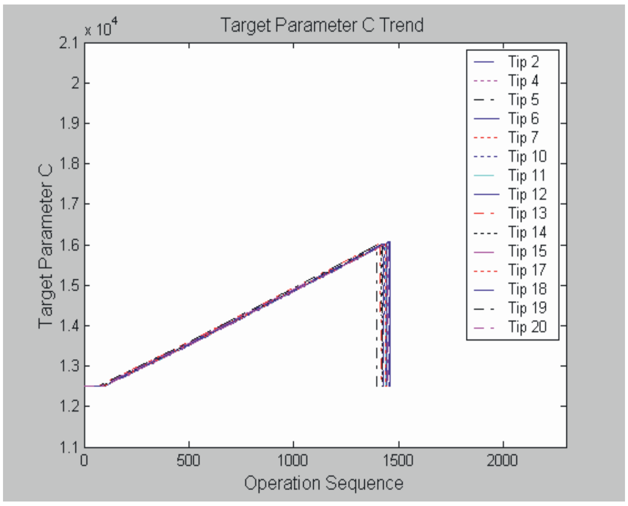


Figure 5: Parameter B Average Trends   Figure 6: Target Parameter C Trends

Target Parameter C.

Since the step controller is mainly designed to increase the current, the information of how the current step setting affects the current increment can be obtained by analyzing it. The Target Parameter C value is pre-programmed according to the tip real situation, which has the very similar trend as that of Parameter B and is shown in Figure 6. It relates to the step setting and is therefore valuable to analyze carefully in order to get more details about its function. In this paper, Target Parameter C Slope is obtained and the result for each sequence of Tip#20 is shown as Figure 7. From the operation sequence Target Parameter C trends, it is clear that the increment is zero for step 1 and 10 Amps for nearly each sequence at step 2. The Target Parameter C of step 3 alternatively increases by 11 Amps for 2 continuous operation sequences and then 10 Amps for 1 operation sequence(averagely 10.667Amps). Table 3 shows the results of current steps 2 and 3 and the effect on Target Parameter C.

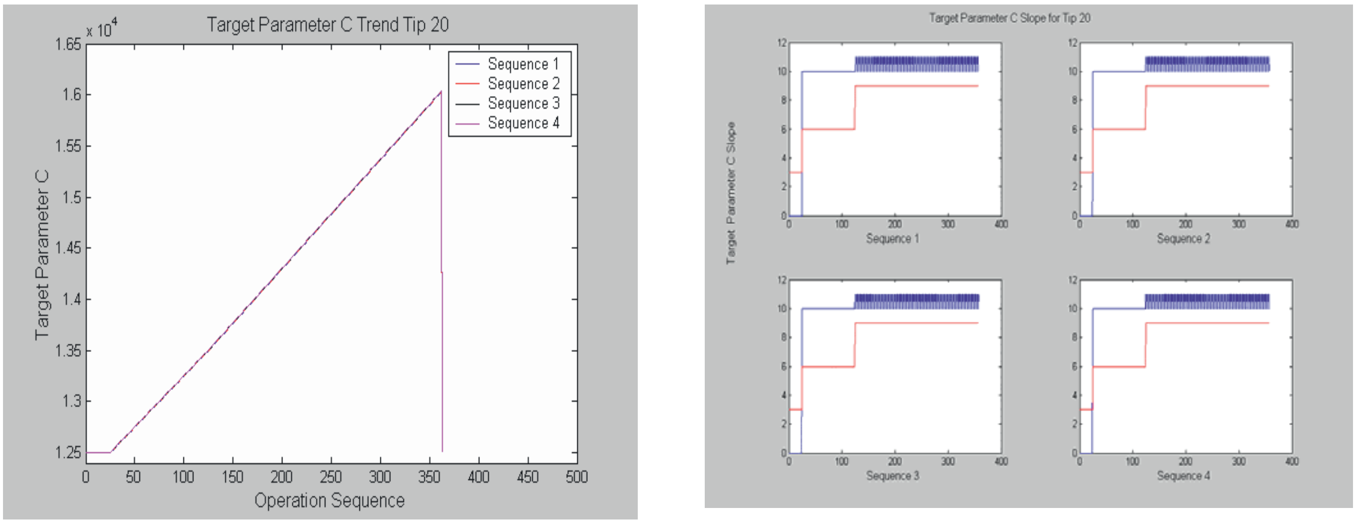

Figure 7: Target Parameter C and its Slope Behavior for each Sequence of Tip 20

The Target Parameter C for each Operation sequence starts at 12500 Amps. At the 25th part (100 operation sequences), step 2 begins. The Target Parameter C for operation sequence 1, 2, 3 and 4 starts at 12500, 12502, 12505 and 12507 respectively with the same increment as used in step 2. Therefore, the total current increment can be obtained. For Tip#20, the total operation sequence number is 1452, therefore there are 363 operation sequences in each of the four sequences. The total current increment is 3538.67 Amps and the increment percentage is 28.31% compared with the Target Parameter C of the first operation sequence(12500 Amps), which is listed in Table 4.

Correlation Analysis.

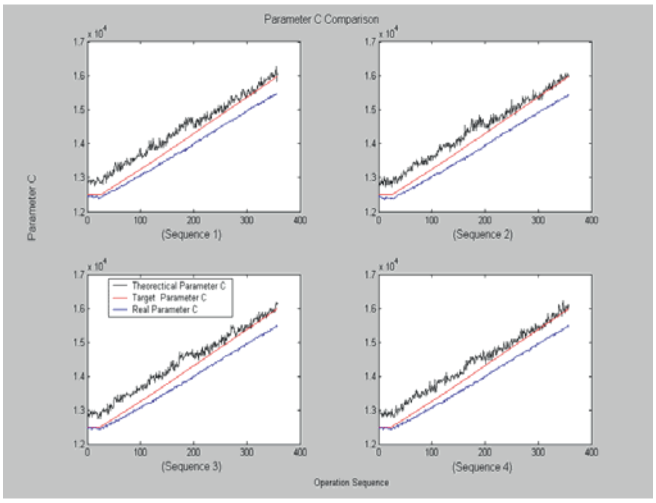
From Equation 2, it is clear that Real Secondary Current equals the Parameter E times Parameter D. Current Correlation among Real Secondary Current, Target Parameter C and Theoretical one(Parameter B times turn ratio) for each sequence of Tip#20 are shown in Figure 8. The current difference between the real and Target Parameter C of all tips is shown in Figure 9.

Table 3: Step effects for Target Parameter C

Tip	Step 2				Step 3			
	Operation Sequence 1	Operation Sequence 2	Operation Sequence 3	Operation Sequence 4		Operation Sequence 2	Operation Sequence 3	Operation Sequence 4
4	10	10	10	10.01	10.6652	10.6695	10.6652	10.6652
6	10	10	10	10.01	10.6667	10.6667	10.6667	10.6667
13	10	10	10	10.01	10.6638	10.6681	10.6681	10.6638
17	10	10	10	10.01	10.6638	10.6681	10.6681	10.6638
18	10	10	10	10.01	10.6639	10.6681	10.6681	10.6639
19	10	10	10	9.97	10.6638	10.6681	10.6681	10.6652
20	10	10	10	10.01	10.6667	10.6667	10.6667	10.6667

Table 4: Target Parameter C increment for tip 20

Tip	Total operation sequences	Sequence operation number	Sequence 1			Total current increment(Amps)	Increment Percentage
			Step 1	Step 2	Step 3		
20	1452	363	25	100	238	100*10+238*10.6667=3538.67	28.31%



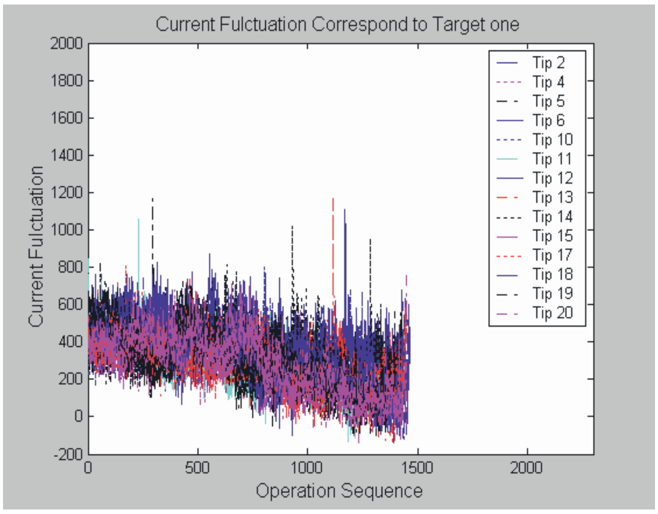


Figure 8: Parameter C Correlation **Figure 9. Parameter C Fluctuation for Tips**

From results, it is clear that, for quality concerns, both Real and Theoretical Parameter C have been programmed to be constant and much higher than the target one at step 1. However, this will greatly deteriorate the tip life, especially at an early age because of the small contact area and high pressure. It also wastes a lot of power on those operation sequences before the 100th operation sequence. At step 2, the real and Target Parameter C both increase, but with different rates. The difference between both of them becomes less as operation progresses. Finally, the Real Parameter C becomes equal to or less than its Target one at about 1000 or 1200 operation sequences. This demonstrates that the Real Parameter C could be a good indicator of operation sequence quality and Target Parameter C can be used as a reference. As the number of operation increases, resistance increases while operation parameter C decreases. This also verifies that the real one needs to be increased using the step settings to guarantee the current density is maintained within set limits with the progress of tip mushrooming.

3 STEP AND TIP WEAR SIMULATION

3.1 Simulation Assumptions

For simulation simplicity, the following assumptions have been made:

1) The same working conditions as exist on the real production line are adopted.

2) Parameter D follows the general models obtained.

3) Since current operation sequence quality is near 100% at this plant, we can use the 100th operation sequence current density as a standard to obtain the starting current point at the 1st operation sequence, based on the same current density.

4) Simulation will continue as long as control indicators fall within predefined acceptable limits

5) The same tip is used and tip wear development samples are shown in Figure 10 and 11. Table 5 shows the Tip contact area model characteristics. The tip contact area development is based on the Weibull Function and will be modified by later experimental work using the same equipment

Table 5: Electrode Dimension (in inches)[9]

Tip model	Operation Face A	Gage Line Diameter B	Length C	O.D.	Replacement Diameter D1	Area ratio A/A1	Contact Area Model

3.2 3.2 Simulation

Assume current at operation sequence order is z, then the proposed Current at any point z is obtained and listed in Table 6. The current trend is shown in Fig. 12.

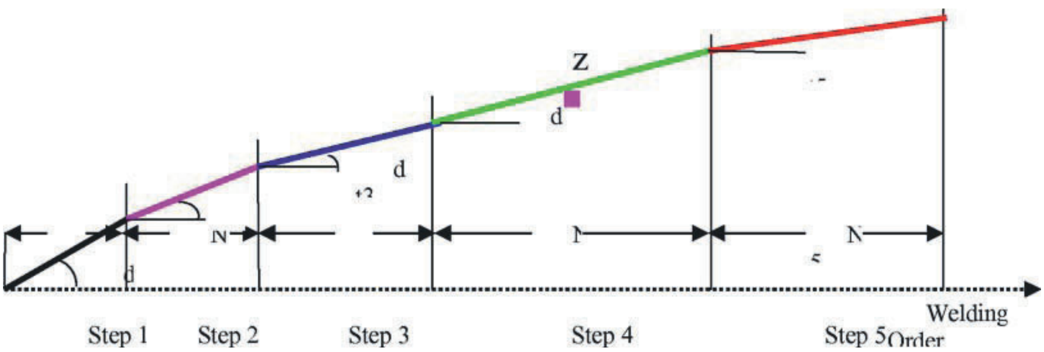

Figure 12: Proposed Current

The simulation interface is shown in Figure 13. This simulation is carried out to control two important indicators within their proper limits. One is the Parameter E consisting of Real Secondary Current and Parameter D, which should be constant or vary only slightly through the whole process (i.e. within 8%). The other is current density consisting of Real Secondary Current and Real Contact Area, which should fall in acceptable band limits during all stages (i.e. within 20%). The acceptable fluctuation percentage and each step current increment can be adjusted and optimized by the user until the final maximum operation sequence number is obtained. After simulation, the trends of current density, Parameter E and Real secondary Current will be displayed on the interface. Each stepper operation number and two indicator control limits are also shown on the interface. Each step can be adjusted and optimized and the indicator trend curves show operation amount per step and expected total operation amount will be displayed. Results show that the step setting can be optimized to give more good operation sequences throughout the life of the tip. At the beginning of each cycle, Real Secondary Current can be set very close to the Target (which is much lower than the existing setting level), so power is minimized and the tip useful life is extend.

Table 6: Proposed Current

Step	Current Increment	Operation number	Secondary Current at any point z	Starting Point of z
Step 1	dt1	N1	PC1=PC+z*dt1	0
Step 2	dt2	N2	PC2(z)=PC+N1*dt1+(z-N1)*dt2	N1+1
Step 3	dt3	N3	PC3(z)=PC+N1*dt1+N2*dt2+(z-N2-N1)*dt3	N1+N2+1
Step 4	dt4	N4	PC4(z)=PC+N1*dt1+N2*dt2+N3*dt3+(z-N3-N2-N1)*dt4	N1+N2+N3+1
Step 5	dt5	N5	PC5(z)=PC+N1*dt1+N2*dt2+N3*dt3+N4*dt4+(z-N4-N3-N2-N1)*dt5	N1+N2+N3+N4+1

4 SUMMARY

This paper addresses the current and tip wear problem for a robotic manufacturing process. The step compensation methodology is investigated. Then the development of optimum current step settings used at a local manufacturing plant are introduced, and then all the information related to step control from the real production line has been analyzed and modeled. The step function and the effects on other operation process parameters are obtained through reverse and correlation analysis of Target Parameter C, Theoretical and Real Secondary Current. The proposed Secondary Current for any operation sequence is then obtained based on this control methodology.

A simulation model for optimum step control for this kind of robotic manufacturing process has been developed. The correlation between tip contact area and operation count order is also proposed using a Weibull Function. Some assumptions are made and simulations are carried out to control two important indicators within their proper limits. One is the Parameter E consisting of Real Secondary Current and Parameter D, which should be constant or vary only slightly through the whole process. The other is current density consisting of Real Secondary Current and Real Contact Area, which should fall in an acceptable band during all stages. Each step can be adjusted and optimized and the indicator trend curves showing operation amount per step and expected total operation amount will be displayed. Results show that the step setting can be optimized to give more good operation sequences throughout the life of the tip, save energy and to extend the tip useful life. It is concluded that it is worthwhile to consider the Optimum step setting after using the information from this simulation.

5 ACKNOWLEDGEMENTS

Thanks are extended to industrial partner for providing the opportunity to work on this project. We further thank Dr. Kornel Farkas, Mr. Brian Morris for providing us with their help in the experimental work. We appreciate Dr. Sam Li and Mr. Barry Kavanaugh for their valuable information and suggestions for this project

OPPORTUNISTIC ELECTRODE REPLACEMENT IN A ROBOTIC SPOT WELDING SYSTEM

Mechefske CK and Zheng C

Department of Mechanical and Materials Engineering, Queen's University, Kingston, Ontario, Canada K7L 3N6

Abstract: This paper addresses the electrode replacement problem for a robotic resistance spot welding system consisting of k non-identical robots and the general maintenance optimization problem in a manufacturing setting. The electrode tip wear compensation methodology is introduced. Three kinds of replacement: corrective replacement, preventive replacement and opportunistic replacement policies are described. Polynomial models have been used to predict future tip behavior by modeling the tip wear from field data. Based on this, a tip wear trend as well as high and low limits for tip usage are established. Subsequently, the recommended and maximum number of welds left on a given tip and the corresponding remaining lifetime for a specific tip can be obtained. The expected failure time or replacement time can also be predicted. Through a careful cost investigation, a simulation model for electrode opportunistic replacement in a 6-robot resistance welding system has been developed. Based on some assumptions made, an optimum electrode opportunistic replacement interval achieving the maximum saving is acquired. The total expected cost, tip replace number, production line stoppage times and next replacement time can also be obtained.

Key Words: Opportunistic Maintenance, Resistance Spot Welding, Tip Replacement, Optimization Simulation.

1 INTRODUCTION

Spot resistance welding is the most inexpensive and the most common form of resistance welding. Robotic spot welding is becoming increasingly important for the automotive industry due to the fact that there are between 3,000 and 5,000 spot welds in a typical car. Consequently, the integrity of spot welds plays a critical role in the reliability of cars.

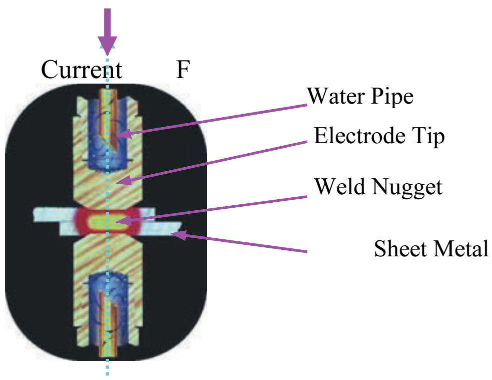

Figure 1: The spot resistance welding process

Figure 2: Tip wear samples (MPG266 GCAP)

However, bad welds are often produced due to the erosion of the welding electrode. Firstly, with usage, electrodes will "mushroom" (tip becomes blunt and contact area increases as shown in Figure 2). As the contact area increases a lower current density develops, which results in a smaller weld nugget. Secondly, when welding galvanized steel, the zirconium, chromium and zinc coating vaporize as the temperature rises, resulting in the electrode losing its hardness very rapidly and brass being formed on the electrode-weld face. This phenomenon makes the contact area sticky and larger. When an acceptable tip size and shape to form a good weld is no longer present, the electrodes need to be replaced or dressed back to the original shape.

In most modern welding production lines, there are often many weld robots varying from several to hundreds of robots. Each robot may consist of one or several stochastically failing parts with increasing failure rate, such as electrode tip in the servo gun. Generally, a weld gun on an automotive assembly line may make as high as 160,000 welds in one week [1]. In such a high productivity line, it is not cost effective to stop the whole line or change the schedule intentionally just to replace one tip. However, since robotic welding electrode tip failure time is different when performing different tasks, and the tip is relatively inexpensive compared to the cost penalty for stopping the production line, a lower cost can be achieved to replace one tip in conjunction with other tips which fall in the failure control limit than to perform them individually. In addition, most components in a robotic welding cell, i.e. servo gun and control unit etc., are subject to deterioration with usage and age, and they need to be maintained or repaired. Maintenance on them can also create a chance for replacement of other tips due for replacement. Thus, in this case, it is possible and much more cost effective to employ an opportunistic replacement policy. However, there still is a trade-off between replacing some tips together at the same time to reduce the number of line stoppages and using each tip as long as possible.

In this paper, the spot welding robot servo gun tip opportunistic replacement policy will be studied. Van-Rob, an automotive parts manufacture, has been chosen to formulate an opportunistic replacement policy, and the policy is evaluated using simulation.

2 OPPORTUNISTIC REPLACEMENT POLICY AND MODEL DESIGN

2.1 Opportunistic Replacement Policy Review

In the past 4 decades, opportunistic replacement policy has been of great interest for many real applications. The concept of Opportunistic Replacement (OR) stems from the fact that there is the possibility of dependence among various components in a multi-component system [2]. Opportunistic replacement policy means that aging constituents of a system are replaced before their normal terms while the system is down because another constituent has failed or is due for replacement. The main concern is reduced overall cost. This is particularly true in the case of a continuous system, where the failure of any one component results in stoppage of the whole system, so it is possible to do opportunistic replacement policy to non-failed subsystems at a reduced additional cost while failed subsystems are being replaced. An optimum balance between the savings obtainable from this simultaneous action and the cost of premature replacement of units that could otherwise be used for a longer period is required. Many investigators have been involved in the research of opportunistic maintenance policy.

Berg [3] suggested a preventive replacement policy for a machine with two identical components which are subject to exponential failure. Under this policy, upon a component failure the other component as well as the failed one is also replaced if its age exceeds a pre-determined control limit L. Later, Berg extended it to such a policy: both units are replaced either when one of them fails and the age of the other unit exceeds the critical control limit L, or when any of them reaches a predetermined critical age.

Zheng and Fard [4] examined an opportunistic maintenance policy based on failure rate tolerance for a system with k different types of units. Using this policy, action limits are employed in a system with repairable IFR (Increasing Failure Rate) units. When a unit is replaced, either when the hazard rate reaches L or at failure with the failure rate in a predetermined interval (L- u; L), all of the operating units with their hazard rate falling in the interval (L- u; L) are replaced at that time.

L'Ecuyer and Haurie [5] reported a dynamic programming model for the sub-optimal policy in which all failed components are replaced at scheduled inspections and also all other components whose ages exceed threshold levels at these inspections. Dagpunar [6] introduced a general policy where replacement of a component within a system is available at an opportunity. An opportunity arises if the failure of some other parts of the system allows the component in question to be replaced. Radner and Jorgenson [7] proposed an (n_i;N) policy for a series system consisting of one IFR component and M CFR (Constant Failure Rate) components. Yuna and Ferreirab [8] developed a simulation model to assess the inventory requirements of alternative rail sleeper replacement strategies. The main aim of the model is to determine the optimal replacement strategy. Pham and Wang [9] investigated the opportunistic maintenance of a k-out-of-n system with imperfect preventive maintenance (PM) in aircraft engine maintenance.

From the above review, it is clear that most of the research work on opportunistic maintenance is concentrated around (n;N) type policies. Nearly all of these consider single OM age for each of the IFR components irrespective of which other component is taken down. When the number of IFR components increase, just like robotic welding line which consists of so many robots and failure time for different components is different, the complexity of the model increases. No successful application in robotic welding production has been reported.

2.2 Replacement Policies Design for Robotic Welding Electrode

Each replacement policy has its specific advantages and disadvantages. The best replacement policy depends on the particular circumstance. The policy considered here is an (n_{ij};N_{ij}) policy based on tip failed and classification of opportunities.

Where

j, the opportunity class

n_{ij}, the OR age for tip i when the system is taken down for replacing tip j

N_{ij}, the OR age for tip i at which PR or CR is performed on component j

Therefore, three types of replacement policies have been proposed for robotic servo gun maintenance and some of them have already been employed.

Corrective Replacement Policy (CRP)

The tip is replaced immediately by a new one upon sudden failure. The phenomenon does happen sometimes when the current is too high. Corrective replacement is still one of the most commonly used replacement methods in industry. This policy should be avoided if possible due to its expense. It is a random variable but it does create opportunity for other tips' replacement.

Preventive Replacement (Maintenance) Policy (PRP)

Components are maintained periodically to avoid abrupt breakdowns, which carry great penalty. Research indicates [10] over 80% of all weld guns are repairable up to three times before a new gun purchase is necessary. Servo gun repair or replacement can include all parts showing wear or damage: such as air cylinders, transformer, gun arms, water cooled cables, etc. In this case, the replacement or maintenance interval is a decision variable which is based on the life expectancy of each component and production process economy. For robotic spot welding, the maintenance records based on number of welds made will be a good guide. One of the real experience suggested that every 125,000 welds could provide an opportunity to check and replace tips as needed [1].

Opportunistic Replacement Policy (ORP)

Replace all the failed tips (active replacement) either when the age reaches T or its next failure time falls in a predetermined interval. Namely, for the same predetermined interval L of all tips, when a tip is replaced due to the tip wear reaching T, all of the operating tips in this production line with their tip wear falling in the interval (T; T+L) are replaced at the same time.

They can also be replaced in groups at repair or replacement of other components, each shift change, Maintenance or retooling of the production line as shown in Table 1. In this project, the electrodes are monitored continuously, so the next expected failure time of each tip can be easily obtained. Then the OR ages for each tip can be obtained corresponding to each opportunity class, irrespective of the component taken down for CR or PR or OR. In this study, minimization of times of line downtime, which consists of the main part of total cost, has been considered as a main objective.

Table 1

Work schedule for production line

No	Time	Total (min)	Description
1	7:00 – 7:10	10	Idle
2	7:15 – 7:24	11	Maintenance on GEO 2

3 EXPERIMENTAL SETUP AND DATA ANALYSIS

3.1 Industrial Partner Van Rob.

The experimental development and implementation phase of this work has been conducted on the robotic resistance spot welding system, which consists of 6 Nachi SH166-01 robots or GEO Station robots which are shown as Figure 3, at Van Rob. The product concerned in this experiment is an automotive part consisting of 4 sequences [11].

Figure 3: Van-Rob robotic welding system

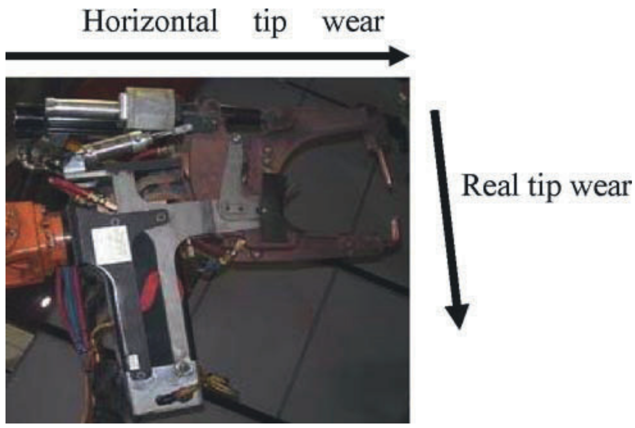

Figure 4: Servo gun tip wear compensation methodology

3.2 Tip War Monitoring and Compensation Methodology

As welding continues, the soft copper mushrooms resulting in a larger distance between the upper and lower tips. This should be compensated for, to guarantee a good weld. Therefore, Van-Rob has employed a monitoring system to realize the tip wear control. That is, the welding robot performs a tip check with no current passing through after welding several sequences (welds). The process is automatically compensated by a preset horizontal gun holder forward value (4 at the beginning in this case) shown in Figure 4. This value is automatically collected and input into the PLC, and then transferred to an internal database. Although it needs to be transferred to the real tip wear, it still could be a good indicator for current application when the real tip wear is not measured directly.

3.3 Tip Wear Data Analysis

Tip wear model and band limits

The real field data have been obtained on the servo gun of robot LHsub1. 21 tips have been used in this period. Data sample for tip 18 is shown in Table 2. The relationship of the tip wear compensation value with welding number is summarized and shown in Table 3.

The results show that the total weld number is around 1450 welds and total tip wear compensation amount will be about 2.1-2.6mm for each tip. The data also indicates that there exists a similar tip wear trend. It is therefore, possible to find a suitable model for all tips. The behaviors of the refined curve fitting models show that 4th and 7th order polynomial functions work very well for nearly all tip shifts. After averaging the models of the representative tip shifts, the general model of tip wear can be obtained and expressed as equation 1. Where x equals to welding count divided by 100. The tip wear trends, its general model and band limits behaviors are shown in Figure 5.

$$Y(x) = -5.4431e-005x^7 + 0.0029115x^6 - 0.062392x^5 + 0.69198x^4 - 4.3739x^3 + 16.984x^2 - 54.363x + 520.16 \quad (1)$$

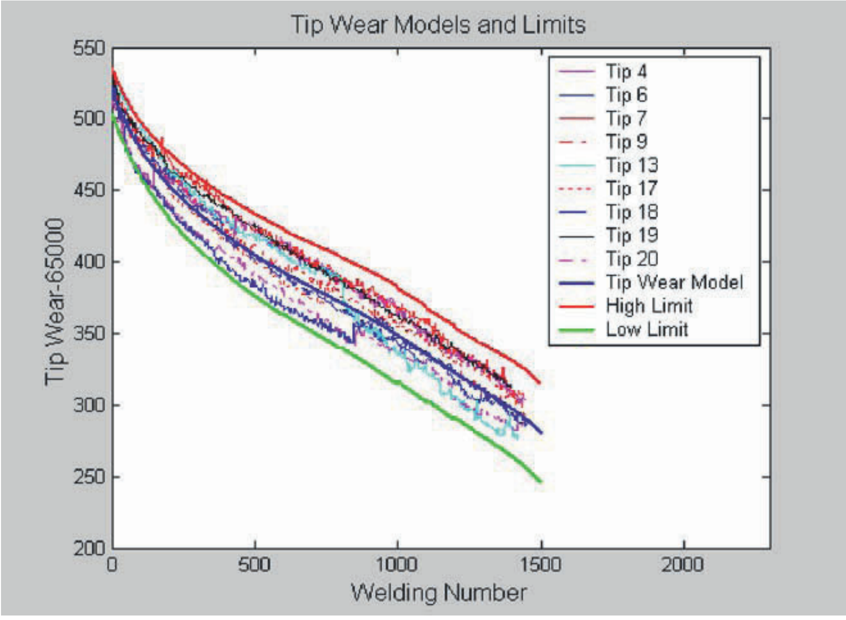

Figure 5: Tip wear model with its band limits

Table 2

Data sample for tip 18

Date &Time	Log #	Part #	Sequence #	Tip Wear(*100)	Note
2003-6-12 4:54	4761	210	1	65519	
2003-6-12 4:54	4762	210	2	65519	
2003-6-12 4:54	4763	210	3	65519	
2003-6-12 4:54	4764	210	4	65519	
2003-6-12 4:54	4765	210	24	65519	Tip Check
2003-6-12 4:55	4766	211	1	65515	
2003-6-12 4:55	4767	211	2	65515	
2003-6-12 4:55	4768	211	3	65515	
2003-6-12 4:55	4769	211	4	65515	
2003-6-12 4:55	4770	211	24	65515	Tip Check

Table 3

Relationship of the Tip Wear versus welding number

Tip No.	Total weld number	Tip Wear value (Staring from)	Tip Wear value (Ending at)	Total Tip Wear (compensated)
4	1448	65525	65304	221
6	1464	65520	65287	233
7	1441	65533	65306	227
9	1426	65530	65304	226
13	1424	65535	65276	259
17	1452	65531	65294	237
18	1460	65519	65278	241
19	1401	65531	65314	217
20	1452	65513	65282	231

3.4 Tip Time and Weld Order

The life time versus weld count for weld tip sample are shown as Figure 6 and listed in Table 4.

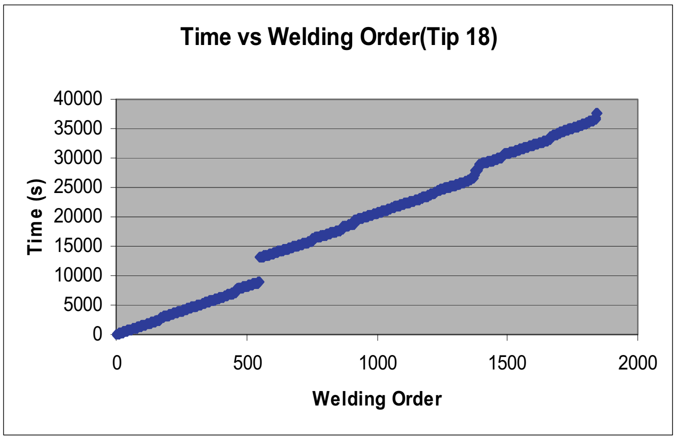

Figure 6: Time vs welding order

Table 4

Total time and time per weld

Tip No.	Total time (hours)	Time per weld (sec)
18	10.48	20.46
2	9.064	17.98
12	10.82	21.26
4	9.85	19.08
Average	10.05	19.69

From the above results, most tips last about 9 to 11 hours and each weld takes about 19.696 seconds for this gun. The real weld time should be considerably less due to the fact that there is significant idle time between welds and sometime is used to move the gun or rotate the parts to get to the next weld. It is also clear that the life expectance of each tip even in the same gun is different, but generally they may have a distribution (i.e. Weibull Distribution). Based on the average weld time, real tip wear and band limits, we can obtain the recommended and maximum number of welds left and the corresponding remaining lifetime for a specific tip.

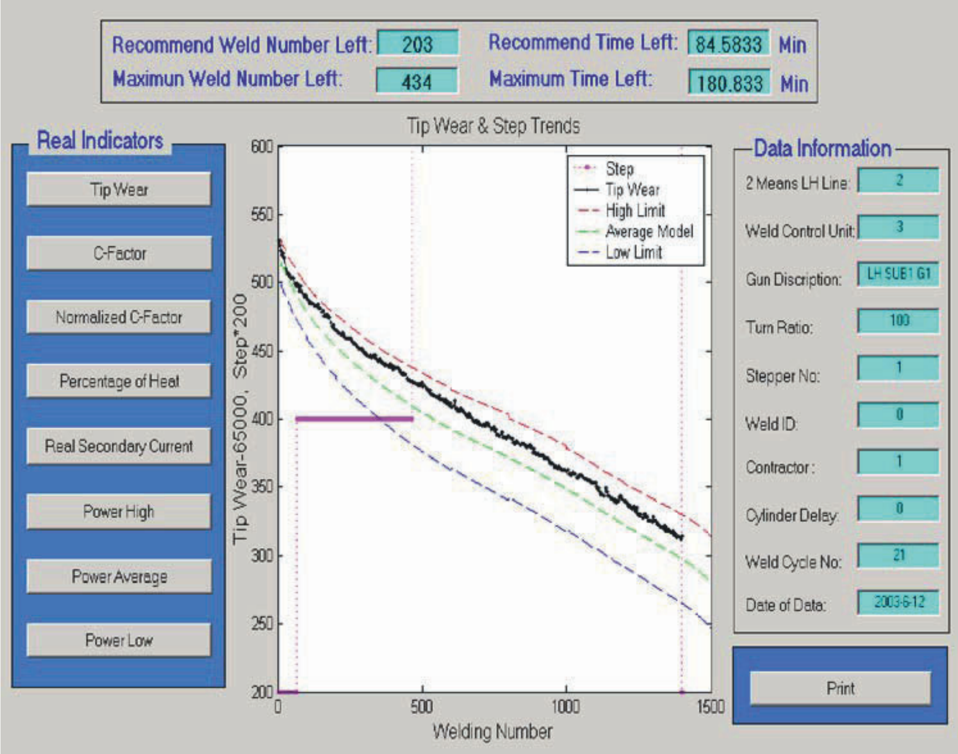

Figure 7: Tip wear next failure time prediction interface

4 OPPORTUNISTIC REPLACEMENT POLICY SIMULATION

Although many mathematical models exist, Tip Opportunistic Replacement cannot be easily modeled using mathematical models. In nearly all the case studies of real-life situations, the simulation approach has been adopted. It has been demonstrated to perform well in tackling maintenance problems and it can also model the multi-component system with relative ease. Therefore, the simulation approach is adopted in this paper.

4.1 Assumptions

For simulation simplicity, the following assumptions have been made:

1). Only the electrode tip is an Increasing Failure Rate (IFR) for each robot. Other components are constant failure rate (CFR) and no corrective replacement. The tip wear status is known and at no cost due to the condition monitoring.

2). Every tip failure causes production line failure and needs replacement right away.

3). The time to failure of each new tip under normal working condition follows the similar tip wear trend obtained and simulation starts at a fixed failure time for each robot.

4). A replacement constitutes the installation of a new tip or the removal of the current tip. However, replacement time is negligible compared to times between failures.

5). Cost assumption. All replacement activities are performed by permanent employees. Manpower cost is fixed. For this continuously operating system, downtime costs are more predominant. For simplicity, each CR, OR and PR downtime for specific components are assumed to be constant although they will vary over a wide range depending on the amount of work done. Among these three costs, CR cost is the highest because it will carry a cost penalty when a component suddenly fails. PR and OR costs are the same if tip condition monitoring is performed well. Based on the production economy, production line maintenance parameters are listed as Table 5.

For each specific replacement interval control limit L, the total cost of the replacement for adopting OR is as follows.

Table 5

Production line maintenance parameters

Parameters	Symbol	Value
Tip Life distribution	T	$W(\alpha, \beta)$
Corrective replacement cost	C_{cr}	$10/each
Preventive replacement cost	C_{pr}	$5/each
Opportunistic replacement cost	C_{or}	$5/each
Loss of production	C_{loss}	$25/each
Cost of electrode	C_{tip}	$1.2/each
Cost of tip working productivity	C_{waste}	$20/hour

$$TC_{new}=N_{cr}*C_{cr} + N_{or}*C_{or} +N_{pr}*C_{pr} +N_{tip}*C_{tip}+C_{loss}*(N_{cr}+N_{or}+N_{pr}) \quad (2)$$

The total cost of the replacement if not adopting OR is as follows (Each time need to stop line for tip replacement or preventive maintenance).

$$TC_{old} = N_{tip}*(C_{tip}+C_{loss})+(N_{cr}+N_{pr}) *C_{loss} \quad (3)$$

Then the saving cost between adopting OR method and not adopting OR method will be

$$TC_{saving} = TC_{old} -TC_{new} \quad (4)$$

The total money wasted, due to the tip life wasted that could be used for more welds because of adopting OR method, will be

$$TC_{waste} =Sumtime_{waste}*C_{waste} \quad (5)$$

Therefore, the final saving between money saved and wasted after adopting the OR will be

$$TC_{finalsave}=TC_{saving} -TC_{waste} \quad (6)$$

Where:

N_{or} : Number of Opportunistic Replacement times

C_{or} : Each Opportunistic Replacement cost

N_{cr}: Number of Corrective Replacement times

C_{cr} : Each Corrective Replacement cost

N_{pr}: Number of Preventive replacement times

C_{pr} : Each Preventive Replacement cost

N_{tip}: Total number of tip replacement

C_{tip}: Cost of each tip

C_{loss}: Cost penalty for loss of production

TC_{old}: Total cost of the replacement if not adopting OR

TC_{new}: Total cost of the replacement if not adopting OR

TC_{saving}; Saving cost between adopting OR and not adopting OR

TC_{waste}: Total money wasted due to still useable tip life wasted

$Sumtime_{waste}$: The total useable tip life wasted that could be used for more welds

C_{waste}: Cost of tip working productivity (for lose of tip life due to OR)

$TC_{finalsave}$: Final saving between money saved and wasted after adopting the OR

From the final saving for each control limit, we can obtain the optimum replacement interval by finding the maximum savings. Namely:

$$\frac{\partial TC_{finalsave}}{\partial L} = 0 \tag{7}$$

4.2 Simulation and Results

The simulation interface developed is shown as in Figure 8. Each expected robotic tip life can be changed directly or by the controller according to the real situation. The simulation system can be simulated for any period of time with the imposition of the policy after selecting the simulation time length.

Results for any interval control limit

First, for any gradually increased replacement interval L, this simulation process is executed within one year. Irrespective of the component taken down for CR or PR or OR, all the operating tips whose age reaches its life expectance T or the difference between next replacement time and current age is less than the replacement interval L , have been replaced at the same time. And then the tip replacement and cost are obtained. Using this simulation approach, it is easy to get the cost trends and obtain the optimum replacement interval to save the maximum amount of money. After simulation with opportunistic replacement policy, the total number of replaced tips and line stoppage, total saved cost, total wasted cost due to the wasted tip life and final money saved are obtained and shown in Table 6 for each specific control limit. Each robot's next replacement age is also displayed on the interface.

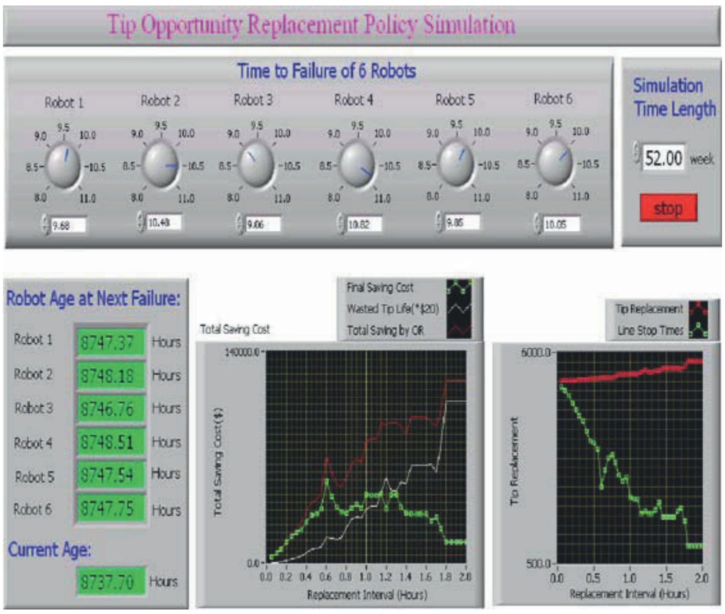

Figure 8: Simulation result interface

From the table, it is clear that the replacement interval L plays a significant role in tip opportunistic replacement due to the fact that it decides how many tips can be replaced at a time and how many times it needs to stop the production line. Both of these contribute a lot to the total cost. As the replacement interval L becomes larger, the total saved cost, total wasted cost and the total number of replaced tips all increase, but the total number of line stoppages for OR replacement deceases significantly. All of these trends become constant when the interval limit reaches 1.8 hours, (namely replacing all tips each time). Based on the cost assumption, the total money saved is obtained for each specific control limit and the results show that it will increase first and then decrease. There does exist a maximum value at interval control limit of 0.6 hours. Up to $53,944 per year can be saved after employing an opportunistic tip replacement policy for this 6 robot system. Currently there are 72 Servo guns working continuously at Van Rob, some of them need to replace tips at around 2.5-3 hours or even less than 1 hour. It is also estimated that only the tip purchase cost at Van-Rob is $500,000/year. Therefore, it is expected to save more than $300,000 /year after employing the opportunistic replacement policy for all robot cells.

Results under constant interval limit but with increasing welding time

The trend under constant interval limit but with increasing welding time is also simulated. The optimizing interval limit (L=0.6hr) is chosen and the results are shown in Figure 9 and Table 7. From the above figures, it is clear that the total expected cost, the total stop line times and the total tips being replaced are increased linearly with the welding time. Therefore, it will save money in the long term

Table 6

One year simulation results for 6-robot welding system

Simulation interval L(hr)	Total tips been replaced(TNR)	Total stop line times (TST)	Total expected cost save using OR($)	Note

5 SUMMARY

This paper addresses the electrode replacement problem for a robotic resistance spot welding system consisting of 6 non-identical robots and the general maintenance optimization problem in a manufacturing setting. The electrode tip wear compensation methodology for tips that mushroom as the number of welds increases is introduced. Three kinds of replacement policies are described. They include; corrective replacement, preventive replacement and opportunistic replacement. Polynomial models have been used to predict future tip behavior by modeling the tip wear from field data. The results show that a 7th order polynomial model can represent the tip wear trend. Welding order and time analysis results show that most tips last about 9-11 hours and each weld takes near 20 seconds. Based on this, a tip wear trend as well as high and low limits for tip usage were established. Subsequently, the recommended and maximum number of welds left on a given tip and the corresponding remaining lifetime for a specific tip can be obtained.

The expected failure time or replacement time can also be predicted. Through a careful cost investigation, a simulation model for electrode tip opportunistic replacement on a 6-robot resistance welding system has been developed. Based on the assumptions, the first simulation results show that there do exist a maximum saving value at interval control limit of 0.6 hours. Up to $53,944 per year can be saved after employing for tip opportunistic replacement for this 6 robot system under such a situation. The second simulation shows that under increasing welding time, the total expected cost, the total stop line times and the total tips been replaced are increased linearly. It is concluded that it is worthwhile to consider the an Opportunistic Replacement Policy.

6 ACKNOWLEDGEMENTS

Thanks are extended to Van-Rob for providing the great support on this project. We further thank Dr. Kornel Farkas and Mr. Jeffrey Liaw for providing their help in the experimental work. We also appreciate Mr. Brian Morris and Dr. Sam Li for their valuable information and suggestions.

INDUCTION MOTOR FAULT DETECTION USING HYBRID METHODS

Li W and Mechefske CK

Department of Mechanical and Materials Engineering, Queen's University, Kingston, Ontario, Canada K7L 3N6

Abstract: This paper presents the comparison results of induction motor fault detection using stator current, vibration and acoustic methods. A broken rotor bar fault and a combination of bearing faults (inner race, outer race and rolling element faults) were induced into variable speed three-phase induction motors. Both healthy and faulty signatures were acquired under different speed and load conditions. Spectral differences are compared and characterized under constant speed conditions. Experimental results show that the stator current method is sensitive to the broken rotor bar fault while the vibration method is sensitive to bearing faults. The acoustic method is very attractive in that it contains less noise and interference within the analyzing frequency band. With the proper selection of monitoring and analysis methods, induction motor faults can be detected accurately under both stationary and non-stationary states.

Key Words: Induction Motors, Motor Current Signal Analysis, Vibration Signal Analysis, Acoustic Signal Analysis, Varying Speed, Varying Load.

1 INTRODUCTION

Over the past few decades, condition monitoring techniques of induction motors have been extensively conducted with an emphasis on motor current signature analysis (MCSA). MCSA, a noninvasive monitoring technique, is sensitive to most motor faults. As a result, a large amount of research has been directed toward the analysis of motor current [1-3]. Besides MCSA, vibration analysis is also an effective monitoring technique in detecting motor bearing and broken rotor bar faults [4-5].

The signal analysis methods range from time domain statistical analysis to joint time-frequency analysis and include the uses of artificial neural network and wavelet transforms [6]. Spectral analysis of motor current signatures was performed by Benbouzid et al. [7]. Several motor asymmetrical faults were compared in the frequency domain. Higher-order spectral analysis was also applied to detect motor faults [8]. The analysis is effective in detecting phase couplings which occurs when motors have faults. Yaz c and Kliman [9] used the short time Fourier transform (STFT) as a pre-processing method to extract fault features from motor current signatures. Filippetti et al. reviewed the applications of artificial intelligence (AI) methods in the diagnosis of motor faults and analyzed the factors influencing the current components [10]. The analysis provided insights in calculating the amplitudes of current, torque, and speed spectral components in a transient model. Ye at al. [11] applied a wavelet packet decomposition (WPD) method to analyze the characteristics of the stator current under normal and faulty conditions. The feature coefficients extracted from the WPD were then used detect rotor bar breakage and air-gap eccentricity faults.

By reviewing the past work it is noted that although advanced signal processing methods have been extensively employed, conventional statistical calculations and Fourier series based spectral analysis still provide vital preliminary information. For instance, both the neural network and model based methods rely heavily on the calculations of motor signatures (e.g. RMS, Kurtosis, etc.) and fault frequencies (via FFT). Therefore, understanding about the characteristics of motor related faults under different speed and load conditions is desirable in order to extract efficient features.

To address the above issue, this paper is intended to make comparisons of motor fault detection capabilities using different methods. In addition to the widely used motor current and vibration methods, an acoustic method, a noninvasive monitoring scheme, is also employed in this paper. Comparisons are to be made under different load and speed conditions in the frequency domain.

2 MOTOR FAULTS

As described in the previous section, failures of motor core components such as stators, rotors and bearings account for a large percentage of motor breakdowns. Hence it makes more sense to simulate the most common motor faults in an experimental setting. In this paper, a broken rotor bar fault and a combination of rolling element bearing faults are induced experimentally.

2.1 Broken Rotor Bars

Rotor failures account for 5-10% of induction motor problems. A broken rotor bar fault has distinctive characteristic frequencies which can be calculated as

$$f_{brb} = (1 \pm 2ks) f_0 \quad , \; k = 1,2,3,\cdots \tag{1}$$

Where f_0 is the driving frequency and s is the fractional slip of the motor.

Once there is a broken rotor bar fault, sidebands around the driving frequency can be expected in the power spectrum. In particular, the first-order sidebands (e.g. $k = 1$) are of particular interest in the detection of broken rotor bar fault. The left sideband $(1-2s) f_0$ is due to electrical or magnetic rotor asymmetry caused by broken rotor bars while the right sideband $(1+2s) f_0$ is due to the speed ripple or variation [10]. The amplitudes and presence of the sidebands depend on the physical position of the broken rotor bars, speed and load. The locations of the sidebands will shift outwards as the speed and load are increased. It is acknowledged that the sidebands may also be observed when the motor has no broken rotor bar fault as rotor ellipticity and shaft misalignment could both induce rotor asymmetry to a certain extent [9]. However, the sideband amplitudes produced in those cases are much smaller compared with those produced by broken rotor bar fault. Benbouzid suggested that when the amplitudes of these harmonics are over 50 dB smaller than that of the fundamental frequency component, the motor could be considered healthy [3]. Such a judgment needs to take into account the speed and load factors. In this paper, a motor with one broken rotor bar was pre-manufactured and used in the tests to simulate the broken rotor bar fault.

2.2 Bearing faults

Of the large power machine failures, bearing problems account for over 40% of machine breakdowns. Failure in rolling element bearings is often a gradual process starting from fatigue fissures located beneath the bearing raceways. As a result of the continued concentration of stress, the fissures propagate toward the surfaces resulting in minute cracks. These cracks, under cyclical loading, develop into large cracks and cause the surface material to break loose in the form of flaking and spalling. Other causes of bearing failure include improper installation, lubrication, contamination and corrosion.

Rolling element bearing fault frequencies include ball pass frequency outer race (BPFO), ball pass frequency inner race (BPFI), ball spin frequency (BSF), and fundamental train frequency (FTF). All of these frequencies can be calculated from bearing geometric dimensions. In our tests, a combination of bearing faults including inner race, outer race and rolling element faults were seeded in a SKF bearing 6203. Table 1 lists bearing geometric dimensions and fault frequencies.

Table 1

The test bearing specifications and frequencies.

Bearing model	SKF 6203
Number of balls	8
Bore diameter	17 mm
Outside diameter	40 mm
Ball diameter	6.75 mm
BPFI	4.95
BPFO	3.05
BSF	1.99 or 3.99
FTF	0.382

The bearing frequencies listed in Table 1 are related to inner shaft rotation frequency in Hertz. For instance, if the shaft is rotating at 1 Hz (60 RPM), the BPFO is 3.05 Hz (3.05×1 Hz). Two BSFs are given in Table 1. The first (1.99) is called the rotation frequency of rolling element and the other is called the over-rolling frequency of one point on a rolling element which occurs when an element has defects. However, it should be noted that, unlike BPFO or BPFI, BSF may not always be present as the ball may change its rotational axis and thus not always be over-rolled at the same point.

3 EXPERIMENTAL METHODS

Experimental tests were conducted in a laboratory environment using a dynamic fault simulator. The system consists of an induction motor, variable speed controller, a gearbox and a magnetic brake unit. Figure 1 illustrates the simulator system and the associated data acquisition instrumentation.

The test motor is a two-pole three-phase induction motor with rated output power of 3 HP (2.24 kW). To change the speed of the motor, a digital variable speed controller is attached to the test rig between the power line source and the AC motor. The controller can be programmed to any specific shaft rotation speed between 0 and 3600 RPM. A gearbox is used to reduce the output shaft rotational speed. To apply the load, a magnetic brake unit is employed on the output shaft of the gearbox. The brake unit has an adjustable load range of 0-70 lb-in (0-7.9 Nm).

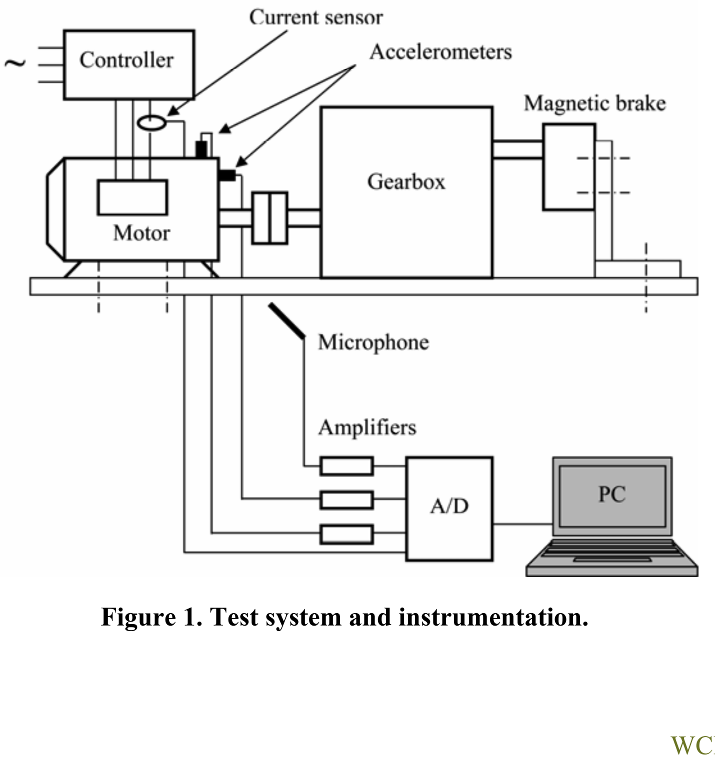

Figure 1. Test system and instrumentation.

One Hall-effect current sensor, two accelerometers and a microphone were used to acquire the stator current, vibration and acoustic signatures. One accelerometer was placed on the top of the motor in the radial direction and the other was glued to the right-hand side surface along the axial direction. The microphone was pointed to the center of motor shaft and positioned about 15 cm away. Three motor conditions were simulated in the tests: normal, one broken rotor bar and a combination of bearing faults on the inner race, outer race and a ball. The tests were conducted under 5 speed and 4 load conditions. The speeds were increased from 15 Hz up to 55 Hz with a step of 10 Hz each time. At each speed, four loads were applied to the gearbox output shaft at the percentage of 0%, 33%, 66% and 100% of the maximum 70 lb-in.

4 EXPERIMENTAL RESULTS

In this section, the experimental results are presented in three subsections in the order of broken rotor bar fault, bearing failure.

4.1 Broken rotor bar

Figures 2 to 5 show the spectral comparisons of vibration, current and acoustic signatures around the driving frequency under normal and broken rotor bar fault conditions at 25 Hz (1500 RPM) and 100% load. The radial vibration spectra in Figure 2 show the sideband differences between normal and broken rotor bar on both sides of the driving frequency (25 Hz). Under the normal condition, amplitudes of the first-order sidebands are around -28 dB (left) and -30 dB (right) respectively. Under the faulty condition, the sideband amplitudes are increased to -19 dB and -21 dB, a difference of 9 dB. The axial vibration spectra in Figure 3 display the first-order left sideband difference of around 5 dB while the first-order right sidebands are almost the same. This fact indicates that the radial vibration is more sensitive to the broken rotor bar fault than the axial vibration. It is observed from Figures 2 and 3 that the frequency positions of the maximum vibration spectral components were shifted leftward to about 24.4 Hz. This is because the accelerometer signals are linked to the speed of the rotor which is slower than the speed of the magnetic fields (25 Hz in this case) due to the effect of slip.

The comparison of the current spectra in Figure 4 shows more distinctive differences. The differences in the first-order sideband amplitudes are clearer than those of the vibration spectra. The sideband amplitudes of the broken rotor bar are 9.6 dB (left) and 11.3 dB (right) higher than those of the normal condition sidebands. Compared with vibration spectra, it is noted that the sidebands under the normal condition are more clearly visible. The current spectra also display the amplitude differences at other higher-order sidebands. For instance, both the second (25 ± 2.2 Hz) and third-order (25 ± 3.2 Hz) sidebands under the broken rotor bar condition are comparatively higher than those of the normal condition sidebands.

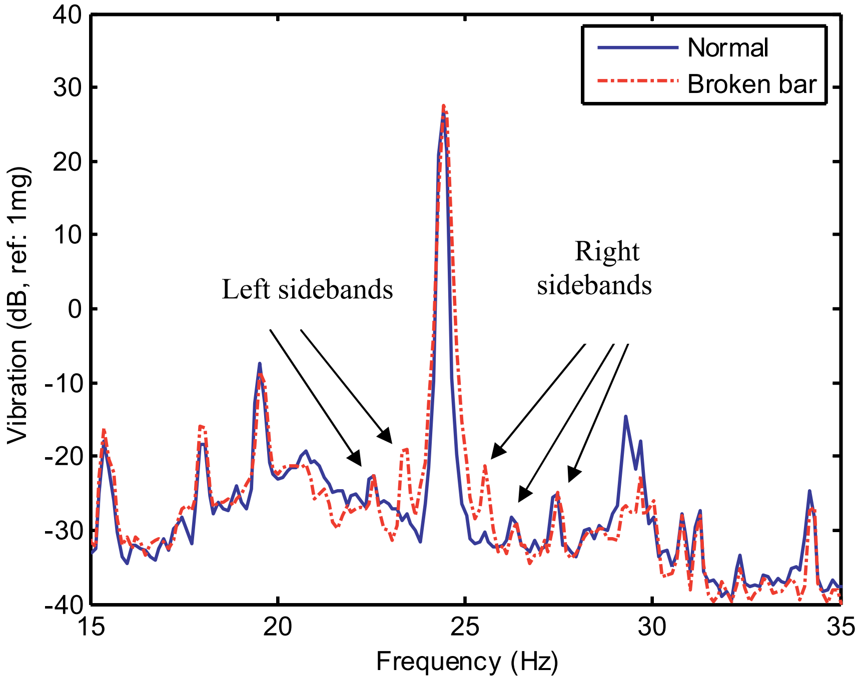

Figure 2. Radial vibration spectra of normal and faulty motors

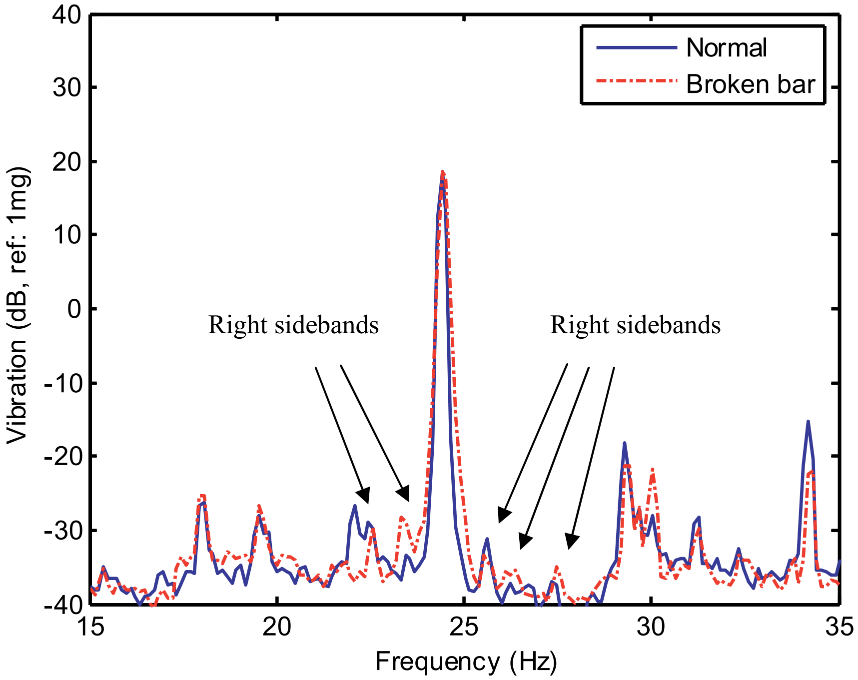

Figure 3. Axial vibration spectra of normal and faulty motors

The acoustic spectral comparison is given in Figure 5. First, the amplitude of the 25 Hz driving frequency is not as distinguished as those in vibration and current spectra. This may be explained by the fact that the sound generation mechanism is different from that of vibration. The 25 Hz driving frequency would not necessarily produce the loudest sound pressure level (SPL). Second, it is noted that the overall sound pressure level of the faulty spectrum (dash dot line) is higher than that of the normal spectrum. However, such a difference in overall spectrum amplitudes is not consistent in other types of faults. For instance, the faulty bearing acoustic spectrum is lower than the normal bearing spectrum. This is clearly because different motors have different baseline acoustic levels that affect the overall sound pressure levels. It is noted from Figure 5 that both the normal and faulty spectra show first few order sidebands. The faulty sidebands are relatively higher than the normal sidebands as a result of its higher spectral level. The differences between the first-order sidebands are 0.5 dB (left) and 1.7 dB (right).

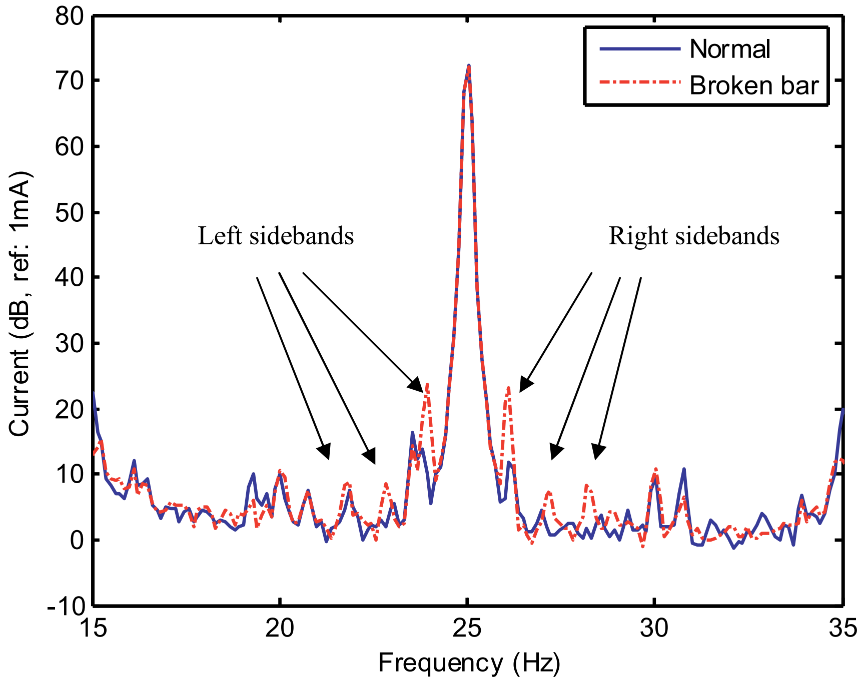

Figure 4. Current spectra of normal and faulty motors

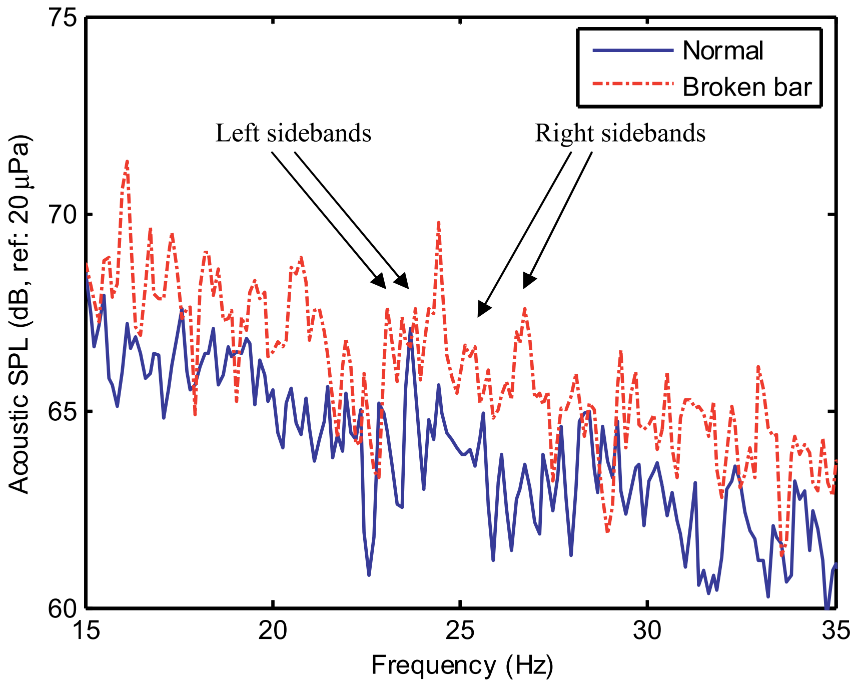

Figure 5. Acoustic spectra of normal and faulty motors

The influence of load on broken rotor bar induced sidebands is illustrated in Figure 6. Figure 6 shows the comparisons of both the left and right sideband amplitudes between normal and broken rotor bar at 55 Hz and under 4 load conditions (e.g. 0%, 33%, 66% and 100% of 70 lb-in.). First, the two vibration spectra in Figures 6 (a) and (b) show that the amplitude differences of the left sidebands are more distinctive that that of the right sidebands. Second, the current sidebands in Figure 6(c) show a gradual increase in amplitude differences against the load. Clearly, the sidebands from motor current signatures are more sensitive to load variations than those from the vibration signatures.

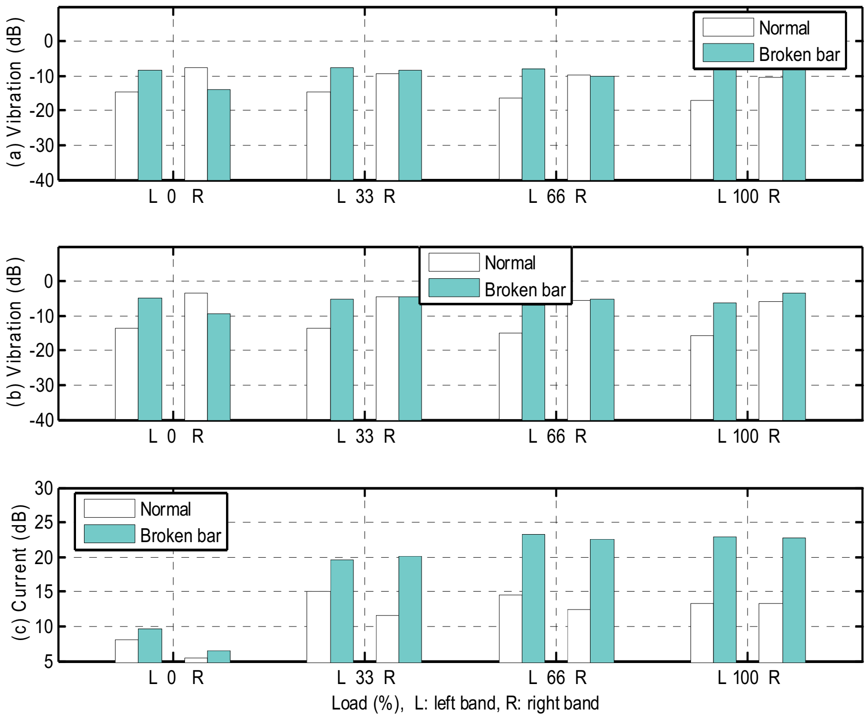

Figure 6. Influence of load on sideband amplitudes at 55 Hz; (a) radial vibration; (b) axial vibration; (c) current.

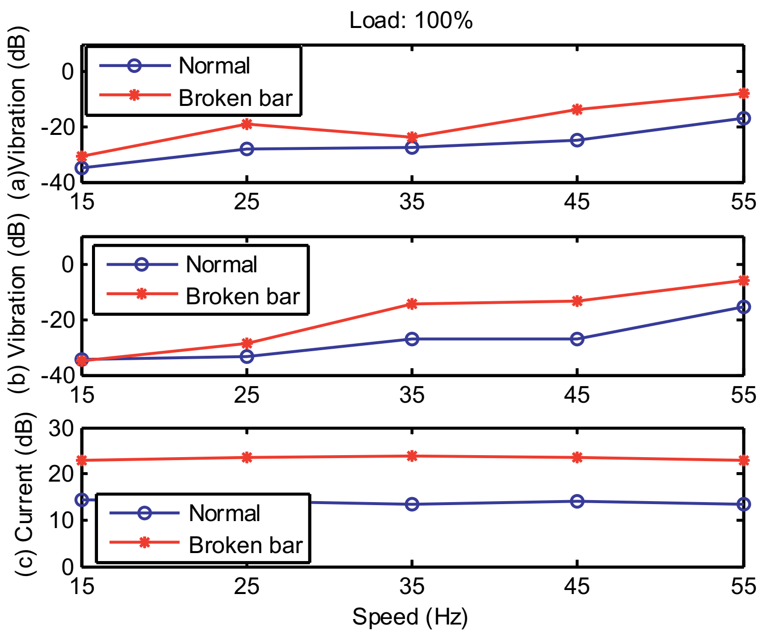

Figure 7. Influence of speed on the left sideband amplitudes at 100% load; (a) radial vibration; (b) axial vibration; (c) current.

Figure 7 compares the influence of speed on sideband amplitudes at full load conditions. The vibration sidebands in Figures 7(a) and (b) show that both the normal and faulty sideband amplitudes increase with speed. The comparison of current sideband amplitudes in Figure 7(c), on the other hand, shows that the sideband amplitudes and their differences remain almost constant of all speeds stated. The comparisons of sideband amplitudes at other load conditions show similar trends against the speed.

In general, for the detection of broken rotor bar faults, current analysis is more sensitive than vibration and acoustic methods. By analyzing the current signatures in the frequency domain, significant sideband differences could be observed. Vibration analysis is also able to show certain differences in sideband amplitudes. However, the differences are more likely to be influenced by shaft driving frequency than load. The acoustic analysis is barely able to detect broken rotor bar induced sideband differences due to high noise levels.

4.2 Bearing faults

The spectral comparison between normal and faulty bearings' radial vibration signatures at 25 Hz and 0% load condition is illustrated in Figure 8. The amplitudes of BPFO are 8.1 dB for the normal bearing and 33.1 dB for faulty bearing respectively, a difference of 25 dB. The amplitude difference of BPFI, about 23.8 dB, can also be observed around 123 Hz. On the other hand, the difference of BSF amplitudes (about 4 dB) is barely distinguishable. It is noted from Figure 8 that the radial vibration spectra contain a variety of spectral components and harmonics from shaft rotation and gearbox, etc. This may make the comparison of bearing conditions more difficult using vibration signatures. The spectral comparison of axial vibration signatures is similar to that of Figure 8.

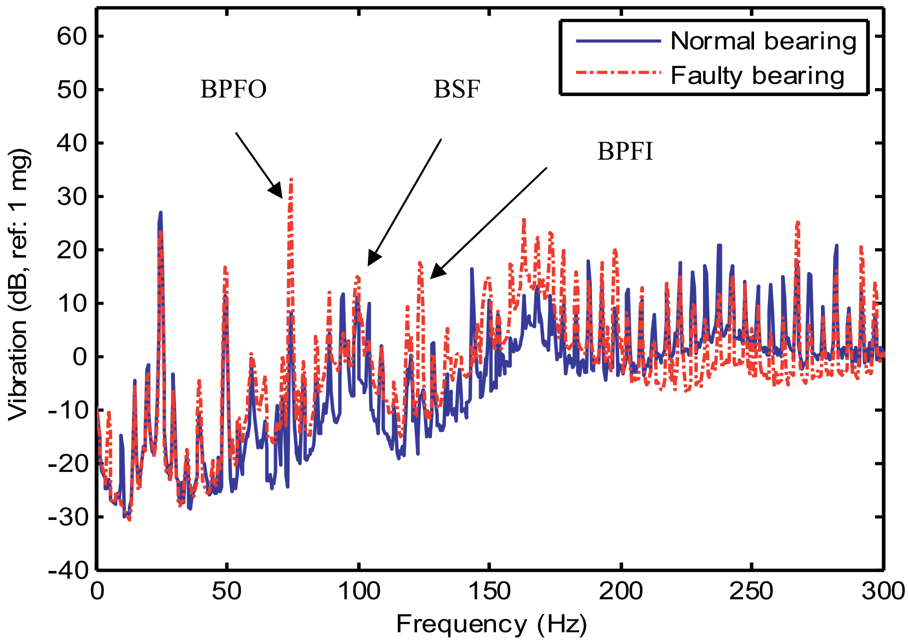

Figure 8. Spectral comparison of radial vibration signatures at 25 Hz and 0% load

Figure 9 shows the comparison of current spectra between normal and faulty bearings. The amplitude differences of bearing fault components are 3.1 dB (BPFO), -1.35 dB (BSF) and -2.7 dB (BPFI) respectively. Still, similar to the vibration spectra in Figure 8, the current spectra in Figure 9 are inundated with strong interferences and background noise.

The spectral comparison of acoustic signatures is shown in Figure 10. The comparison is made in two subplots because the sound pressure level distribution of the normal bearing is much higher than that of the faulty bearing. Such a difference in baseline spectra might be due to the acoustic contributions from background noise and other interferences. In Figure 10(b), the BPFO component at 76 Hz is clearly visible with an amplitude of 70.7 dB. Its second-order harmonic at 152 Hz has an amplitude of 57 dB. On the other hand, although the overall normal spectrum in Figure 10(a) is higher, it shows no sign of the BPFO component. The BPFI component at 123.2 Hz is barely observable with an amplitude of about 45 dB. The peak corresponding to the BSF could not be identified from the faulty spectrum in Figure 10(b).

From the above comparisons it can be seen that the BPFO fault is the most consistent one among the other faults. This is because the outer race fault has shorter distances to motor outer surfaces where the accelerometers are mounted. The rolling element fault, on the other hand, is not present at all test conditions as explained earlier (the faulty ball may change its rotational axis and thus may not always be over rolled at the same point). The BPFI fault is less strong in appearance than the BPFO fault as the BPFI related signal may undergo more attenuation through the bearing. Hence the following comparisons of the influences of speed and load on bearing faults are limited to outer race fault only.

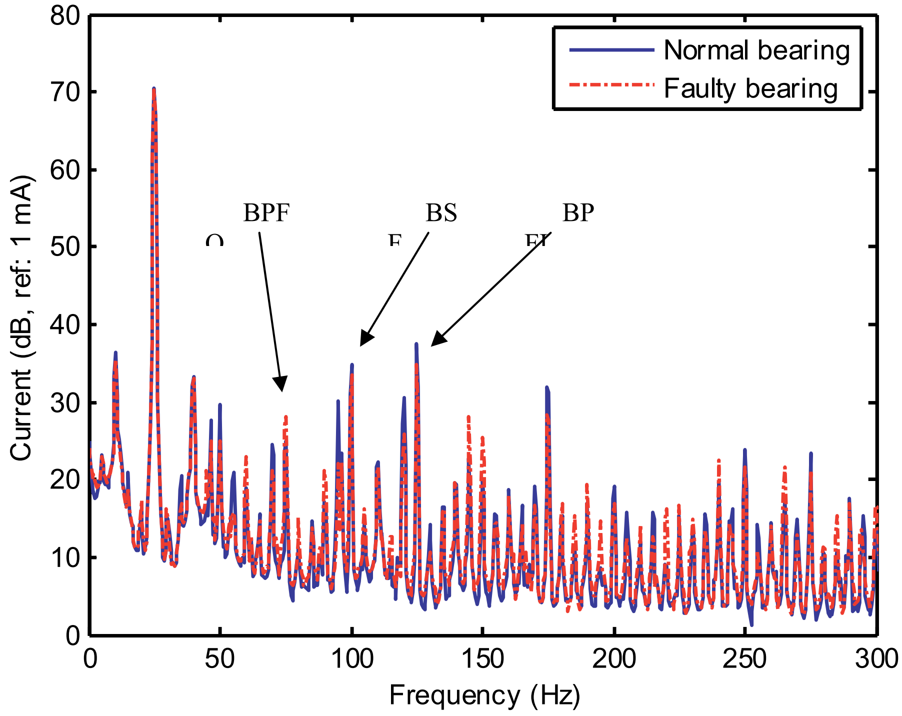

Figure 9. Spectral comparison of current signatures at 25 Hz and 0% load

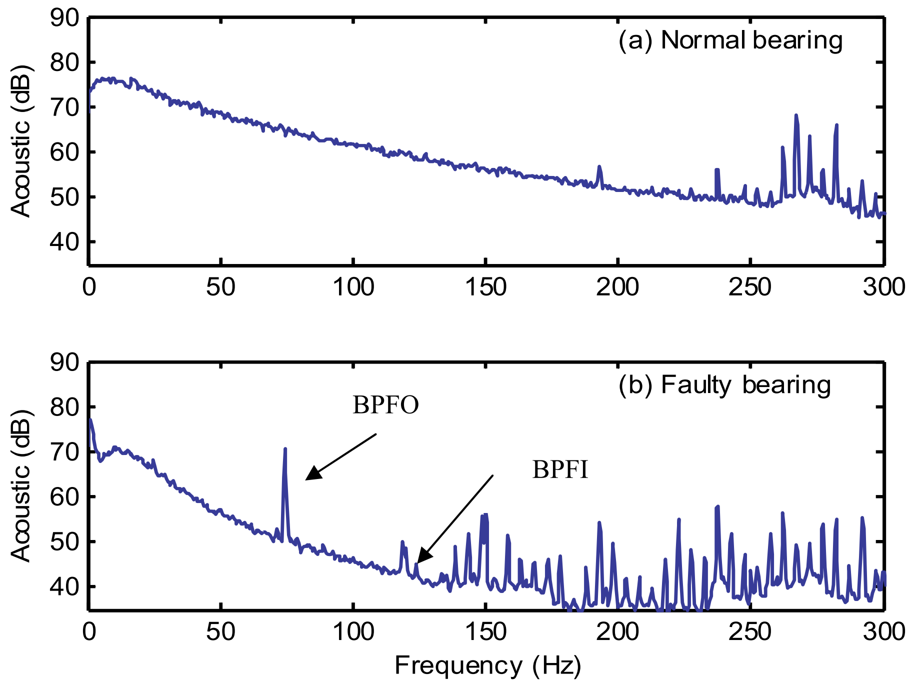

Figure 10. Spectral comparison of acoustic signatures at 25 Hz and 0% load

Figure 11 shows the influence of load on BPFO amplitudes at 15 Hz from the radial vibration signatures. First, both the normal and faulty BPFO spectral amplitudes decrease with the increase of load. Hence, the influence of load on bearing fault spectral amplitudes is limited. This is confirmed by the fact that the increase of load resulted in the decrease of spectral amplitudes at other driving frequencies and other faults (e.g. BSF and BPFI). Second, the amplitude differences between the normal bearing (circled line) and faulty bearing (stared line) in Figure 11 are the result of BPFO fault.

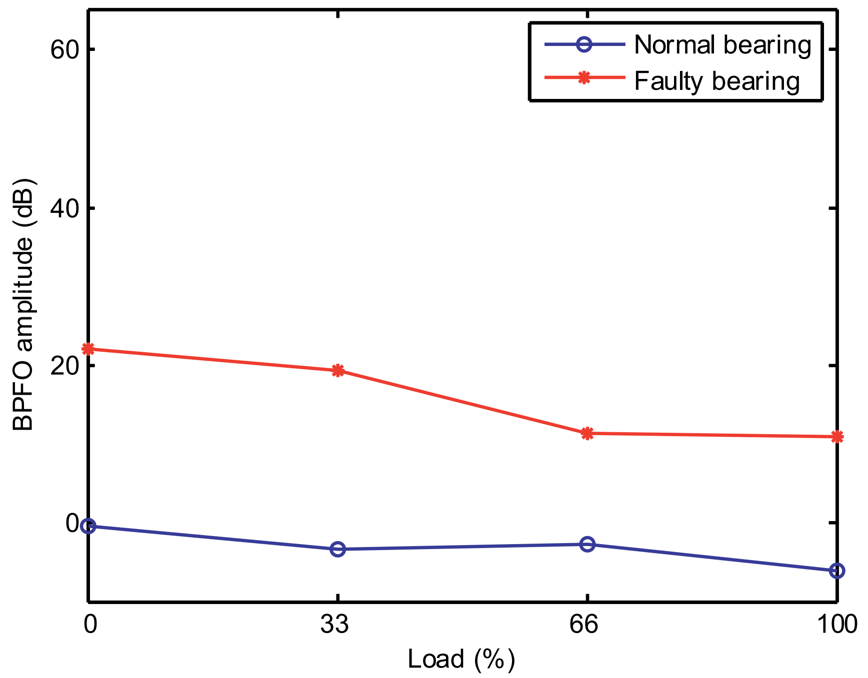

Figure 11. Influence of load on radial vibration BPFO amplitude at 15 Hz

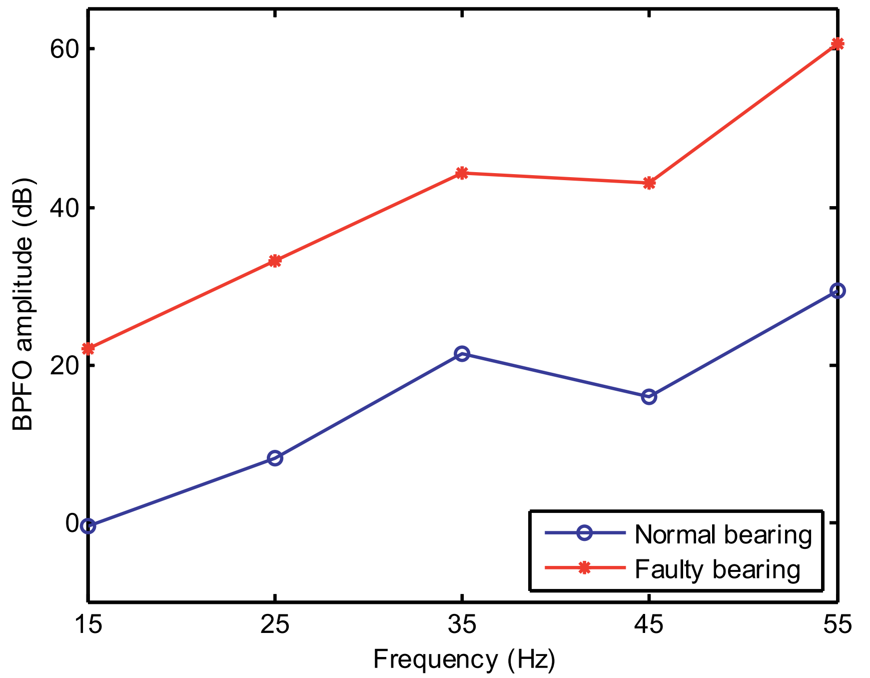

Figure 12. Influence of speed on radial vibration BPFO amplitude at 0% load

The influence of driving frequency on the radial vibration's BPFO spectral amplitudes is illustrated in Figure 12. In Figure 12, both the normal and faulty bearing spectral amplitudes increase with motor speed. The comparison clearly indicates that the spectral amplitudes are more prone to be influenced by motor speed. Figure 13 shows the acoustic spectral comparison of BPFO amplitudes between normal and faulty bearings at no load (0% load). Similar to vibration spectra in Figure 12, both amplitudes increase with motor speed.

In general, the analysis of vibration signatures is able to show significant differences in rolling element bearing faults over all load and speed conditions. However, vibration signatures contain a variety of interferences and harmonics from other vibration sources such as the gearbox. This, to some extent, makes the detection of bearing faults difficult in the presence of interferences. The analysis of acoustic signatures shows that the bearing fault frequencies are clearly identifiable in acoustic spectra. Furthermore, acoustic signatures contain fewer interferences and harmonics than vibration and current signatures in lower frequency bands. This makes acoustic analysis very attractive in the detection of bearing faults. The baseline spectral difference is clearly due to the change of motors. The current signature is least sensitive to bearing faults. Hence bearing faults would more likely induce significant changes in vibration and acoustic signatures rather than in current signatures.

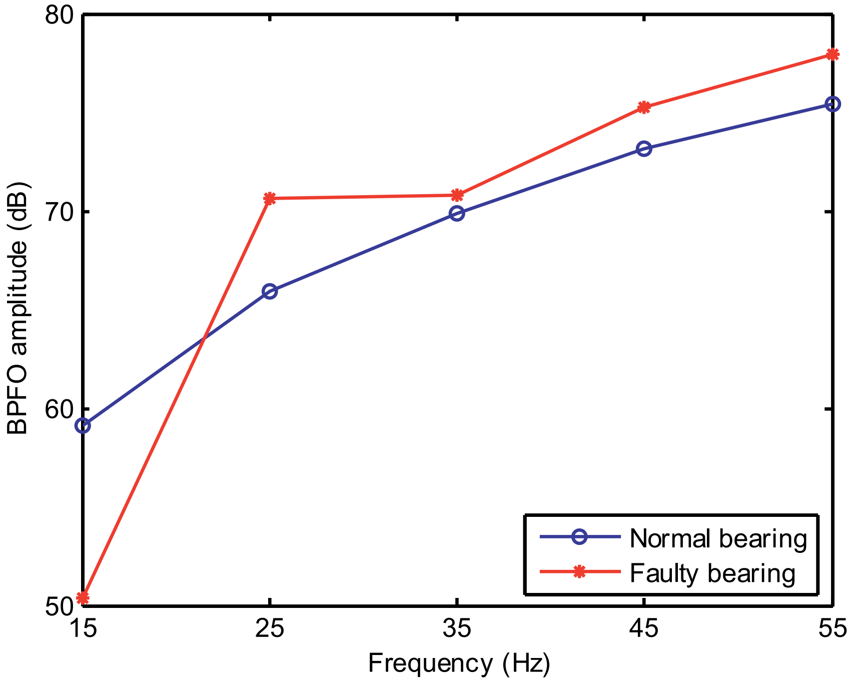

Figure 13. Influence of speed on acoustic BPFO amplitude at 0% load.

5 CONCLUSIONS

For the detection of the motor broken rotor bar fault, the stator current is the most sensitive method. The spectral analysis of stator current signatures indicated that the first few order sideband harmonics could be identified from the Fourier series based spectra. The amplitudes of these sidebands increased when the load was increased. The analysis of both the radial and axial vibration signatures was also able to show the spectral differences between motors. Contrary to the stator current method, the sideband amplitudes from the vibration signatures depended more on motor speed than on external load. The acoustic signatures also contain motor broken rotor bar information. The spectral analysis of the acoustic signatures was able to reveal the sidebands around the driving frequency.

Comparatively, the vibration method is most sensitive to the detection of bearing faults. The spectral differences between normal and faulty bearings at bearing fault frequencies are higher than those from current and acoustic spectra. However, vibration signatures contained a variety of harmonics and interferences making it difficult to identify bearing fault frequencies. Similar to vibration analysis, the current signatures were also inundated with harmonics and interferences make the method less sensitive to bearing faults. The analysis of bearing acoustic signatures showed that most bearing fault-related components could be easily identified in acoustic spectra. In the lower frequency band, the acoustic signatures contained fewer interferences and harmonics. This makes the acoustic analysis more attractive in bearing fault detection.

In general, the successful detection of induction motor faults depends on the selection of appropriate monitoring methods. From the results presented in this paper, it can be stated that the stator current method is sensitive to motor electrical faults while the vibration method is sensitive to motor mechanical faults. The acoustic analysis can be used as a supplementary method in the presence of noise and interferences.

YOU CANNOT MANAGE WHAT YOU CANNOT MEASURE: AN INFORMATION SYSTEMS BASED ASSET MANAGEMENT PERSPECTIVE

Abrar Haider, Andy Koronios, Gerald Quirchmayr

School of Computer and Information Science, University of South Australia, Mawson Lakes, Adelaide 5095, Australia.

Abstract: Measuring the impact of implementation of information systems for asset management is a complex issue; due to the stochastic nature of process variables, substantial effects of information systems on the way users embrace these systems and consequently execute the business processes, and the high expectations that asset managing businesses associate with the use of information systems. This complexity can partly be attributed to the technology push strategy, rather than technology pull strategy, that asset managing businesses adopt to introduce information systems in to the business. Therefore, in order to take optimum advantage of information systems with regards to process efficiency, effective control, and management, it is important to have effective measurement mechanisms that help managers to measure Information systems utilisation for asset management process. This paper presents a measurement framework that assesses the impact of information systems at each stage of asset lifecycle management. The proposed framework based on generative learning, such that it examines the interpretation of asset management strategy through the use of information systems within the business and its assessment provides for strategic indicators for recalibration of asset management strategy as well as highlights the roadmap for future technology investments. This assessment allows for asset management processes and their stakeholders to adopt a technology pull strategy, which provides the strategic fit between processes and technology; thereby allowing the business to leverage optimum advantage of technology through rationalized investments.

Key Words: Asset Management, Asset Maintenance, Performance Evaluation, Information Systems.

1 INTRODUCTION

Rationalising size and quality of investments in information technologies along with improvements in organisational performance is on the strategic agenda of businesses around the globe. Nevertheless, businesses also take a few aspects for granted when it comes to adoption and implantation of information technologies. A common example is the massive investment in enterprise resource planning systems that carries the belief that its adoption would become a driver of operational excellence and an important source for business value. However, adoption of information technologies, particularly that of information systems (IS), entails taking stock of existing competencies, business architectures and processes that may be impacted by technology adoption [1]. This has particular relevance for the high risk and capital intensive businesses, such as engineering enterprises (see for example [2]). Generally, a fundamental issue with engineering enterprises is that they do not match their competencies, critical resources, and systems, with investments in technology. Consequently, there is little fit between the adopted technology and the way business is executed. This technology push strategy hampers the organisational adaptation to technology and the same time does not allow the business to take optimum advantage of technology. Nevertheless, in order to achieve this the business requires appropriate evaluation mechanisms that assess process performance, such that the assessment provides an understanding of the underperforming areas along with the reasons that contribute to the below par performance and the impact this underperformance man have on other areas of the business. This not only provides for the review of the performance of existing technology, but also provides for the useful indicators for future investments in technology. There are various advantages of having such a generative learning based performance measurement mechanism. Most significantly, it provides a holistic view of the whole business area and therefore highlights a road map for continuous improvement, whereby it facilitates the right choice of technology that best suits the business environment and ensures that the investments in technology are not just aimed at facilitating isolated business processes, rather each process contributes towards the overall strategic aims and objectives of the business.

This paper focuses on the IS utilised for asset life cycle management processes. It takes an asset lifecycle perspective and proposes a performance measurement framework for asset management, which assists engineering enterprises to evaluate the effectiveness of the IS utilised in the asset management lifecycle. The framework provides a cyclical approach to performance measurement such that it assesses and informs the role of IS in translating and informing the asset management strategy in a single cycle, thereby allowing for generative double loop strategic learning to enhance competitiveness of asset managing engineering enterprises.

2 PERFORMANCE ISSUES IN ASSET MANAGEMENT

An asset is the physical component of a manufacturing, production or service facility, which has value, enables services to be provided, and has an economic life of greater than twelve months [3], such as manufacturing plants, railway engines and carriages, aircrafts, water pumps, and oil and gas rigs. Accordingly, management of these assets represents a set of disciplines, methods, procedures and tools to optimise the whole life business impact of costs, performance and risk exposures associated with the availability, efficiency, quality, longevity and regulatory/safety/environmental compliance of a company's assets [4]. British Standards Institute [5] terms asset management as "combination of management, financial, engineering, and other practices applied to physical assets in pursuit of economic life-cycle costs. Its practice is concerned with specification and design for reliability and maintainability of plant machinery, equipment, buildings, and structures with their installation, commissioning, maintenance, modification, and replacement, and with feedback of information on design, performance, and costs". Nevertheless, the fundamental aim of asset management processes is the continuous availability of service, production and manufacturing provisions of assets. Consequently, asset management processes interact with a variety of other business processes, such as enterprise planning and product development, which necessitates timely and quality information interchange and coordination of activities with other functions within the business as well as with business partners, in order to allow for activities such as materials procurement, logistics, maintenance and repairs of assets, and customer relationship management. In crux, asset management is policy driven, information intensive, and is aimed at achieving cost effective peak asset performance. Asset management is not a set of isolated processes that support the life cycle of assets utilised by engineering enterprises, but these processes are actually embedded with the strategic processes of the business and have a direct impact on the overall profitability and efficiency of the businesses, as shown in Figure 1.

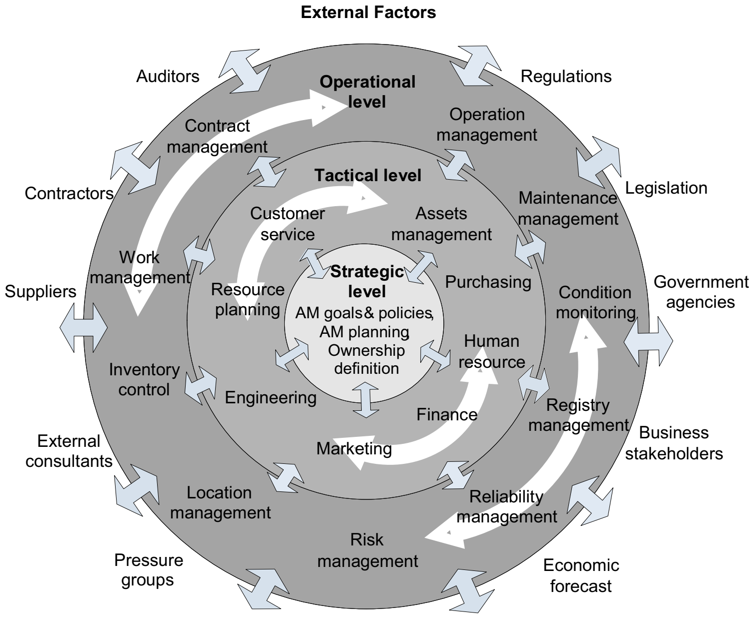

Figure 1: Asset Management Overview (source [3])

An asset lifecycle starts at the time of designing the manufacturing or production system, and typically illustrates, stages such as, asset commissioning, operation, maintenance, decommissioning and replacement. Market demand and supply dynamics derive product and services design, and this product and services design derives production. Production specifies the operational workload of an asset. Operational workload and asset design generate maintenance demands to keep the assets in running condition, whereas maintenance determines the future production capacity of the assets as well as their remnant life span. Table 1 summarises the processes and the activities involved in asset lifecycle management.

Table 1

Asset Management Lifecycle Management

Actions	Description
Strategic Planning	Planning of asset management objectives, functions, processes, technology, lifecycle costing, level of service, support infrastructure, and activities to meet business goals, stakeholder requirements, and demands management.
Focus	Strategic planning aims to provide the strategic fit between the overall business objectives and each activity performed in asset lifecycle management. Focus of strategic planning is to enhance competitiveness of the businesses through effective management of asset lifecycle.
Core Asset Management Actions	Creation or procurement, operation, condition assessment, maintenance, refurbishment, replacement, and disposal assets.
Focus	Ensuring availability, efficiency, quality, longevity and regulatory/safety/environmental compliance an asset at minimal costs
a. Asset creation/acquisition	Capital investment to acquire, construct, or improve an asset to satisfy or improve level of service, stakeholders' demand management, and production or manufacturing efficiency.
Focus	To ensure asset reliability, compliance and increased availability through effective design and best possible economic tradeoffs; for example high development costs might be traded off against lower maintenance costs through improved reliability. Development costs themselves may be offset through increased asset availability leading to increased production output.
b. Asset Operation	Smooth asset operation through close collaboration with maintenance function, and providing feedback on asset operational behavior to design function.
Focus	Efficiency and quality, regulatory/safety/environmental compliance of asset operation through conformance with planned operating conditions, as designed instructions, and environmental regulations.
c. Asset Operation Assessment	Asset operation condition monitoring to assess the ability of asset to meet required service levels and mitigate operational risks, including continuous or periodic inspection, assessment, measurement, reporting and interpretation of resulting information to indicate the condition of the asset in order to specify the nature and timing of maintenance.
Focus	To ensure asset longevity by proactively assessing asset condition in order to predict developing failure conditions, such that the subsequent maintenance execution and resources could be planned.
d. Asset Maintenance	Sustain and where necessary performance necessary repair and maintenance on assets in such a way that they continue to fulfil their functions and make the required value adding contribution to the manufacturing or production process, including actions such as spare supply chain management, maintenance planning and maintenance workflow execution, routine repairs, and testing.
Focus	Ensuring efficiency and longevity of asset by taking necessary actions to retain an asset to near original asset configuration and condition by decreasing its rate of deterioration, thereby minimising asset downtime.
e. Asset Rehabilitation	Rehabilitation of an asset through technology refresh, end of need, or maintenance; including actions such as treatments for improving condition either to attain as designed/as constructed condition or to exceed the as designed/as constructed condition in order for the asset to function at a satisfactory level of service for a prolonged time frame.
Focus	Review of asset configuration, type, location, and service delivery aspects, and their fit with the strategic business objectives.
f. Asset Replacement/Disposal	Investment aimed at replacing or reconstructing an existing asset in order to enhance level of service, and/or improved configuration, and/or change in physical location. Asset disposal or retirement means rationalisation of an asset according to safety/regulator requirements when it is no longer in service.
Focus	Continuous improvement opportunities in asset design and configuration, in order to provide elevated level of service.

Continued

Actions	Description
Asset Lifecycle Support	Asset lifecycle support is aimed at having requisite infrastructure supporting life cycle decisions of an asset, whereby the essential gaol is to identify all available options and select the most efficient and cost effective option.
Focus	Financial and non financial infrastructure aimed at enhancing the quality of asset lifecycle management.
Asset Lifecycle Costing	Calculation of asset lifecycle cost benefit analysis including asset design, asset procurement and/or construction, asset operation, asset maintenance and support, and asset retirement and disposal costs. It also contributes to assessment of high-cost contributors; cause and effect relationships; potential areas of risk; and identification of areas for cost reduction.
Focus	A systematic approach to recording and analysing costs associated with each stage of asset life cycle, so as to provide asset lifecycle management decision support in terms of economic tradeoffs and cost benefit analyses.
Asset Lifecycle Decision Support	Availability of complete, current, and accurate information on each asset, including its design, construction, configuration, location, workload, health status and history, cost benefit analysis, and the physical environment that it operates in.
Focus	An integrated approach to economic and performance tradeoffs and lifecycle decisions, through organization of information relating to asset design, operation, condition, maintenance, refurbishment; skills and support infrastructure to ensure asset reliability, availability, and quality; analytic models that predict future changes in asset design, operation, condition, as well as the variations in support mechanisms to forecast and plan for resources; and cost benefit analysis for tradeoffs regarding asset design, operation, maintenance, renewal, and decommissioning etc.
Asset Lifecycle Technology Support	Combination of hardware; software; information acquisition, processing, communication and storage infrastructure; and skills of employees to process information with the hardware and software; to accomplish various asset management processes and providing required outputs for effective asset management.
Focus	Strategic fit between technology and asset management processes, aimed at availability of timely, consistent, complete, accurate, and reliable information.
Asset Management Performance Assessment	Review and assessment of asset lifecycle management actions to measure their effectiveness in satisfying business needs.
Focus	Audit and assessment of implementation and execution of planned activities against documented gaols, objectives, strategies, and stakeholder requirements aimed at continuous improvement of the asset management process.
Asset Lifecycle Learning	Profiling asset operation, managing lifecycle knowledge, and feedback for cost effective, better understanding, and continuous improvements in asset design, operation, maintenance, reinvestment, compliance, and asset lifecycle support infrastructure and resources.
Focus	Preservation and use/reuse of asset management knowledge for subsequent strategic planning cycles.

(Adopted from [3], [4], [6-10])

It is clear from the above that IS utilised in asset management not only have to provide for the decentralized control of maintenance tasks but also have to act as instruments for decision support. An important aspect of asset lifecycle management is the learning or knowledge gained at each stage, which provides for the feedback to other processes. For example, asset operation profiling has significance for asset redesign as well as asset maintenance and asset operation cost benefit analyses and lifecycle decision support. Therefore, the most crucial feature of IS for asset management is their ability to provide an integrated view of asset specific information, such that engineering enterprises are able to leverage the full potential of the IS utilised for asset management. This requires appropriate hardware and software applications; quality, standardised, and interoperable information; appropriate skill set of employees to process information; and the strategic fit between the asset management processes and the IS.

3 INFORMATION SYSTEMS FOR ASSET MANAGEMENT

Information technologies are utilised at three levels for asset lifecycle management; firstly, they are used in assets, such as microcontroller operated motors. Secondly, information technologies that are used in facilitating asset lifecycle management support processes, such as digital sensors and other condition monitoring equipment, and process control infrastructure, such as Supervisory Control And Data Acquisition system (SCADA). Thirdly, the IS that not only facilitate execution of each stage of asset lifecycle but also provide for decision support for asset life cycle management, such as asset design, maintenance planning and execution, resource allocation, and maintenance workflow execution. Standardised and quality information, therefore, is the most important ingredient of effective asset lifecycle management.

Having its origin in mass production aimed at capturing market share, quality management calls for standardization of processes managed by standardised data and facts that focus on certain targets set by informed choices. However, value of these informed choices cannot be guaranteed in business areas where such positivist assumptions are invalid (see [11], [12]). Asset maintenance is one such area within asset management, which has by and large routine processes, yet these processes operate in unpredictable environments and function on basically non-market transactions. Hence, the basic issue in asset management IS is not just the quality of converting input to output, but also the control of information guiding it and the eventual use and reuse of the resulting knowledge for decision support and enterprise wide planning. In simple words, the issue is not only doing things right, but also to have knowledge of what are the right things to do. On the contrary, while maintenance activities have been carried out ever since advent of manufacturing; modelling of an all inclusive and efficient maintenance system has yet to come to fruition ([13], [14]). This is mainly due to continuously changing and increasing complexity of asset equipment, and the stochastic nature or the unpredictability of the environment in which assets operate, along with the difficulty to quantify the output of the maintenance process itself [15]. At the same time, in response to the competitive pressures, maintenance strategies that once were run-to-failure are now fast changing to being condition based, thereby necessitating integration of asset management decision systems and computerized maintenance management systems in order to provide support for maintenance scheduling, maintenance workflow management, inventory management, and purchasing [16]. Businesses are now aiming for ways to providing direct connections from their asset management systems to Maintenance, Repair, and Overhaul/Operations procurement systems, which may allow for paperless purchasing of parts and offer considerable time and cost savings compared with traditional purchasing methods.

Nevertheless, in order to leverage the advantages of technology asset managing organisations need to find the fit between technology and the processes. For example, a typical water pump station in Australia is located away from major infrastructure and has considerable length of pipe line that brings water from the source to the destination. In this situation, assets are deployed over an area of various kilometres; however, the demand for water supply is continuous for twenty four hours a day, seven days a week. Although, the station may have some kind of an early warning or process control and condition monitoring system installed, such as Supervisory Control and Data Acquisition (SCADA), maintenance labour at the water stations and along the pipeline is limited and spares inventory is generally not held at each station. Therefore, it is imperative to continuously monitor asset operation (which in this case constitutes equipment on the water station as well as the pipeline) in order to sense asset failures as soon as possible and preferably in their development stage. However, early fault detection is not of much use if it is not backed up with the ready availability of spares and maintenance expertise. The expectations placed on water station by its stakeholders are not just of continuous availability of operational assets, but also of the efficiency and reliability of support processes. Elimination and control of production irregularities and disturbances is, therefore, necessary for continuous production and service provision, and customer satisfaction. However, situation on ground is far from being perfect, for example, data is captured both electronically and manually, in a variety of formats, shared among an assortment of off the shelf and customized operational and administrative systems, communicated through a range of sources and to an array of business partners and sub contractors; and consequently any disparity in data at the acquisition level leads to the inability of quality decision support for asset lifecycle management [17]. In the prevailing circumstances, existing asset management IS could best be described as useful pools of isolated data that are not being put to effective use to create information and business intelligence. Most engineering enterprises mature technologically along the continuum of standalone technologies to integrated systems, and in so doing aim to achieve the maturity of processes enabled by these technologies and the skills associated with their operation [1]. Konradt et al [18] further assert that engineering enterprises adopt a traditional technology-centred approach to asset management, where technical aspects command most resources and are considered first in the planning and design stage. Processes, human and other organisational factors are only considered relatively late in the process, and sometimes only after the systems are operational. Consequently, engineering enterprises struggle to implement cost effective asset management strategies that best suit the business; develop lifecycle asset management competencies; plan an effective exit strategy for assets rendered obsolete through technology refresh or through end of need; and provide a credible charge-back system to allocate costs to the business lines and thus ensure that everyone is involved in avoiding redundancy and wastage of efforts [1]. In order to make an effective investment into technology, it is important for the business to take stock of the existing IS and the asset management processes that they enable.

This highlights the need for a comprehensive performance measurement system that not only provides insights into the effectiveness of the IS used for asset lifecycle management, but also provide feedback on their fit with other business information systems so as to provide a lifecycle perspective of asset management to asset managers. Such a performance measurement system needs to be three dimensional (as shown in Figure 2), with each asset lifecycle management process being measured against the four dimensions of an IS, i.e. information, staff skills, software, and hardware; as well as the impact of each asset lifecycle process in terms of asset efficiency, availability, longevity, quality and reliability, and compliance with the environmental and operating legislations.

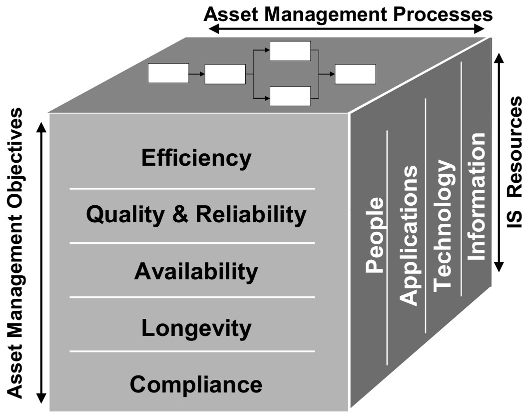

Figure 2: Measurement dimensions for IS based Asset Management

4 PERFORMANCE MEASUREMENT SYSTEMS

There has been numerous business improvement methodologies developed and implemented. These methodologies represent a blend of theory and practice, with each having its own way of performance measurement that is largely dependent upon the target business area. Some of the leading initiatives in this regard include Benchmarking, total quality management, Six Sigma, European Foundation for Quality Management Business Excellence Model (EFQM), business process re-engineering, and balanced scorecard. These methodologies constitute the basis of the most of performance measurement and management initiatives tailored by businesses to meet their needs. Remenyi et al [19] summarise the methodologies developed for performance assessment, and suggest that their focus has been on

a. Strategic match analysis and evaluation,

b. Value chain assessment (organisation and industry),

c. Relative competitive performance,

d. Proportion of management vision achieved,

e. Work-study assessment,

f. Economic assessment - I/O analysis,

g. Financial cost benefit analysis,

h. User attitudes,

j. User utility assessment,

k. Value added analysis,

l. Return on management, and

m. Multi-objective, multi-criteria methods.

Engineering enterprises have adopted these methodologies in a variety of ways aimed at different business areas and processes, such as for manufacturing planning and control [20], product development process [21], human resources development ([22], [23]) and service or facility management [24]. Although research has paved the way for major developments in the filed of business improvement, yet it is interesting to note that asset performance measurement has been largely limited to physical inspection of plant and equipment for its health assessment. Nevertheless, role of IS in asset management is not just of a process enabler, but also of translating strategic business goals and objectives into action. Therefore, it is important to have a performance measurement mechanism that provides for assessment of this strategic translation and also highlights the gaps such that corrective actions could be taken to enhance the competitive of the overall business. These characteristics entail that an appropriate performance measurement system for asset management should:

a. Focus on business processes as well as the structures that deliver value [25];

b. Integrate different aspects of asset management, such that they constitute a chain for business competitiveness ([26], [27]);

c. balance the needs of various stakeholders, such as business partners or third party service providers, customers, employees, regulatory agencies, and society at large ([20]; [25]);

d. be information driven such that it provides inputs to strategy re-calibration rather than being steered by the business strategy alone ([28], [29], [25]);

e. Conform to business objectives ([[28], [30]);

f. Aim at competency development and business intelligence infrastructure development in order to create and sustain value for asset management processes ([27], [25]; and

g. Provide financial [27] as well as non financial assessments [25].

In engineering enterprises strategy is often built around two principles competitive concerns and decision concerns. Competitive concerns set the gaols of manufacturing, whereas decision concerns deal with the way these goals are to be met [48]. It is therefore, important to assess the role of IS in providing strategic executive decision support for value added asset management, in terms of the choice of assets, their demand management, support infrastructure to ensure smooth manufacturing or service provision, and efficient ways of doing business. These efficient ways mean choices of the business such as business partners, outsourcing of asset management functions, and service provision to third parties [47]. Fundamental requirement of IS at this stage is to provide decision support in terms of indications on economic tradeoffs and/or alternatives that help senior management in making strategic decisions. These decisions are not made in isolation; in fact, they are made in conjunction with the asset demand and stakeholders requirements. Therefore at the strategic level it is important to assess the effectiveness and ability of the IS in terms of enabling strategic asset management planning, goals, objectives and executive decisions.

A usual manufacturing cycle starts with specification of the products and services that the business aspires to offer its customers in conformance with its business strategy. Any mismatch between what the market demands, manufacturing process design, and planning has a detrimental effect on the overall performance of the business [49]. Nevertheless, this specification illustrates the types of assets and processes that the business needs to put in place to produce services and products, also called asset demand specification. At this stage, it is important to assess if the designers have access to integrated information in order to process it to obtain knowledge of factors such as, the characteristics of the environment that the business operates in; design, configuration, and workload of each asset; asset and/or site layout design and schematic diagrams/drawings; asset bill of materials; analysis of maintainability and reliability design requirements (e.g. HAZOP); and failure modes, effects and criticality identification for each asset. Planning choices at this stage drives asset behaviour, therefore it is important to assess if the existing information systems are capable of providing the right information, such that choices could be made to ensure asset availability, reliability and quality of its operation, and efficiency.

Design of an asset has a direct impact on its productivity. Productivity, itself, is concerned with minimising the disturbances relating to production or service provision of an asset. A production or service provision disturbance is an unplanned or undesirable function or failure of an asset [55]. It can be classified as asset downtime, speed or operation, and quality losses. It is important to note that disturbances do not only occur due to a mechanical or electrical fault, they can also occur due to some process and procedural issues. Disturbances occur in one of the three ways, as suggested by El-Haram [56], i.e., when an asset become inoperable suddenly, and can no longer perform its required operations; when an asset cannot fulfil some or all of its operations at the same performance standard as originally specified; or when an asset gradually deteriorates to an unsatisfactory level of performance or condition, and its continued operation is unsafe, uneconomical or aesthetically unacceptable. These disturbances can further be attributed to many causes. According to one study, more than one third of the production disturbances were caused by design errors [57]. Therefore, at this stage it is important to assess if the IS are capable of providing integrated feedback to maintenance and design functions regarding factors such as asset performance profiling; detection of manufacturing or production process defects; asset condition monitoring and inspection; asset failure notifications; quality control and assurance at each stage of asset operation; and processes, tests, analysis (FMECA etc) and standards to be applied for the validation of asset performance.

Every asset generates some maintenance during its lifecycle. The aim of asset lifecycle support is to keep or restore and asset to its original or near original condition and service levels. This requires integration of technical, administrative, and operational information of asset lifecycle, such that informed and cost effective choices could be made about maintaining an asset and its remnant lifecycle. Therefore, the IS should be capable of handling the maintenance workflow execution as well as project management along with processing and providing information on factors such as, Asset failure and wear pattern; routine maintenance work plan generation; emergency maintenance scheduling and follow up actions (such as disaster containment, maintenance resources allocation etc); asset shutdown scheduling; maintenance simulation; testing after servicing/repair treatment; identification of asset design weaknesses; and asset operation cost benefit analysis. Maintenance, however, influences many areas of the business, such as asset availability in supporting just in time manufacturing principles [50], relationship between technology and operations [58], product quality [7], and achieving and sustaining a safe workplace and environment [38]. Therefore, it is important to assess the role of IS in providing for the up-to-date information on each asset's health to other functions such as asset design and asset operation. This information is extremely important in asset improvements/refurbishments as well as in finding optimal ways of operating an asset.

Nevertheless, an important aspect of effectiveness of asset management initiatives is the efficiency with which different processes are executed and the competencies of employees who carry out these processes. This efficiency comes from a variety of factors such as application of appropriate socio-technical systems principles and techniques make asset management creative and more productive; availability of asset lifecycle information and knowledge throughout the organisation; and development of employees skills to effectively use technologies associated with asset lifecycle management. IS provide for this value chain integration of asset management, therefore, it is important to assess the effectiveness of IS in terms of operational efficiency, and the ability of employees to operate IS and process information contained in them.

A common trend among engineering enterprises is the outsourcing of core activities such as maintenance. This trend is quite common among for complex assets, such as aircrafts, and oil and gas rigs. In these circumstances neither the asset owning business, and nor the asset maintaining business has a complete understanding of asset behaviour, which obviously impacts asset lifecycle decision support. It is important to assess the level of integration that the IS provide in bringing together business stakeholders, such as business partners, customers, and regulatory agencies like environmental and government organisations. The idea behind this is to assess the level of information and knowledge being shared among the stakeholders to enhance the efficiency and competencies of the asset management process, by examining the IS maturity for factors such as third party services management; contract management; integration of inter organisational applications and processes; customer feedback and satisfaction measurement; and sharing common coding and databases with business partners.

5 IS BASED ASSET MANAGEMENT EVALUATION

From the discussion above, two characteristics stand out. First, IS based asset management performance evaluation entails taking stock of effectiveness of IS in facilitating each asset management lifecycle process; and second, how the IS provide for the functional integration between various asset management processes. Table 2 illustrates an evaluation framework for IS utilised for asset management. In this framework asset management process has been decomposed into seven perspectives, which cover the whole of asset lifecycle as well as provide for the functional interrelations; thereby forming a value chain that provides value added asset management.

Table 2

IS based Asset Management Performance Measurement Perspectives

Perspective	Description	References
Design	Planning of design and/or improvements in asset design and manufacturing processes according to feedback from asset installation, commissioning, operation, maintenance and replacement; and aimed at demand management as per stakeholders' expectations.	[3], [14], [32], [33], [34]
Productivity	Asset availability and reliability by managing quality of operations, and mitigating risks posed to assets and to their operating environment; ensuing flow of information to maintenance and design regarding asset operation feedback.	[3], [4], [16], [20], [33], [34], [35], [37]
Support	Financial and non financial resources support for asset lifecycle aimed at enhancing the quality of asset operation; decision support for effective asset health management; integration of technical, administrative, and operational information of asset lifecycle aimed at keep it, or restore it to original or near original condition and service levels.	[3], [6], [7], [8], [14], [20], [32], [36], [38], [39], [44], [50]
Operational Efficiency	Measure of the factors that contribute to the overall effectiveness and integration of asset lifecycle processes and functions; application of appropriate socio-technical systems principles and techniques make asset management creative and more productive; business value chain integration; skills development of employees to effectively use technologies associated with asset lifecycle management; availability of asset lifecycle information and knowledge throughout the organisation.	[3], [4], [7], [13], [16], [34], [36], [40], [41], [42], [43], [44]
Stakeholders	Integration of business stakeholders to achieve higher levels of asset management through communication and collaboration, sharing of information on asset lifecycle with subcontractors and business partners, and compliance to regulatory and environmental regulations.	[2], [3], [20], [37], [38], [45], [46]
Competitiveness	Availability of executive decision support indicators such as, asset lifecycle cost benefit analysis, operation profile, asset register to better manage asset demand and needs of stakeholders ; ability to measure the actual performance of asset lifecycle management processes against planned gaols and objectives to enhance competitiveness of the business.	[3], [6], [7], [8], [9], [14], [20], [33], [38], [47], [48], [49]
Learning	Profiling asset lifecycle, and managing lifecycle knowledge for better understanding of/and improvements in asset design, operation, maintenance, reinvestment, and compliance.	[3], [6], [7], [8], [10], [43], [51], [52], [53], [54]

Figure 3 provides the graphical representation of the evaluation framework. Here IS act as the bonding glue that provides for the functional integration of asset management process. This framework provides double loop generative learning, as it allows for assessment of IS in terms of translation of strategy into action; and also highlights the gaps between the existing and desired levels of performance, thereby informing the business strategy in the same cycle. In so doing, the organisation learns from one cycle, applies the learnings to the same paradigm and assesses its results in the next cycle. At the same time highlighting of the underperforming areas creates the need for investment in technology, which not only allows for the right choice of technology but also helps in its acceptance in the organisation. This framework is learning centric that provides for preserving the asset lifecycle knowledge, such that it is accessible to every function within the organization. This learning perspective illustrates assessing the way IS are utilised in an engineering enterprise to preserve the knowledge that it creates through other perspectives regarding asset performance and operational knowledge; asset health history; asset operation cost benefit analysis; and historic asset lifecycle performance information. IS evaluation at this perspective means assessing the ability of the existing IS to provide multi dimensional analyses on asset lifecycle information, such that asset managers can take better informed decisions about the asset lifecycle and asset management processes. These analyses provide triggers for change regarding asset design, operation, maintenance, risk management, and other aspects of asset lifecycle management, thereby allowing for creativity in asset lifecycle management. In so doing, this framework provides for continuous improvement based on generative learning.

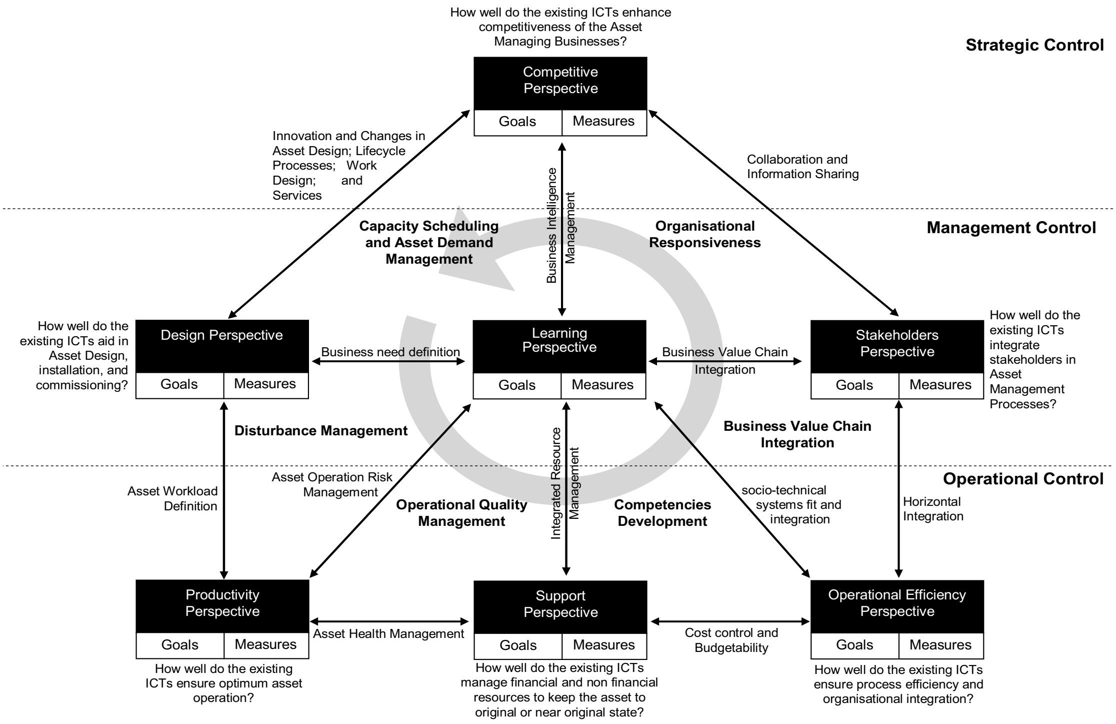

Figure 3: IS Based Asset Management Performance Evaluation Framework

6 DATA COLLECTION

In order to provide an integrated assessment of IS based asset management, as suggested in figure 2, an assessment approach as illustrated in Table 3 could be adopted. Processes under each perspective could be assessed for dimensions of IS, i.e. information, people, software, and technology on a scale of 1 to 5. In the same way, depending upon the characteristics of the process, its purpose, i.e. primary or secondary, could be assessed. This information could be collected though surveys and with the help of Analytic Hierarchy Process (AHP) (Saaty 1990) and Multi-Attribute Utility Theory (MAUT) (Goicoechea et al. 1982) it could be aggregated to provide performance measurement of IS for processes relating to each of the perspectives identified for asset management process.

Table 3

Data Collection Tool for the Proposed Framework

	Asset Performance Criteria						IS Dimensions			
	Efficiency	Longevity	Availability	Compliance	Reliability		People	Software	Technology	Information
Design Perspective										
Asset bill of materials										
Naming and numbering of assets for configuration management										
Use of test and historical maintenance data of similar assets in establishing and evaluating operational tasks										
Identification of risks posed to asset operation (environmental, OH&S)										
Analysis of maintainability and reliability design requirements (e.g. HAZOP)										
Failure modes, effects and criticality identification

Learning Perspective										
Processes										

7 CONCLUSION

This research provides the basis for research into comparative analysis of IS based asset management for industrial and infrastructure assets to be conducted through the Cooperative Research Centre for Integrated Engineering Asset Management (CIEAM). This paper has proposed and theocratically demonstrated an approach for linking asset management to strategic competitiveness of an engineering enterprise through IS maturity assessment and control. It has particularly emphasised the use of IS for functional integration by providing a strategic fit between the structure and infrastructure of asset lifecycle management process. It has also shown how asset managing businesses could benefit by taking a lifecycle perspective of asset management, such that assets are treated as business enablers rather than just production or service provision enablers.

Abstract: We conducted experiments on a bridge to evaluate the ability of fiber optic inclinometers to detect changes in two kinds of vibration characteristics: the characteristic frequencies of steady-state vibration and the average maximum amplitude of impulsive vibrations caused by the passage of heavy vehicles. The experiments were performed on an I-beam girder bridge with tuned mass dampers. The dampers were turned on and off to change the target characteristics. The results showed that the changes in the target characteristics could be detected from the vibration measurements of the inclinometers. Fiber optic inclinometers are thus an effective tool for monitoring bridge health, not only in disaster situations but also under normal conditions.

Key Words: FBG inclinometers, health monitoring, fiber optic sensors, vibration analysis, bridge

1 INTRODUCTION

In a disaster situation, such as an earthquake or flood, many bridges spread out over a wide area may suffer various levels of damage. Safe evacuation of residents and timely delivery of relief supplies requires accurate and quick assessment of the structural damage to each bridge. Under normal conditions, bridges suffer continuous damage from the passage of heavy vehicles and the deterioration of their structural materials over time, so regular maintenance is needed. To meet the information needs for both situations, there is an increasing demand for real-time information gathering, continuous remote surveillance, and quantitative assessment. That is, there is a strong need for bridge health monitoring using sensors and networks[1]. Fiber optic sensors are well suited for health monitoring systems[2,3] because they reduce the number of transmission cables and improve the reliability of data transmission systems compared with conventional mechanical and electrical sensors. This is because many fiber optic sensors can be connected in series through a single optical fiber in 20km without a relay and can be used even without a power supply. Remote surveillance of the girder inclinations of bridges through optical fiber networks enables information about structural damage to be quickly gathered when a disaster strikes, making it possible to judge whether it is safe for vehicles to pass over the monitored bridges.

Fiber Bragg Grating (FBG) sensors, one of the most exploited fiber optic technologies, have excellent sensitivity and frequency characteristics, making them well suited for bridge health monitoring through vibration measurement[4,5]. The measured vibration can be used to identify internal damage at a very early stage. For example, a decrease in the characteristic frequency of a beam means a loss of beam stiffness. Using FBG inclinometers to measure the inclination and vibration of beams enables bridge conditions to be monitored using single-fiber optic sensors in both disaster and normal situations. This sensor system simplification reduces the cost of bridge monitoring systems.

We have evaluated the effectiveness of FBG inclinometers for monitoring bridge health. We experimentally measured the changes in the average maximum amplitude and the characteristic frequencies when the tuned mass dampers on a bridge were turned on and off. Comparison of the estimated characteristics with those obtained from simultaneous tri-axial acceleration measurements showed that vibration characteristics in a particular horizontal direction can be measured by matching the measurement direction of the FBG inclinometer to the target direction.

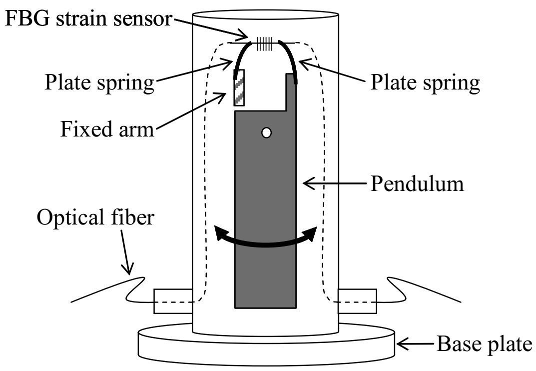

Figure 3. FBG inclinometer mechanism.

2 VIBRATION MEASUREMENT SCHEME AND SENSOR SETUP

We focused on two kinds of vibration characteristics: the average maximum amplitude of impulsive vibrations caused by the passage of heavy vehicles and the characteristic frequencies of the beams. An increase in the maximum amplitude indicates a decline in shoe functionality. Over the long term, however, the average of the maximum amplitude may increase due to an increase in the number of heavy vehicles crossing the bridge. Since such an increase would be a cause for concern, an increase in the average amplitude would indicate the need for an inspection. On the other hand a decrease in the characteristic frequency of a beam indicates a decrease in beam stiffness due to cracks, material deterioration, and so forth.

One way to detect damage due to an incident (e.g. a crack initiation) is to compare the vibration characteristics obtained for the bridge before and after the incident. This entails conducting periodic examinations, often over several years, until an incident occurs. To overcome this problem, we conducted our experiments using an I-beam girder bridge on which vibration-damping devices (tuned mass dampers, TMDs) had been installed (see Figure 1). The vibration characteristics measured when the TMDs were turned on were taken as pre-incident data, and those measured when the TMDs were turned off were taken as post-incident data. In both cases, the measurements were made using a single FBG inclinometer set on a cross beam connecting the I-beams. The ability of the FBG inclinometer to detect changes in the vibration characteristics was estimated from the measured inclination data. To verify the results, we set a tri-axial accelerometer next to the FBG inclinometer (see Figure 2).

The bridge is a part of a three-lane expressway and is crossed by about 60,000 vehicles every weekday. It has three TMDs on its cross beams at the centre of the span to reduce environmental vibration. As shown in Figure 1, an FBG inclinometer and a tri-axial accelerometer were installed on both sides of the span at the centre, the points of the bridge that suffer the most vibration due to deflection and torsion of the girders. These sensor positions are referred to as 'east side' and 'west side', and the direction of vibration to be measured is indicated by the X-, Y-, or Z-axis (see Figure 2). The sampling rate for the inclinometers was 250 Hz, and that for the accelerometer was 180 Hz. These rates are the highest available for these types of sensors.

As shown in Figure 3, the FBG inclinometers have a mechanism for generating strain in proportion to the inclination. It consists of a pendulum and a plate spring. The strain is measured with an FBG strain sensor. We call the direction in which the pendulum swings the 'measurement direction'. With this mechanism, the vibration of the body of the FBG inclinometer can be measured with the strain sensor even if the body is vibrated horizontally or vertically without being inclined. Here, however, data measured with the inclinometers is called the 'inclination'. Only one inclinometer and accelerometer pair was used in each measurement experiment. There were eight measurement patterns, which were the various possible combinations of the three measurement conditions: the sensor pair position (east or west), the inclinometer measurement direction (X- or Y-axis), and the TMD status (on or off). Each measurement was conducted for 24 hours on a weekday to make the traffic volumes comparable. The measurements thus took a total of eight days.

(c) Z-axis acceleration. (d) X-axis inclination.

Figure 4. Vibration data measured with tri-axial accelerometer and FBG inclinometer.

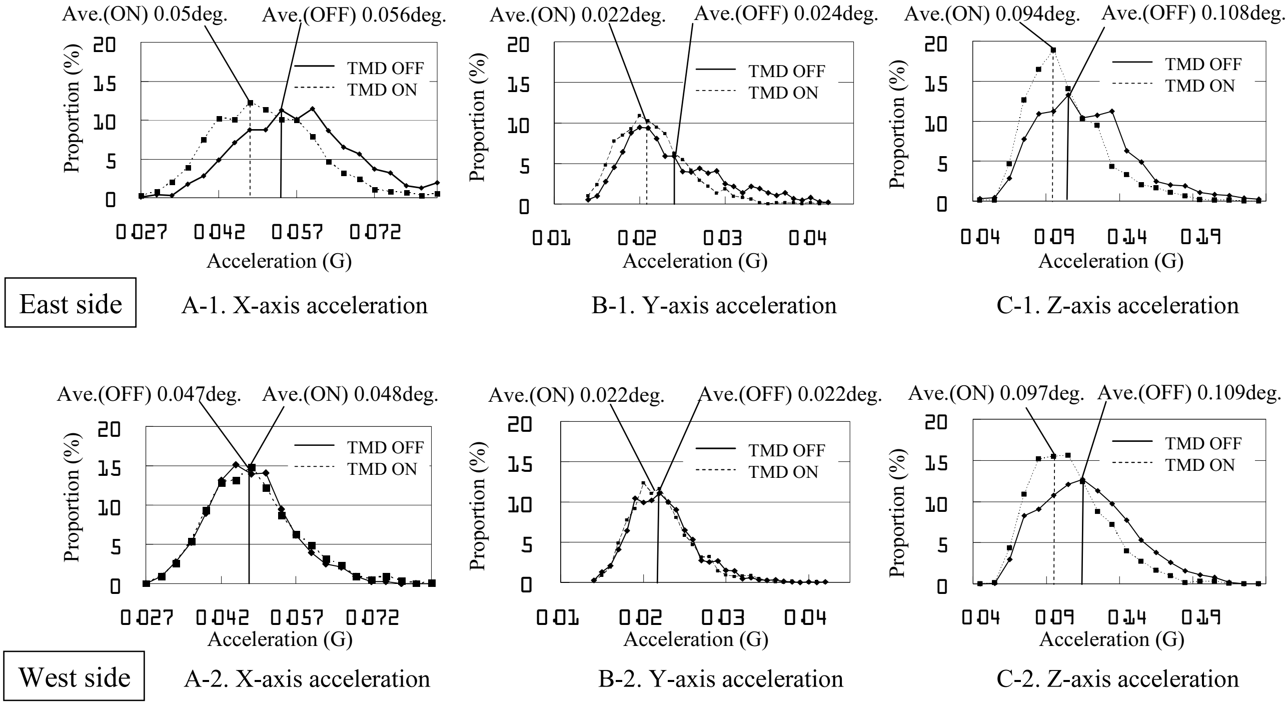

Figure 5. Histograms of maximum acceleration amplitude.

3 DETECTION OF CHANGES IN VIBRATION CHARACTERISTICS

3.1 Average maximum amplitude

To obtain vibration data when vehicles were crossing the bridge, we repeated the following two steps until all Z-axis acceleration data were scanned: (1) a time T at which the acceleration was either over 0.04 G or under -0.04 G was found in the Z-axis acceleration and (2) the data recorded from T−12 to T+28 seconds was extracted from the acceleration and inclination data. This set of data is shown in Figure 4. The total of data sets for the eight measurement patterns was 52,297 sets, so the average number per pattern was 6537.1, which is about 10% of that for the average traffic volume. Considering that a heavier vehicle creates a stronger effect on a girder, these data sets represent the passage of the 10% heaviest vehicles.

The maximum amplitude was calculated as the difference between the maximum and minimum values as shown in Figure 4. Ideally, the maximum amplitudes should be compared for data gathered when the same vehicle crosses the bridge in the different measurement patterns. This is problematic, however, because no other vehicles should be on the bridge at the same time as the measurement vehicle, and the bridge is subject to heavy traffic. Since the distribution of acceleration is usually approximately constant for the bridge, we compared the average maximum amplitudes in the measurement patterns, focusing particularly on the differences between the TMD-on and -off patterns.

Figure 5 shows the histograms and averages of the maximum acceleration vibration amplitudes. ‘TMD OFF’ means that the TMDs were off, and ‘TMD ON’ means they were on. As shown in A-1, B-1, and C-1, turning the TMDs on reduced the average for the east side by over 10% for each axis. Comparing the TMD-OFF and TMD-ON histograms in C-1 shows that above 0.11 G the average decreased, while there were marked increases at around 0.09 G due to turning on the TMDs. For the west side, the average maximum amplitudes for the Y- and Z-axes (B-2 and C-2) decreased while the averages for the X-axis increased slightly (see A-2)

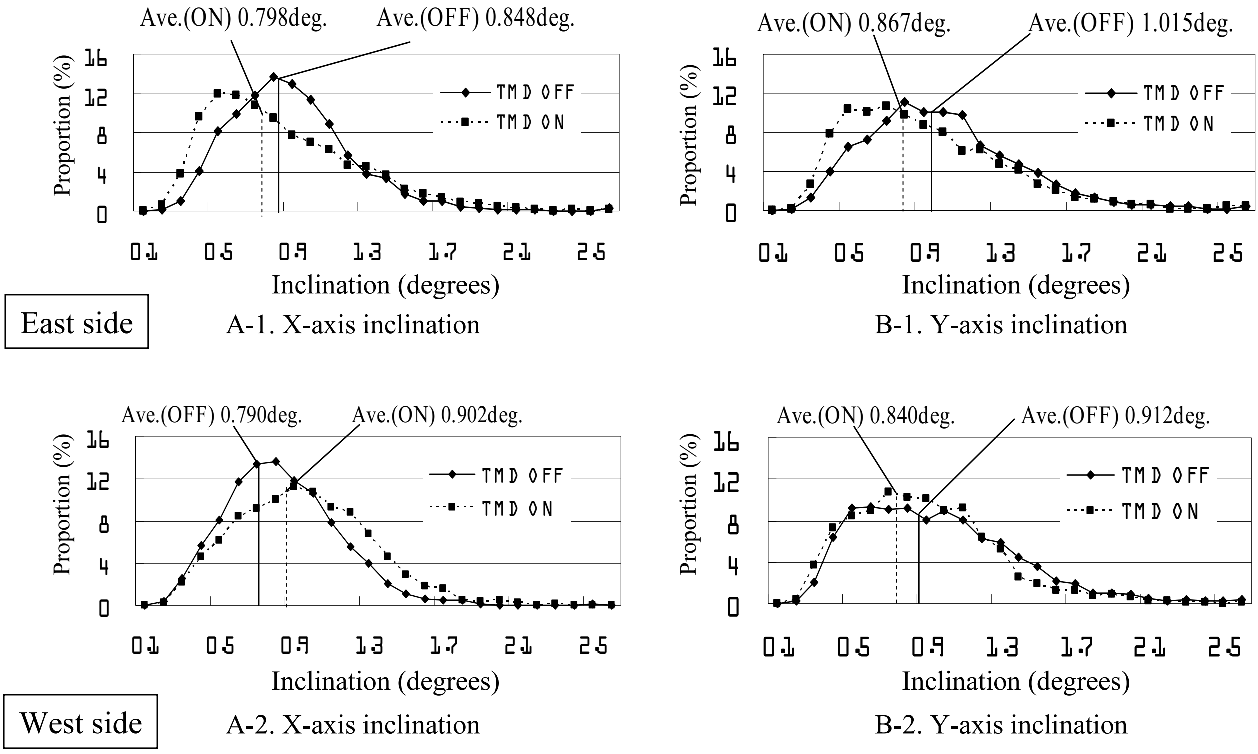

Figure 6. Histograms of maximum inclination amplitude.

Table 1: Decreases in average maximum amplitudes when TMDs were on.

		Acceleration (G)			Inclination (degrees)	
		X	Y	Z	X	Y
East side	OFF − ON	0.00639	0.00262	0.0136	0.05	0.148
	(OFF − ON) / OFF × 100	11.32%	10.83%	12.65%	5.9%	14.58%
West side	OFF − ON	−0.000625	0.000294	0.0119	−0.112	0.072
	(OFF − ON) / OFF × 100	−1.33%	1.31%	11.01%	−14.18%	7.89%

Figure 6 shows the histograms and averages of the maximum inclination vibration amplitudes. (The meanings of ‘TMD ON’ and ‘TMD OFF’ are the same as in Figure 5.) Comparing the TMD-OFF and TMD-ON histograms shows that the average maximum amplitude decreased in every case except when the FBG inclinometer was set on the west side in the X-axis direction (A-2).

The amount and ratio of decreases in the average maximum amplitudes when the TMDs were on are summarized in Table 1 for acceleration and inclination. For both, only the X-axis vibration on the west side increased when the TMDs were turned on. The tendencies of the changes in the X-axis and Y-axis averages thus coincided. This coincidence means that an FBG inclinometer can reliably detect change in the maximum amplitude of horizontal vibration. However, there is no clear quantitative relation between the decreases in acceleration and inclination.

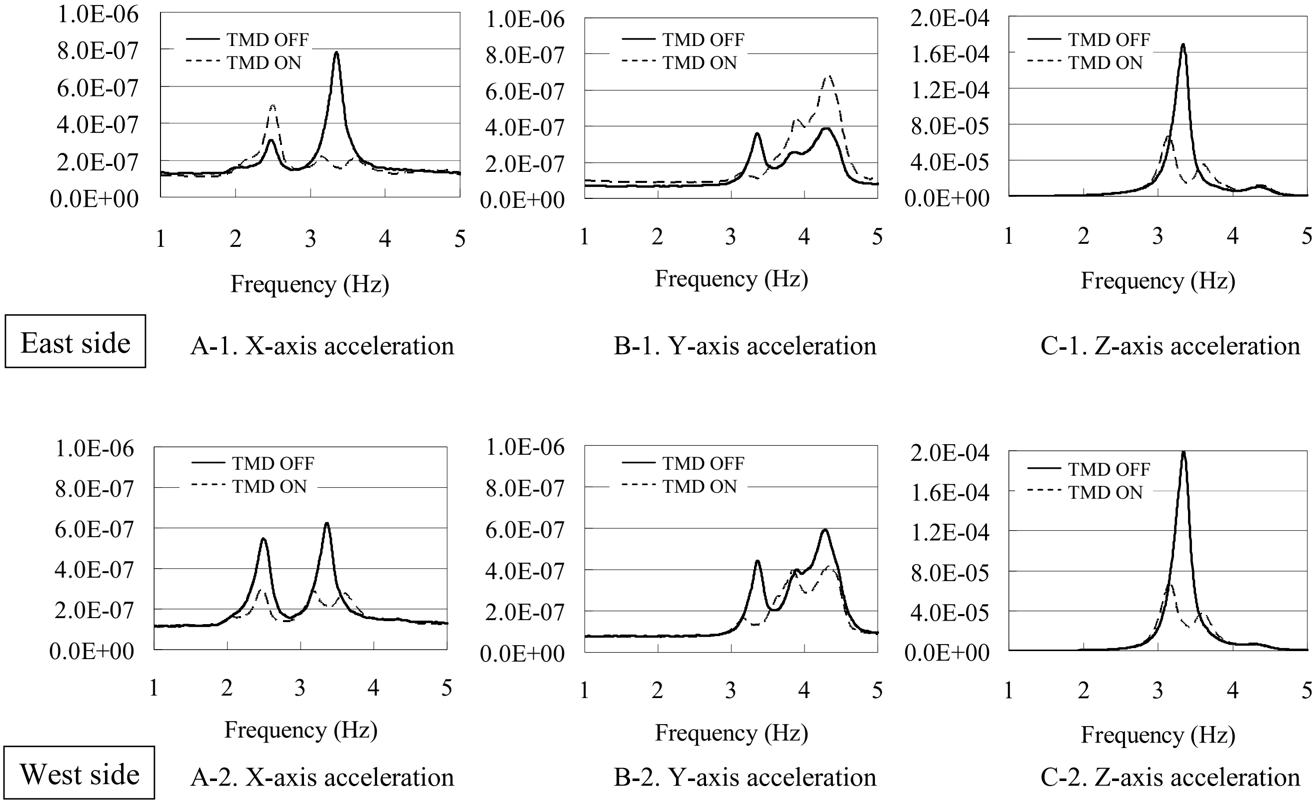

Figure 7. Power spectral densities of tri-axial acceleration.

3.2 Characteristic frequencies

To obtain the characteristic frequencies, we calculated the power spectral density for the acceleration data and the inclination data using fast Fourier transformation (FFT) and then identified peaks in the spectra. Preliminary testing had shown that identifying the peaks in the spectra for inclination vibration is difficult when the vibration amplitude is large. This is because the power of the characteristic vibrations was much smaller than that of the inclinometer pendulum, so that the peaks related to the characteristic vibrations of the bridge were not clear in the spectra. We thus used the steady-state vibration for the inclinometer measurement data. We did this by extracting the steady-state vibration portions of the inclination data. Each portion consisted of 4096 inclination values, each one less that 0.04°, for each of the eight measurement patterns. The power spectral density was then obtained by FFT for each portion. Finally, the power spectral density for each pattern was acquired as the average of the power spectral densities of the inclination parts measured for each pattern.

Figure 7 shows the power spectral densities of the tri-axial acceleration. Note that the vertical axes in C-1 and C-2 range to 2×10^{-4}, 200 times higher than the maximum in the other graphs, because the vertical acceleration was much stronger than the horizontal acceleration. A few characteristic frequencies can be perceived as clear peaks in these graphs. And the following features are found in the characteristic frequencies:

(a) For every case when the TMDs were off, there is a peak at 3.4 Hz. This peak disappeared when the TMDs were on.

(b) For the X-axis vibration, the bridge had a characteristic frequency at 2.4 Hz besides 3.4 Hz.

(c) For the Y-axis vibration, the bridge had characteristic frequencies at 3.9 and 4.4 Hz besides 3.4 Hz.

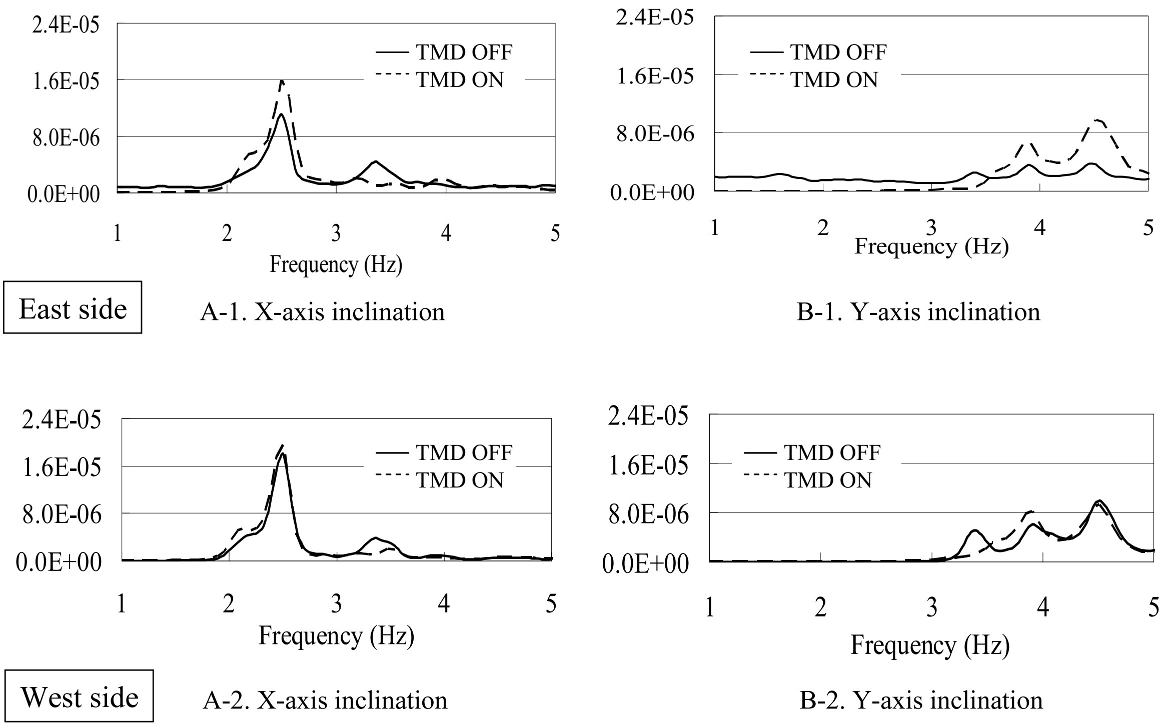

Figure 8. Power spectral densities of inclination.

The same findings hold for the power spectral densities of the inclination, shown in Figure 8. The first one means that an FBG inclinometer can detect changes in the characteristic vibration. The second two mean that an FBG inclinometer can acquire the characteristic frequencies of vibration in either the X- or Y-axis direction if its measurement direction is adjusted accordingly. As mentioned above, the vertical vibration (Z-axis vibration) at 3.4 Hz was about 200 times as strong as the horizontal vibration when the TMDs were off. The horizontal vibration also included characteristic vibration at 3.4 Hz. However, in the power spectral densities of inclination, the vibration at 3.4 Hz was weaker than the other characteristic frequencies at 2.4, 3.9, and 4.5 Hz. This means that it is possible to obtain the characteristic frequencies of horizontal vibration by using an FBG inclinometer without interference from vertical vibration.

4 DISCUSSION

Our comparison of tri-axial acceleration and inclination with regard to the vibration characteristics (average maximum amplitude and characteristic frequency) showed that it is possible for an FBG inclinometer to detect changes in the vibration characteristics caused by turning the TMDs on and off. This means that FBG inclinometers can be used to detect damage to bridges if the damage caused an increase in the vibration amplitude or a decrease in the characteristic frequency.

The experimental results for the average maximum amplitude and characteristic frequency make it clear that measurement using FBG inclinometers can reveal the vibration characteristics in the corresponding measurement direction. Even if only one FBG inclinometer is available, it is easy to change its measurement direction because the installation is on a level surface, unlike FBG strain sensors, which are stuck on surfaces with adhesive. If more than one FBG inclinometer is available, the vibration characteristics in multiple directions can be monitored at the same time because the FBG sensors can be connected in series through a single optical fiber.

However, the measurement directions of FBG inclinometers are obviously limited to horizontal ones. The ability of FBG inclinometers to detect the characteristics of vertical vibration could not be determined from our experimental results. Considering that vertical vibration is stronger than horizontal vibration, as shown in Figure 7, we need to develop a method of using FBG inclinometers to detect the characteristics of vertical vibration. In addition, inclined vibration should also be considered because inclination directly affects the measurement results. Comparison between the acceleration and inclination in the latter half of the measurement data shown in Figure 4 shows that the inclination amplitude changed while the acceleration ones were steady. The acceleration in our experiments was mainly caused by the passage of vehicles on either the east or west side of the bridge, the locations of the accelerometers. However, changes in inclination may be caused by the passage of vehicles on both the east and west sides because inclination is affected by torsion, i.e. rotation on the X-axis. This difference between the measurement characteristics of FBG inclinometers and tri-axial accelerometers may account for the difference shown in Figure 4. Therefore the measurement characteristics of FBG inclinometers for vertical and inclined vibration need to be examined.

5 CONCLUSIONS

We have demonstrated that FBG inclinometers can be used to detect changes in the vibration characteristics of bridges and that FBG inclinometers are an effective tool for monitoring bridge health. Experimental measurements in which two kinds of vibration characteristics (average maximal amplitude and characteristic frequency) were estimated with and without the effect of tuned mass dampers showed that changes in these characteristics are detectable using FBG inclinometers. Comparison of the estimated characteristics with those obtained from simultaneous tri-axial acceleration measurements showed that vibration characteristics in a particular horizontal direction can be estimated by matching the measurement direction of the FBG inclinometer to the target direction.

Future work includes using FBG inclinometers to estimate the characteristics of perpendicular and inclined vibrations. To clarify the measurement characteristics of FBG inclinometers for both kinds of vibrations we plan to conduct vibration tests.

REMOTE MACHINE MONITORING THROUGH MOBILE PHONE, SMARTPHONE OR PDA

W Wanbin and PW Tse

Smart Engineering Asset Management Laboratory, Department of Manufacturing Engineering and Engineering Management, City University of Hong Kong, Tat Chee Ave., Hong Kong, P. R, China

Abstract: Machine condition monitoring is important to the efficiency of a factory and the safety of its workers. A variety of vibration signals analysis techniques have long been using to diagnose machine's status. Since the Web has been invented, researchers have begun to explore web-based machine diagnostic system. Today, the GSM (Global System for Mobile Communication) and the CDMA (Code Division Multiple Access) have already been widely deployed. Mobile communication provides a variety of data services. Java program can be run in any Smartphone or PDA (personal digital assistant). In this paper, we introduce an innovative application of machine fault diagnosis using mobile communication. For example, our system can send warning acknowledgements via short messages. It can also automatically call the mobile phones of concerned engineers to alert them the abnormal status of the monitored machines. Through our system, maintenance managers can obtain machine curtailed data through their mobile phones using WML (Wireless Markup Language) so that they can make managerial decisions based on the machine condition instantaneously. For engineers, they can obtain detailed data through java program running in a Smartphone or PDA so that they can perform machine fault diagnosis correspondingly.

Key Words: Machine fault diagnosis, Remote monitoring, Mobile communication, Web-based applications

1 INTRODUCTION

Machine condition monitoring has been a popular research topic since machinery has been invented. Defects that occur in a machine always exhibit a symptom in the form of vibration or other parameters. There are machine maintenance techniques such as: vibration monitoring, oil analysis, particle analysis, thermography etc. Vibration monitoring is the most effective technique to detect mechanical defects in rotating machinery. When a machine is starting to deteriorate, the forces acting on different components of the machine will be changed. The corresponding vibration spectrum of the machine will also change. Hence, it is possible to using signals analysis techniques to detect the occurrence of faults in the machine. A variety of vibration signals analysis techniques have long been using to diagnosis machine health status through analysing its generated vibration spectrum. These techniques include Fourier Transform, Wavelet transform, neural networks etc. Numerous researches have been conducted in the field of machine fault diagnosis.

On the other hand, the trend of manufacturing is moving toward regionalization. The production machines, which need to be monitored, could be located at a plant that is far away from the office of the managers and fault diagnosis experts. Since the day that the Web has become a stable avenue for idea exchange, researchers began to explore web-based machine fault diagnostic system. Caldwell et al. (1998) described a system, which used the Internet for diagnosing a scanning electron microscope. Ong et al. (2001) presented a Web-based knowledge-based fault diagnostic and learning system which used multi-agent technology. Yuan et al. (2004) described the architecture of a Web-based remote operation and monitoring system served for open NC (Network computer) devices. Wang et al. (2004) employed virtual instruments to provide remote sensing, monitoring and on-line fault diagnosis for equipment, together with a collaborative maintenance platform for international experts to interactively share their experiences in maintenance.

Nowadays, mobile communication is very popular. Messages, voices, even video clips can be sent remotely via mobile communication and received by a mobile phone or PDA. The GSM (Global System for Mobile Communication) and CDMA (Code Division Multiple Access) have already been widely deployed in mobile communication. Wireless Application Protocol (WAP) has also been developed for mobile devices, such as mobile phones and PDAs, to access the Internet. On the other hand, the developments of Smartphone and PDA technologies allow the transformation of a mobile terminal into a mini computer, and make it possible to process data within a mobile phone/PDA. Sun Microsystems provide free binary implementations to their Java ME runtime environment which is supported by all types of Smartphones and PDAs. Hence, the mobile phone grows from a voice communications device into a multipurpose information terminal. The development of these technologies makes it possible to maintain machines from anywhere and at anytime.

In this paper, we introduce our development on the application of mobile communication for machine fault diagnosis. The paper is laid out in four sections with this section as the introduction. Section 2 gives some research background about the development of mobile communication. Section 3 presents the architecture and layout of our mobile communication based machine fault diagnostic system. It describes in details about the automatic warning acknowledgement system. The system can automatically send alert messages to the maintenance managers/engineers' mobile phones, and also call their phones to make sure the managers/engineers have acknowledged the alert messages when the health status of a monitored machine becomes abnormal. The system will publish the information of the machine status in a Web/WAP server. Then, managers get machine curtailed data through WML by mobile phone; engineers get diagnosed data through java program running in the Smartphone or PDA. Finally, section 4 provides the concluding remarks and the future development.

2 THE DEVELOPMENT OF MOBILE COMMUNICATION

In1979, the first commercial mobile phone network was opened for business in Tokyo. This is a cellular telephone system. By the mid-1980s there was a significant expansion of mobile services offered to the general public in the world. Customers were able to avail themselves of the service using a mobile telephone the size of a brick. There are several different mobile systems such as NMT, AMPS, TACS, RTMI, C-Netz, and Radiocom 2000. These systems later became known as first generation (1G) mobile phones.

In the 1990s, second generation (2G) mobile phone systems such as GSM, IS-136 ("TDMA"), iDEN and IS-95 ("CDMA") began to be introduced. Phase I of the GSM (global system for mobile telecommunications) specifications were published in 1990 and the first GSM network was officially opened in Finland on July 1, 1991. 2G phone systems were characterised by digital circuit switched transmission and the introduction of advanced and fast phone to network signalling. GSM provides a variety of data services. Users can send and receive data, at rates up to 9600 bps. A unique feature of GSM, not found in older analog systems, is the Short Message Service (SMS). SMS is a bidirectional service for short alphanumeric (up to 160 bytes) messages.

Not long after the introduction of 2G networks, projects began to develop 3G systems. Inevitably there were many different standards with different contenders pushing their own technologies. Quite differently from 2G systems, however, the meaning of 3G has been standardised in the IMT-2000 standardisation process. This process did not standardise on a technology, but rather on a set of requirements (2 Mbit/s maximum data rate indoors, 384 kbit/s outdoors, for example).

During the development of 3G systems, 2.5G systems such as CDMA2000 1x and GPRS were developed as extensions to existing 2G networks. These provide some of the features of 3G without fulfilling the promised high data rates or full range of multimedia services. For example, CDMA2000-1X delivers theoretical maximum data speeds of up to 307 kbit/s.

The Internet is a simple and efficient method of delivering services to millions of PC users. There is a requirement surfing Internet by mobile phone. Then WAP was specially developed to make the convenience of the Internet available to mobile users. The first commercial WAP services were based on the WAP 1.1 standard, issued in June 1999. WAP2.0, which was released in Summer, 2001, incorporates TCP/IP and xHTML into the WAP standard, offering programmers the facility to develop an application fro both fixed and wireless Internet at once.

The Micro Edition of the Java 2 Platform provides an application environment that specifically addresses the needs of commodities in the vast and rapidly growing consumer and embedded space, including mobile phones, personal digital assistants etc.

Today, 2G or 2.5G mobile systems have already been widely deployed. In some country, users even can choose 3G services. The development of these technologies gives a new research topic of machine fault diagnosis system.

3 THE APPLICATION OF MOBILE TECHNOLOGY IN FAULT DIAGNOSIS

The application of mobile technologies for our machine fault diagnostic system is showed in Figure 1. SAMS (Smart Asset Maintenance Systems) uses LabVIEW development tools for programming and provides a graphical user interface (GUI) that allows users to choose different virtual instruments for machine fault disgnosis (Leung & Tse 2005). SAMS has a number of signal processing techniques for machine fault diagnosis, such as the Fast Fourier Transform (FFT), Continuous Wavelet Transform (CWT), Exact Wavelet Analysis (EXA) (Tse et al. 2004), Orbit Analysis etc. The hardware part of SAMS includes sensors, Web-camera or video-camera, microphones, signal amplifiers or conditioners, data acquisition (DAQ) cards. The sensors collect the running signals from the monitored machine and then transmit the collected signals to the amplifiers. The amplifiers condition the signals into acceptable formats so that the DAQ cards can convert them to digital signals for further fault analysis.

When SAMS detects the health status of the monitored machine becomes abnormal, the Java program running in the server will send short messages and call the concerned engineers' phones through the mobile connected to the Web/Wap server. SAMS will analyse the collected data, perform the necessary diagnoses, and then transmit the diagnostic results and data to the Web/Wap server. The Java program runs in the server will generate the WML file that contains diagnostic results. Users can get machine curtailed data by mobile phones. Engineers will also obtain the detailed data and diagnostic results through the java program running in their Smartphones or PDAs.

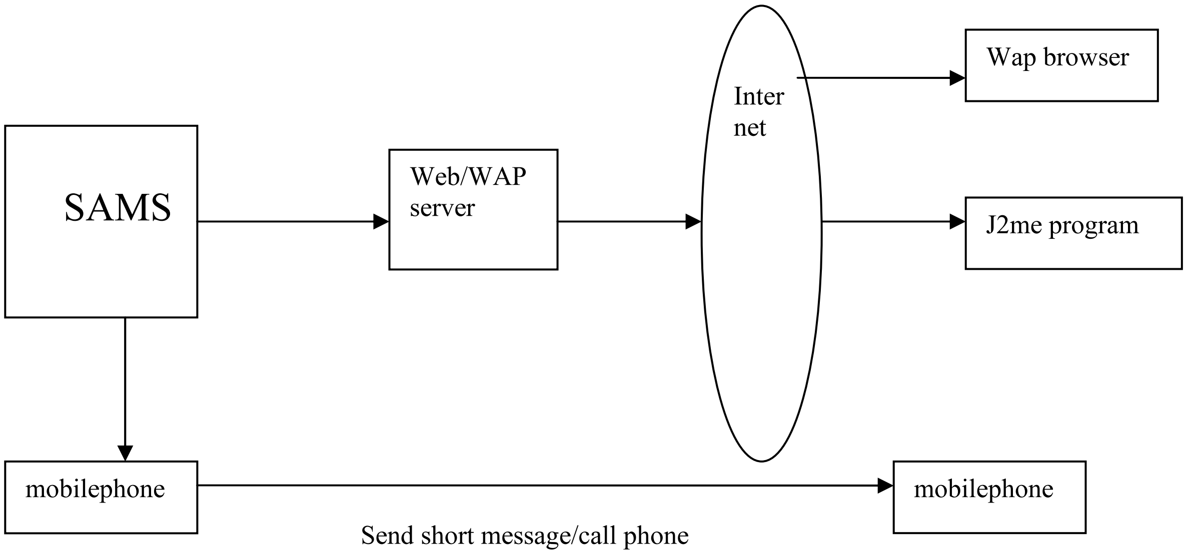

Figure 1. The architecture of mobile communication for our remote machine fault diagnostic system

3.1 Development of the automatic alarm acknowledgment

Short Message Service (SMS) is a service available on most digital mobile phones that permits the sending of short messages between mobile phones. SMS was originally designed as part of the GSM network, but is now available on a wider range of networks, including the 3G network. Using SMS in industry is not a new idea. Wu and Jan (2003) proposed a Home Network System integrated with WAP and SMS to support the connectivity between home and the Internet for mobile communication networks. Al-Ali et al. (2004) presented a system which allows the homeowner to monitor and control his house appliances via his mobile phone by sending commands in the form of SMS messages while receiving the appliances operating status. These systems use the AT commands to send SMS through a GSM modem. AT commands are easy to understand and implement. However, the functions of AT commands is limited.

Our research is based on the Microsoft's Smartphone 2003 smart-phone operating system. It is a revolutionary mobile phone software platform that allows a variety of functions rather than just a phone for talking and listening. It has empowered the developers to build rich and innovative mobile applications by providing powerful and flexible development tools. Developers can target Windows Mobile natively with Visual C++. They can also target the .NET Compact Framework with managed code by using C# or Visual Basic .NET.

Our system can detect an abnormal operation condition of the monitored machine and then issue a warning to users. If such a case occurred, the Java Program will run the programs in Motorola MPX 220 mobile phone that is connected to the server. There are two programs in the mobile phone. One program will send messages to the user mobile phone and the other program will call the user mobile phone. The two programs are coded by Visual C#. The first program needs the user mobile phone numbers and message contents. The second program only needs the mobile phone numbers.

Below is part of the java program called 'Callphone', which is used to call the user mobile phone.

```
cmdString1="rapistart \\Storage\\callphone"+"  "+CallPhonenum;

Process proc2 = Runtime.getRuntime().exec(cmdString1);
```

The command 'rapistart' is used for remotely starting an application on a PDA or Smartphone. It is a part of the Windows Mobile Developer Power Toys which can be downloaded from Microsoft's website. The command 'callphone' is an exe program which has been installed in the Motorola MPX 220. The command 'Storage' is a directory where the Callphone program is saved. Callphone is coded by Visual C# and uses Smartphone 2003 API to make a call. The command 'CallPhonenum' is the phone number which is retrieved from the text file saved in the computer. The command 'Runtime.getRuntime().exec()' is a java method that executes the specified string command. Here, it executes the command 'rapistart' to run the program in the MPX200 for calling a specified mobile phone.

The Java program will send short messages containing the current health status of the machine to engineers and managers. Figure 2 gives a sample of the message that the engineers and managers will receive when the monitored machine becomes abnormal. It includes the name of the company or the factory, the machine identification, the monitored machine component, the time and date that the message is produced, and the current health status of the machine.

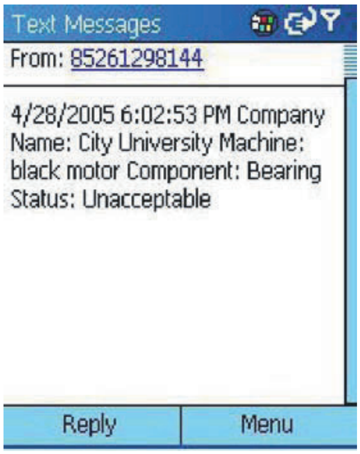

Figure 2. The SMS message sent to users to acknowledge them the abnormal status of the monitored machine.

3.2 Get machine health information via WAP browser

The Internet is a simple and efficient method of delivering services to millions of PC users. WAP was specially developed to make the convenience of the Internet available to mobile users. In 1997, several wireless-phone manufacturers organized an industry group to formalize the WAP standards. The standards are used to define communication protocol and implementation for wireless-network applications. WAP allows cell phones, PDAs, and other low-computational-power devices access to the Internet.

Services made up in the Hypertext Markup Language (HTML), which is used for the layout of Internet pages on the Web, do not take sufficient account of specific circumstances that arise in a mobile environment. The WML (Wireless Markup Language) is the mobile variation of HTML. It is designed for creating WAP based applications. It is user-interface independent. It supports text, images, user input, variables, navigation mechanisms, multiple languages, and management server requests. The WML has been designed to adapt high-latency and narrow-band types of wireless networks. When a user gains access to a WAP site, it will send contents in a deck of cards through which the user can browse. The WML is supported by almost every new mobile phone browser around the world.

Our system will write important machine health information via the WML and publish the information by a Web/WAP server. Figure 3 gives an example on how the important machine health status can be displayed in the small screen of a Motorola MPx-220 phone. It shows a menu for displaying the current health conditions of a machine in our laboratory. The cursor can be scrolled up or down to select a particular point to view its health status, and to get the real time image of the machine. The point's health data and the image of the monitored machine are available on the screen of the mobile phone/PDA.

The WML menu page, of which the user can obtain the machine's data, image, may seems very simple. However, many new technologies have been employed to implement such page. The system gets the collected vibration data and diagnostic results from the SAMS every 20 seconds (the interval can be reconfigurable as desired) and generates a WML file to contains the information. The WML file includes the menu page and the details of a selected sensor measuring point (referred to a particular component of the monitored machine). By choosing a particular sensor measuring point option, the remote user can get the detailed information of that measured point. The information includes the source of data, its values, the health status, and the reference used to determine its health status of the measured point or component. The health status can be classified as 'Good', 'Satisfactory', 'Unsatisfactory', and 'Unacceptable'. The reference (REF) in Figure 4 shows that the RMS (the root-mean-square value of the collected vibration data) is LT (less than) 0.2 mm/s (vibration in velocity unit). This means that the machine health status is good. If the RMS is greater than 0.8 mm/s, then the monitored machine's health may be classified as 'Unacceptable'. For demonstration purpose, we are only using the RMS value as reference. In future, we will use other machine health vibration indicators, such as kurtosis, crest factor, higher order statistical values, to synthetically determine the health of the monitored machine component.

On the menu page, by clicking the 'Machine Picture' link, the WAP browser will download the picture of the currently monitored component (as shown in Figure 5) from the Web/WAP server. The Java program running in the server uses JMStudio to capture an image of the machine every 30 seconds (the interval can be reconfigurable as desired) through a Web camera. JMStudio is a Java application that uses the JMF (Java Media Framework) 2.0 API to play, capture, transcode, and write media data. A VI program sends this JPEG file to the web server and then web server publishes it to the Internet.

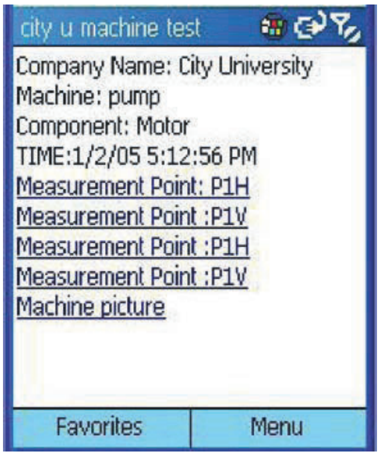

Figure 3. The content of the SMS that acquiring machine health status via mobile phone.

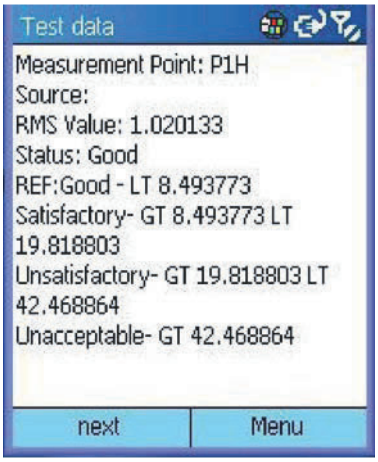

Figure 4. The health status of a particular machine component (through the choice of a sensor measuring point).

Figure 5. The image of the currently measuring point of the monitored machine.

3.3 Get machine data using Java program running in the Smartphone or PDA

Java is an object-oriented programming language that can be run on any platform. Java technology is used in applications on PCs, servers and is also applied to various embedded devices. Hoshi (1999) gave some examples of applications of Java in the manufacturing industry. In our research, we use java program which run in the Smartphone or PDA to get the machine data file. Figure 6 shows a demo for running the Java program in a device emulator of the J2ME Wireless Toolkit, which is a set of tool for creating Java applications that run on devices compliant with the Java Technology for the Wireless Industry. The URL is the default location of the machine data file. It can be changed by input different URL using the mobile phone keys. Figure 7 displays the content of the file that contains the collected machine vibration data. Because of the memory limitation of mobile devices, the machine data file cannot be too large.

Figure 6. The screen of a mobile phone showing the Web address to get the machine diagnostic information.

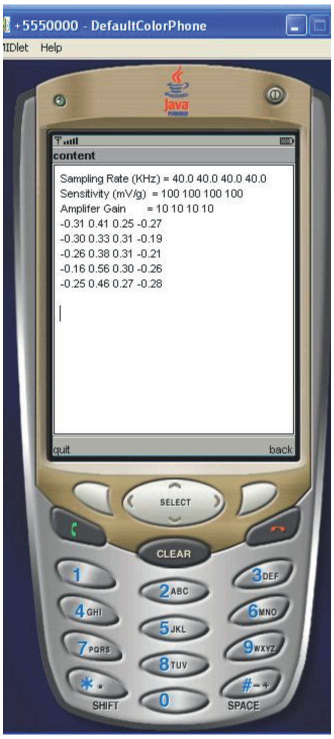

Figure 7. The curtailed vibration data collected from the monitored machine.

4 CONCLUSIONS

With the continuos improvements in machine condition based monitoring and diagnosis and the requirement of globalization in manufacturing, there is a strong demand on the use of remote machine health monitoring, especially through mobile communication, such as mobile phones and PDAs. In this paper, we introduce our development of using mobile communication to inform concerned users the health status of a machine which is located remotely from the users. The users can remotely and wirelessly obtain the current operating and health conditions of any manufacturing machine even without the access of a Web wired connection. Through our system, maintenance managers can obtain machine curtailed data through their mobile phones using WML (Wireless Markup Language) so that they can make managerial decisions based on the machine condition instantaneously. For engineers, they can obtain detailed data through java program running in a Smartphone or PDA so that they can perform machine fault diagnosis correspondingly.

Today, the developments in Smartphone and PDA allow the transformation of a mobile device into a mini computer, and make reasonably large amount of data to process within a mobile phone/PDA. Our future work will concentrate on the potential of analysing collected machine data directly in a Smartphone or PDA rather than from a Web/WAP server as we currently used. The third generation of mobile communication is expected to be capable of transmitting data of text, digitized voice, video, and other multimedia data at a rate of 2 megabits per second (Mbps) and higher. Hence, remote and wireless machine health monitoring and fault diagnosis through mobile communication will become a trend in modern maintenance and engineering asset management.

Abstract: All kinds of machines require proper maintenance, especially when the operation of machines involves human beings. In order to minimize machines' failure rate, researchers have been searching more sophisticated methodologies for the earliest detection of the machine faults prior to causing any catastrophe. On the other hand, the industry requires such sophisticated methods easy-to-use and affordable. Hence, this paper presents a machine condition and its degradation monitoring system with the state-of-the-art capability yet easy-to-use and low-cost. In most of the rotating machines, bearings are the most frequent failure parts. Traditionally, maintenance persons would recognize the health of these parts through the monitoring of their vibration frequency spectra. However, modern machineries are so complex that many components may generate vibrations and affect each others. The vibration signals generated from bearing rolling parts may be overwhelmed by other higher amplitude vibration signals generated by nearby larger components. Hence, maintenance persons always encountered difficulties to distinguish the difference of vibrations generated by a bearing or nearby components. Hence, sophisticated machine fault diagnoses are required. Although a number of advanced diagnostic methods are available, they are either not ready for commercial use or too expensive and difficult to use without comprehensive learning. Therefore, we have designed and implemented an economic but yet efficient machine condition and its degradation monitoring system called the 'Smart Asset Maintenance System (SAMS)'. Here, we have described its effective functions on machine fault diagnosis and prognosis, added-valued capabilities, such as automatic report generation, smart data management, and ready to use Web-based remote monitoring. Most surprisingly, even equipped so many advanced functions, SAMS has been made for user-friendly and low-cost.

Keywords: Machine condition monitoring; vibration analysis; noise cancellation; vibration trend; remote sensing.

1 INTRODUCTION

All rotating machines generate noise and vibration, even small amplitudes of vibration can cause a large amount of damage in different parts of the machine. In ideal case, machine running as a prefect condition would not produce any vibration or sound it is because all the energy is transfer into the work to be done. However, in real life, vibration should occur when the machine is running and energy would excite through the structure in the form of vibration. As long as the excitation energy, the vibration would be a typical level and contain a characteristic frequency shape when the machine is in normal. And the analysis of the produced vibration can be used to give information on the condition of the machines. Thus it is important to monitor or record the vibration signal in order to distinguish the health condition. In fact, when the machine begin to be defective, the force acting on different components will be changed, which will result on changing of the vibration spectrum. Therefore, a variety of signal processing techniques have been applied in the machine monitoring to detect the change or defect of the machine. The conventional techniques include the Fast Fourier Transform (FFT), Envelop Detection, and Impact Test. Recently, a number of new signal processing techniques have been developed to enhance the accuracy and efficiency in machine fault diagnosis. Some of them are Continuous Wavelet Transform (CWT), Exact Wavelet Analysis (EWA), Active Noise Cancellation (ANC), Orbit Analysis, and Vibration Trend Prediction. In this essay, an innovative system for maintenance would introduce. The novel system is called the Smart Asset Maintenance System (SAMS), especially made for the industry to uplift the technology used in machine condition monitoring and fault diagnosis. SAMS has embedded with all the aforementioned technologies. In section 2, we have discussed the methodologies, both conventional and new ones that are embedded in SAMS. Besides, in section 3, the configuration of Data acquisition system was also introduced. At last, some of selected industrial applications using SAMS to monitor the machine health are also presented.

2 SELECTED DESCIPTIONS ON WEB-ENABLED VIRTUAL INSTRUMENTS OF SAMS

Vibration signals are usually consist of very many frequencies occurring simultaneously so that we cannot immediately see just by looking at the amplitude – time pattern (time waveform). Therefore, we need some signal analysis technology, such as the FFT and wavelet, so that we are able to track down the source of undesirable vibration.

2.1 Conventional maintenance algorithm

In tradition, FFT algorithm is used to calculate a spectrum from a time domain signal. The spectrum shows the magnitude of signal in frequency domain. If the bearing or gear has defects, the impact signal would produce abnormal components in the spectrum. According to the shape of these abnormal components and their frequencies, the experienced operator could identify that defect is BPFO, BPFI or gear teeth broken.

2.1.1 2.1.1 Fast Fourier transforms (FFT)

FFT is a popular and widely adopted tool for vibration based machine fault diagnosis. It constructs a frequency spectrum from the captured temporal signals. A typical FFT spectrum has been shown at the bottom window of Figure 1.

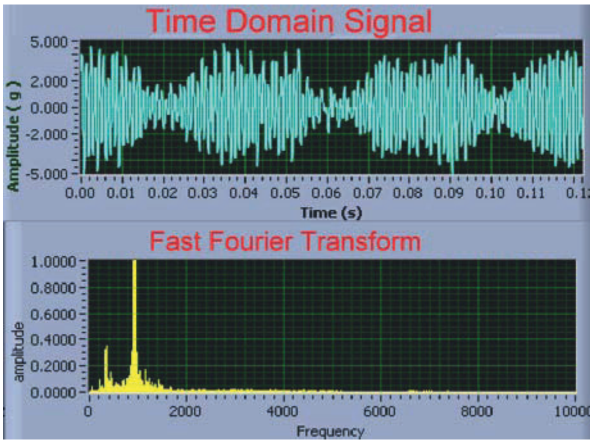

Fig. 1 the FFT spectrum shows the magnitudes of signals in the frequency domain.

If a component of the machine is defective, the magnitude of the vibration generated from this component will increase at its related excitation frequency. Comparison can be made to confirm the existence of fault by using the spectrum generated at the normal operating condition.

According to R.B. Randall, the function of Discrete Fourier Transform can be express as

$$X(k) = \sum_{n=1}^{N} x(n) * \exp(-j * 2 * pi * (k-1) * (n-1)/N),$$

for , 1 <= k <= N. Eq [1]

where N is the data length with vector x.

In Figure 2, the top diagram shows a defective bearing with a scratch occurring on the surface of the bearing outer-race. Every time when a ball or roller passes through the defective surface, an impact will occur. When the bearing is rotating at high speed, a series of impacts will be generated. Such impacts will create impulsive signals at high frequency region of the FFT spectrum as shown in the middle diagram of Figure 2. For comparison purpose, the frequency spectrum of a normal bearing is shown at the bottom diagram of Figure 2. Note that at high frequency region of the normal bearing's spectrum, there is no significant increase of amplitudes as compared to the one for defective bearing. During the test, since there were no other vibration generated from other nearby components, the results on the FFT spectra become obvious. Such results will allow the operator easily recognize whether a bearing is defective or not by only observing the comparison of the FFT spectra.

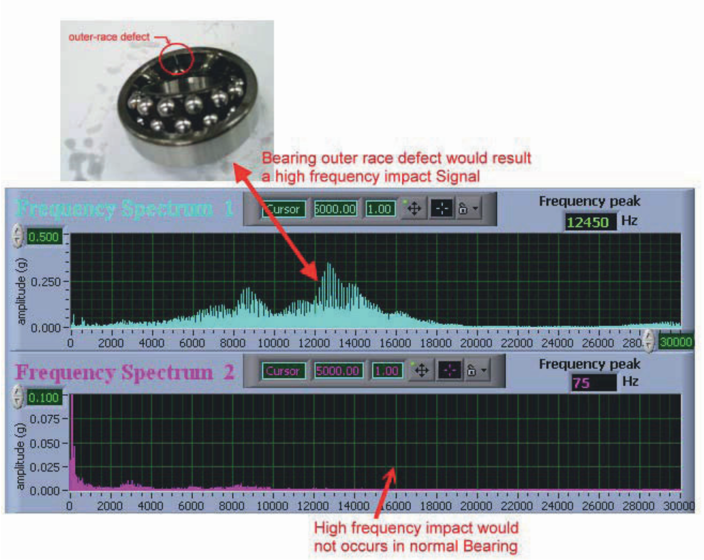

Fig 2. Difference in FFT spectra between a normal bearing and an outer-race defective bearing.

2.1.2 2.1.2 Vibration Trend Analysis

A vibration trend is a 3D plot that consists of many FFT spectra obtained at different time or days. As shown in Figure 3, the y-axis of the trend plot is the vibration amplitude, the x-axis is the Frequency, and the z-axis is the number of record obtained at different time. Since the trend plot shows the temporal information of vibration, it is helpful to observe the change of vibration in a particular range of frequency. If a component in a machine is deteriorating, its vibration level will be continuously increasing. Hence, by observing the increase of vibration level in the trend plot, one can determine the seriousness of a damaged component.

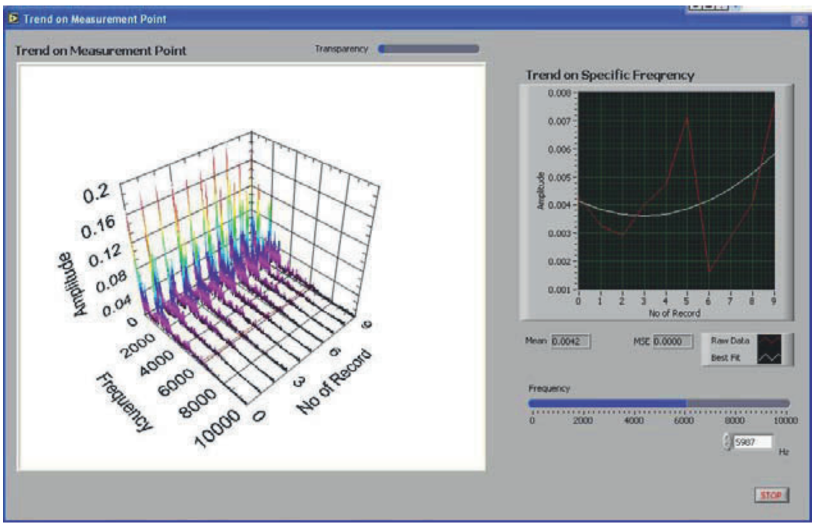

Fig. 3. The vibration trend analysis embedded in SAMS.

According to Larsen and Son, "the resulting trends curves can be extrapolated forward in time to indicate when the condition will reach a danger limit". If the operator wants to inspect the trend of a particular frequency range, he may specific that frequency range by clicking the frequency slide bar or input the desired frequency range in the given text box as shown on the right hand side of Figure 3. The vibration trend for the specific frequency range will be displayed on the right hand side graph. SAMS will provide a polynomial best-fit curve to fit the temporal values. Based on this curve, the operator can determine the future trend of the plot that related to the future deterioration rate of the damaged component. He then can prepare proper remedy in advanced.

2.1.3 Higher order statistical Analysis – Kurtosis (machine health indicator)

One mathematical representation of the deviation of an amplitude distribution from Gaussian is the so-called "fourth moment", or kurtosis. Kurtosis is a statistical indicator used to characterize the pulse character of a signal. It is a dimensionless parameter characteristic the flattening of the signal probability density. It corresponds to the 4th-order moment

The Gaussian distribution has a kurtosis of 3, and higher values of kurtosis indicate increased crest factor of the vibration signal. Kurtosis is a valid measure of the degradation of a machine, but it does not give any indication of the diagnosis of the problem. It has been reported that kurtosis is especially well suited to monitoring of reciprocating machines for fault detection.

For the data Y_1, Y_2... Y_N, the formula for kurtosis is:

$$Kurtosis = \frac{\sum_{i=1}^{n}(Yi - \bar{Y})^4}{(N-1)S^4} - 3 \qquad \text{Eq [2]}$$

$\bar{Y}$ is the mean,

S is the standard deviation,

N is the number of data points.

Because of the Kurtosis value for a normal distribution is three. Sometime we would minus three to reduce the Kurtosis value for normal distribution to become zero. For this reason, we change the representations of Kurtosis as below.

One possible advantage of using kurtosis as a fault detection parameter is that it does not need to be trended over time to be effective. A kurtosis of 3 generally is taken as indicating a healthy machine, with higher values indicating progressive states of fault progression. Besides, Kurtosis can be assimilated with a shape factor, the value of which does not depend on the signal amplitude:

Kurtosis is particularly suited to the monitoring of bearings of low speed rotating shafts, where frequency-based techniques are limited. Kurtosis is also widely used to detect non periodic shocks. In practice, Kurtosis is often calculated after filtering. It can reach values greater than 100, especially when the selected frequency band coincides with a structure resonance. Also, it is often associated with envelope analysis to determine the area to demodulate.

2.2 Enhanced fault diagnosis methodology

2.2.1 2.2.1 Continuous Wavelet Transform (CWT)

According to Strang G., and Nguyen T, the wavelet transform can be expressed as:

$$C_{(a,b)} = \int_{-\infty}^{\infty} f(x) Wa, b(x) \partial x$$

$$\text{where } W_{a,b}(x) = \frac{1}{\sqrt{a}} W\left(\frac{x-b}{a}\right) \qquad \text{Eq [3]}$$

From Tse and Yang, the machine fault signals are always buried with other irrelevant signals due to the problems of overlapping and energy leakage. FFT may not easily detect the defect due to the abandonment of the time information. In SAMS, both wavelet transform related techniques - CWT and EWA, have been developed to enhance the ability in machine fault diagnosis. Particularly, the EWA can minimize the problems of overlapping and energy leakage that always occur in the results of conventional wavelet transforms. For wavelet transforms, SAMS provides Mexican Hat, Mayer, Morlet, Coif, and Daubechies wavelets. Their parameters are manually adjustable to suit the analyses for different type of signal with different characteristics. The diagnosing results by applying the CWT to analyse the vibration signals generated by a normal bearing and a defective bearing are shown in Figure 4. The bright colour spots and strips as shown in the right hand side diagram of Figure 4 reveal the high-energy impulses caused by the defective bearing. They form an advanced warning for serious faults may occur if the defective bearing is allowed to be deteriorated. Note that the CWT provides a time-frequency analysis simultaneously that the conventional FFT spectrum fails to provide.

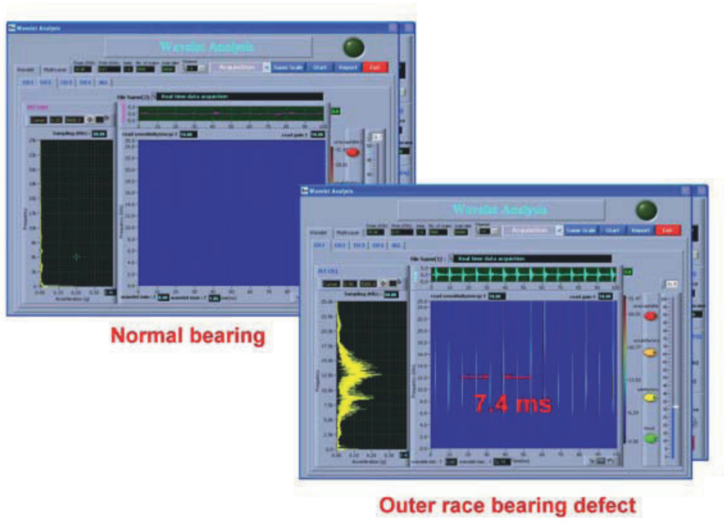

Fig. 4. a captured bearing vibration signal, with outer race defect, under Wavelet analysis.

Using the common equations for obtaining the bearing characteristic Frequencies, the outer-race defect frequency, f_{od}, generated by a bearing with known specifications can be calculated as:

$$f_{od} = 0.5 * (1 - \gamma) Z f_{s,} = 5.8\, f_s = 135 \text{ Hz (7.4ms)} \qquad \text{Eq [4]}$$

where Z is the number of rolling elements, f_s is the fundamental rotational frequency, and γ is a parameter related to the dimensions of the bearing and its contact angle.

Given that the inspected bearing is SKF 1206 EKTN9, the calculated outer-race defect frequency should be 135 Hz or about 7.4 ms. Note that in the right hand side diagram of Figure 4, the impacts occur at a time interval of 7.4ms, which is similar to the calculated value of the outer-race defect frequency. Hence, the cause of impacts is an outer-race bearing defect. To conclude, with the help of the time-frequency analysis offered by CWT, one can easily observe the faulty impacts and identify the cause of defect.

Another advantage to use CWT in machine fault diagnosis is the CWT can provide signal decomposition, which is especially suitable for identifying the excitation frequency generated by each component. Note that in the right hand side diagram of Figure 4, the excitation frequency of the bearing housing is peaked at around 12.5 kHz. Since, different structure should have different excitation frequency, hence, the vibration generated by each location of the machine could be revealed at its related excitation frequency. By observing the change of each excitation frequency, the health of the component at that particular location can be determined. Therefore, the signal decomposition plot is useful in identifying the source of severe vibration.

2.2.2 Active Noise Cancellation (ANC)

Although the CWT and EWA can provide time-frequency analysis to enhance the accuracy in fault identification, they work better if the inspected machine is large and each component is well apart from each other. If the inspected machine is small with vibration generated by each component interfering each other, then a more advanced technique should be employed to minimize the inference. If the interference has not been minimized, the results generated by any technique will be very difficult to be interpreted. Inexperienced operator or maintenance staff may misinterpret the results and false alarms may occur. To minimize these undesirable effects, the SAMS has embedded with the virtual instrument called active noise cancellation (ANC). ANC is capable of minimizing interference as well as optimizing the desired signal. SAMS has provided two types of ANC for different need. The first type of ANC is for known interference, that is, the operator knows which source of signal should be minimized. Its block diagram is shown in Figure 5. The primary signal should contain the desired signal and the interference, whilst the reference signal should contain only the undesirable interference. The output signal will mainly compose of the desired signal.

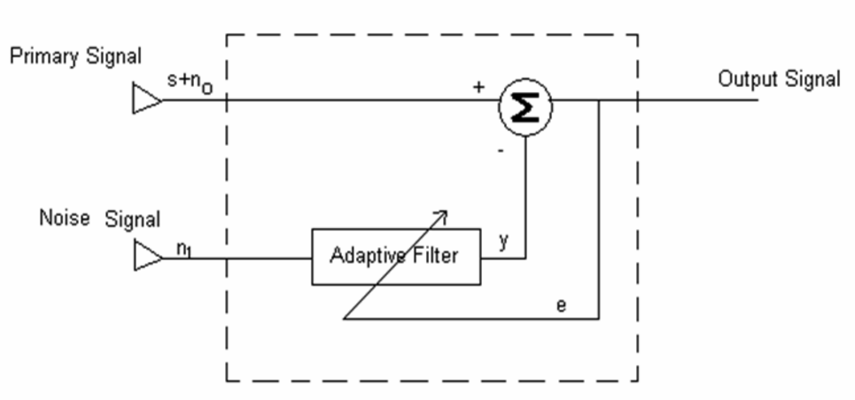

Fig. 5. The first type of ANC for canceling interference.

Sometimes, the interference cannot be identified, but the desired signal can be simulated, likes the classical Model Reference Control. Therefore, the first type of ANC must be modified to suit for inputting the desired reference instead of the interference. In such case, the second type of ANC has been developed. Its block diagram is shown in Figure 6. This time, the primary signal is also the aggregation of the desired signal and the interference, whilst the reference signal should contain only the simulated desired signal. After the applying of ANC, the output signal will mainly compose of the real desired signal.

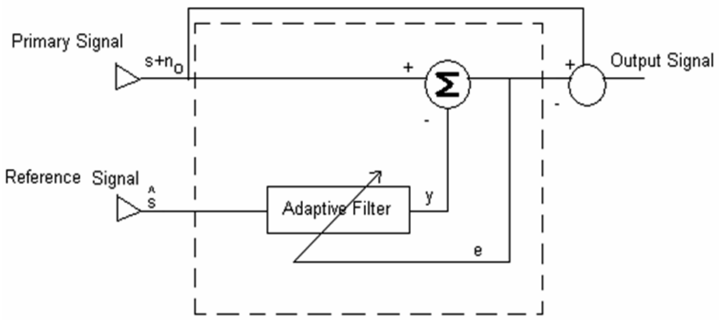

Fig. 6. The second type of ANC with feed-forward loop.

With the help of ANC, the faulty signal becomes easier to be revealed and false alarms can be avoided. To verify the effectiveness of the first type of ANC, a series of tests using microphones to capture the vibro-acoustic signal generated from a roller of a print press were conducted in a printing factory. As shown in Figure 7, two microphones were used. One microphone was pointing at the inspected roller. Another microphone was pointing at the surrounding environment. The sound collected by the microphone pointed to the roller is shown at the top diagram of Figure 7. The sound collected by the microphone pointed to the surrounding environment roller is shown at the middle diagram of Figure 7. Note that by comparing the top and the middle diagrams, the first sound has been modulated by the surrounding sound. By using the first type of ANC, the surrounding sound has been minimized. Hence, the vibro-acoustic signal from the roller can be recovered as shown in the bottom diagram of Figure 7. Therefore, the fault related signals are easier to be revealed in after the application of ANC. Here, at least two microphones have to be used to make ANC becomes effective.

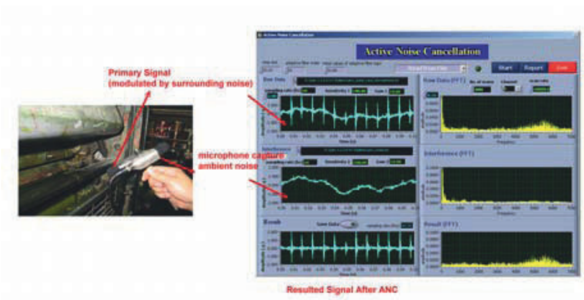

Fig. 7: The recovered faulty signal after applying ANC.

2.2.3 Orbit Analysis

Orbit Analysis is useful to check misalignment and unbalancing occurred in all rotating shafts. The orbit plot is constructed by combining the displacement signals collected by a horizontal sensor (in X direction) and a vertical sensor (in Y direction). In SAMS, we calculate the displacements by integrating twice the acceleration signals captured by the two sensors or accelerometers. The reason to obtain displacement signals from acceleration signals is to save the extra cost of buying displacement sensors as accelerometers are already existing and needed for other fault diagnostic techniques. Beside integration, the processes of de-trending and filtering out other signals except the signal related to the fundamental rotational frequency must be employed to obtain a clear track of orbit.

Figure 8 shows two orbit plots, one from a balanced shaft and another one from an unbalanced shaft. Generally speaking, a balance shaft will produce a much smaller and round orbit. Whilst, an unbalance shaft will produce a relatively bigger orbit with irregular shape biased to a certain angle. Note that the SAMS' orbit analysis is very sensitive to problem shaft. Even a slight misalignment or unbalancing will generate a substantial large orbit as compare to a normal orbit.

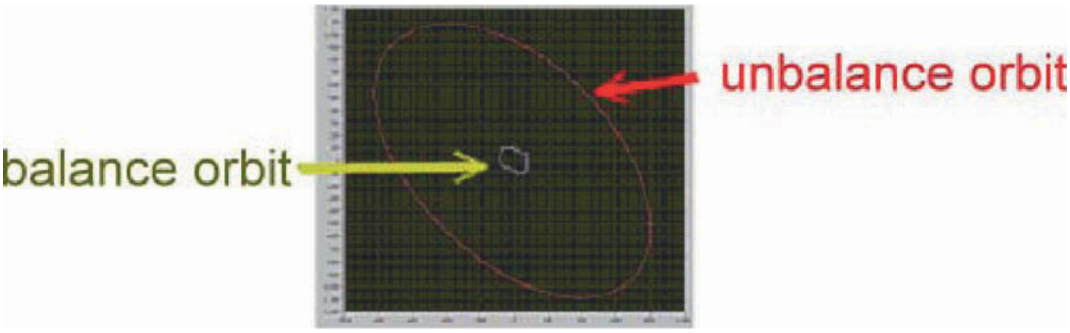

Fig. 8. Unbalance orbit is obvious in orbit analysis.

3 CONFIGURATION OF SMART ASSET MAINTENANCE SYSTEM (SAMS)

Table 1	
The device used for capturing the sound and vibration signal.	
	1. Accelerometer - a wide range of frequency and high sensitivity accelerometer is required to detect the vibration signal.
	2. Microphone - a pre-polarized free field and wide frequency range microphone is used to detect the sound signal.
	3. Signal conditioner - provide amplification and filtering of analogy signal. It will provide power to ICP type of sensors.
	4. Data Acquisition - capture and transform the analogy signal to digital.
	5. Portable Computer – a notebook PC or a PDA for software installation and data recording.

3.1 Instruments used for conditional signal acquisition

Refer to the introduction; vibration is normally a destructive by-product of the force transmission through a machine. Also, vibration carries much information relating to the machine health. Therefore, sensing of the vibration is important for maintenance. To acquire the vibration or vibro-acoustic signals generated from an inspected machine, a number of devices must be employed, a portable vibration analyser set and level recorder is excellent. Table 1 shows all the devices that are currently cooperated with SAMS.

For vibration type of machine fault diagnosis, we use the ICP accelerometers and microphones to acquire vibration and vibro-acoustic sensory signals respectively. For other purposes, such as acquiring pressure, temperature, current, voltage etc., SAMS has built-in functions to collect these data. Here, we only concentrate on the description of using SAMS for vibration type of machine fault diagnosis. The signals collected by the sensors will be conditioned by a multi-channel signal conditioner prior to input to a data acquisition (DAQ) card for capturing and converting conditioned signals to digital format ready to be accepted by a notebook computer or a PDA. Figure 9 shows the overall instruments required by SAMS from capturing signals by a sensor to a computer embedded with a DAQ card. In short, the computer becomes a physical analyzer for vibration monitoring and fault diagnosis.

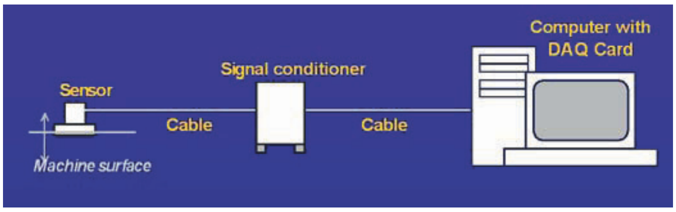

Fig. 9. The overall instruments work with SAMS.

Usually accelerometers are used for collecting vibration generated from a machine as long as the accelerometers can be mounted on the desire locations on the machine's surface. However, a lot of components of the machine may be moving or difficult to be accessed so that mounting the accelerometers on the components' surfaces is not feasible. In such case, then microphones may be used to replace accelerometers as they are non-contact to the surfaces. Due to high background noise in a factory or plant, using one microphone for collecting vibro-acoustic signals will definitely have a very low signal-to-noise ratio. Hence, advanced methods, such as ANC and BSS must be employed to separate noise from real vibration signal. Usually, these advanced methods may require at least two microphones. By using the method of microphones to collect signals, it has significantly increased the flexibility in data collection that has encountered access difficulty.

3.2 Selected description on SAMS 's function

SAMS is acting like a portable virtual analyser for machine monitoring and fault diagnosis. Its platform provides a graphical user interface (GUI) that allows the user to choose different virtual instruments for different diagnostic techniques. Besides, SAMS contains a comprehensive set of tools for acquiring, analysing, displaying, publishing and reporting, as well as a database for the storage and retrieval of the acquired machine data. Figure 10 shows the GUI menu of SAMS.

Fig. 10. The graphical user interface of SAMS.

The functions of SAMS include five main areas, 1) the DAQ and signal processing; 2) the data base manager; 3) the fault analysis and trend prediction; 4) the automatic report generation, and 5) remote monitoring via the Internet.

In the panel of DAQ and signal processing (see Figure 10), the input signals are sampled in accordance with the prescribed sampling rate, number of samples, sensor sensitivity and its gain. Once the prescribed number of data has been acquired, the sampled temporal waveforms will be displayed in one of the four channels as shown in Figure 10. The data collection process can be continuous and all four waveform plots will be updated momentarily. Statistical values of the captured signals, such as RMS, peak, mean, standard deviation, Kurtosis, skewness, and crest factor etc. will be determined and displayed here for reference.

Four LED indicators are included on the right hand side of each temporal waveform plot. Each LED indicator is intended to be lighted up according to its associated energy level contained in the vibration signal captured by each of the four channels. Different colours, like the green, yellow, orange and red colour have been assigned to each LED to represent good, satisfactory, unsatisfactory, and unacceptable vibration levels respectively. Simply by observing which colour of the LED has been lightened, the machine operator can instantaneously determine the health condition of the monitoring machine.

A Digital Filtering menu is also included in this panel. The digital filters are available for the removal of undesirable frequency components in the acquired signals. A set of selectable high-pass and low-pass filters are available for such purpose. Scaling of the amplitude axes can be made instantly by simply typing the required scale into the Axis Scale control box. The machine operator has all freedom to choose his desirable scale for each display axis. Moreover, integration buttons for all channels are installed so that the operator can collect the vibration signals in terms of acceleration, velocity, or displacement as desired.

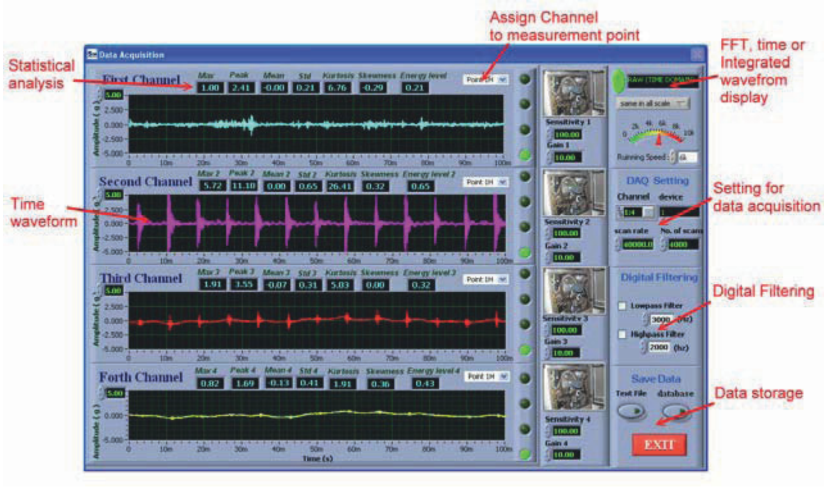

Fig. 11 the Data acquisition and signal processing panel.

To enable the operator to analyse vibration data, a database with data management facility has been developed in SAMS. As shown in Figure 12, the hierarchy of the database consists of 5 entities, namely, the company identification, the machine identification, the inspecting component, the measurement location and orientation, and the data. To store the sensory data into the database, the user must first define the properties of the company, machine, component and measurement in the database. For a company, its properties could be its address and telephone number, whilst, for a machine, its properties could be its power and running speed. In addition, a visual data explorer (data manager) is included in SAMS. The data manager will keep tracking all the data records that have been collected according to their properties automatically.

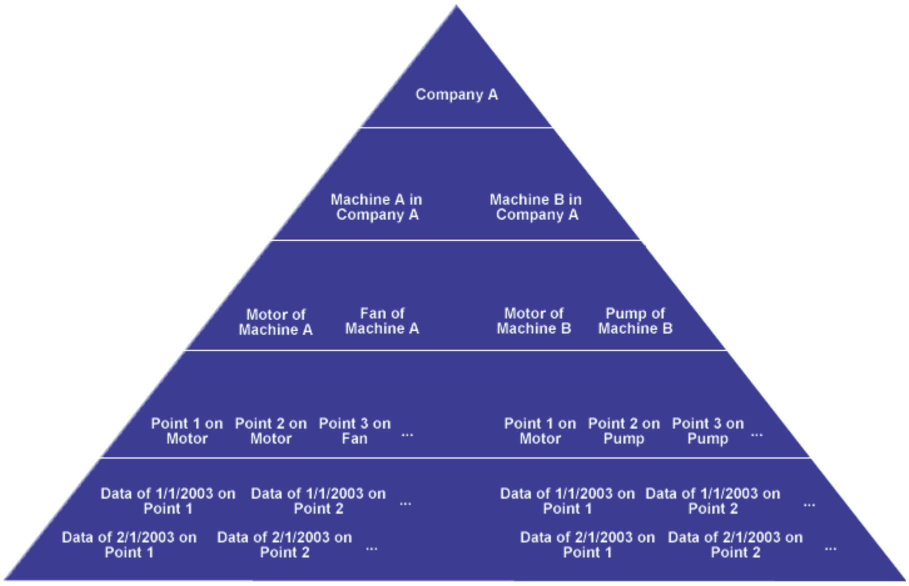

Fig. 12. The database construction in SAMS

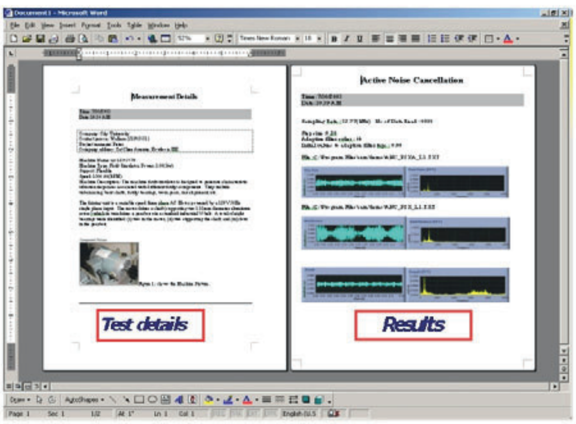

Fig. 13. Automatic generation of analysis report in Word format.

In commercially available machine monitoring systems, after the data acquisition and the fault diagnosis processes have been completed, operators or experts have to spend a lot of time on reporting and documentation. To ease such works, SAMS has a built-in function for generating reports and documents simply by pressing a button. On each page of panel or virtual instrument, there is a button called “Report”. Once the button is pressed, the displayed window with its analysing results, related sampling data, and details of the inspected machine etc., will be automatically inserted into a formatted Word document as shown in Figure 13. This can not only save the documentation time, but also ensure all the technical and physical references are in the generated document or report. Since the document is in Microsoft Word format, it is very convenience for the operator or expert to further edit the file according to his preference.

4 SELECTED INDUSTRIAL APPLICATIONS

SAMS has been tested on many industrial machines. A list of tested machines includes traction motors on trains, chillers in buildings, water pumps, stacker cranes for logistics and warehouse, printing press and associated machines, beverage production lines, coal milling machines, catering production line etc. Over 20 companies that belonged to the sectors of public utilities, mass transportation, logistics, and large manufacturing has been using SAMS on their equipment monitoring and fault diagnosis. Figure 15 shows some of the industrial machines that have been tested by SAMS. Due to the limited length of this paper, only a few selected applications are highlighted here.

Fig. 14. Some industrial machines tested by SAMS.

5 CONCLUSIONS

In this essay, an innovative solution for equipment health monitoring called, the smart asset maintenance system (SAMS) has been introduced. With the help of the advanced virtual instruments embedded in SAMS and its powerful methodology, the machine operators can easily detect the occurrence of faults directly from the machine-operating signal. Besides, SAMS contains many comprehensive functions for acquiring and analysing machine running signals, displaying the fault diagnostic results, publishing the results and acquired data on Internet, predicting the deterioration rate of a defective component, automatically generating reports, as well as forming a user-friendly database for the storage and retrieval of the acquired machine data. SAMS has been tested with many industrial machines owned by more than 30 companies, including companies in public utilities, mass transportation, logistics, and large manufacturing. Currently, SAMS is equipped with wireless communication ability that enables a PDA to collect machine data wirelessly. With so many advanced functions built-in SAMS, the current cost of SAMS is less than US$2,000 per system. Hence, SAMS is low-cost yet equipped with the foremost functions for machine health monitoring and its degradation prediction. For continuous developments, the future SAMS will allow not only wirelessly collecting signal, but also wirelessly controlling the monitoring equipment. Moreover, the health information of the inspected machine can be transmitted to remote user via SMS and GPRS that are currently available on smart mobile phones.

SECURITY CONSIDERATIONS FOR MODERN WEB-BASED MAINTENANCE OR REMOTE SENSING SYSTEM

Alan N. Cheuk and Peter W. Tse

Smart Engineering Asset Management Laboratory (SEAM) Department of Manufacturing Engineering and Engineering Management City University of Hong Kong, Tat Chee Avenue, Hong Kong, P. R., China E-mail: meptse@cityu.edu.hk Tel: (852) 27888431 Fax: (852) 27888423

Abstract: In an ever-increasing competitive environment, companies must maintain the quality of their production and services. Hence, machinery or equipment that is critical to production and providing services must be maintained with minimum downtime or a near zero-break down rate. The concept of Web-based maintenance helps to detect faulty equipment at an early stage without the constraints of distance. It provides a convenient platform for maintenance personnel to evaluate the performance of machines even when they are distant. As the Internet is an open environment, its traffic or on-line communication can be easily intercepted. Users who do not adequately protect their Internet communication are exposed to risk. This paper intordouces a Web-based maintenance system with security considerations. With the assistance of several security measures, the data security of our Web-based maintenance system has been enhanced. The data can be transferred safely and the accuracy of the results can be verified. Our Web-based maintenance system works more securely in comparison to conventional Web-based maintenance systems that have been reported thus far.

Key Words: Web-based maintenance; Remote sensing; Data encryption; Internet security.

1 INTRODUCTION

Manufacturing industries are currently faced with the challenge of reducing manufacturing costs but maintaining high productivity and customer satisfaction. An effective maintenance strategy is thus important to survival in a competitive environment. A Web-based maintenance system allows operators to remotely monitor equipment and perform fault analysis. Through the Internet, sensory information and the operating conditions of various types of equipment can be transferred from a factory, for example, to a remotely located office. The managers or engineers can evaluate the working condition of equipment using built-in and Web-enabled virtual instruments that are provided by the server via the Internet. Hence, the cost of maintenance and labour can be reduced, and unscheduled downtime can be minimised. Internet use creates security concerns. While the Internet provides a convenient medium for performing remote monitoring and analysis, the security risk cannot be ignored. As the Internet is as an open medium, hackers can enter Internet channels and intercept information. They can then divert or alter the intercepted information for their own advantage. To deal with the problem of data security, cryptography is a solution. In our Web-based maintenance system, several security mechanisms have been put in place to protect the privacy of data. Confidentiality, authentication, and message integrity are usually the key components of secure communication [1]. Each of these performs a unique role in securing information systems. Data confidentiality is the protection of data from unauthorised disclosure. It protects data from passive threats. Authentication is the protection of data by proving identity. On the Internet, everyone is anonymous. It should be possible for the receiver of a message to ascertain its origin. Integrity is the protection of data from tampering or forgery. The receiver should be able to verify that it has not been modified in transit. By ensuring data confidentiality, integrity, and authentication, machine data can be transferred more safely, which may lead to accurate machine fault identification.

2 SECURITY TECHNOLOGIES

Cryptography is the art and science of keeping messages secure. It helps to prevent intruders from being able to use the information that they intercept. Maintaining data confidentiality, integrity, and authentication are the main issues of protection. The design and implementation of the security mechanisms that are used in our system can be described in three ways: the encryption, message digest, and digital signature. Confidentiality is achieved by encryption, message integrity is accomplished by message digest and authentication is attained by digital signature.

Encryption is the process of changing information (plaintext) into a format (ciphertext) that is unreadable or unusable [2] and [3]. It can be classified into two categories: symmetric and asymmetric. A symmetric algorithm applies the same key for encryption and decryption. Once the key is agreed upon by two communicating parties, it is known by only the sender and the receiver. No one else can access it. An asymmetric algorithm applies different keys (a public key and a private key) for encryption and decryption [4]. A public key is available to everyone, which means that anyone can perform encryption and signature validation. A private key is undisclosed and is used to decrypt messages that have been encrypted by a corresponding public key. A sender encrypts a message with the recipient's public key and sends the encrypted message to the recipient. Only the recipient who knows the corresponding private key can decrypt the message [5]. A symmetric algorithm is an efficient encryption method that can be performed quickly. However, there is a problem with key distribution [c]. An asymmetric algorithm can solve the problem of key distribution, but it has the drawback of slow performance. An alternative solution is to use both symmetric and asymmetric algorithms [6] and [7]. Thus, both symmetric and asymmetric algorithms are applied to our Web-based maintenance system to achieve both advantages. An asymmetric algorithm is used to exchange the undisclosed secret key that is used in the symmetric algorithm. Subsequently, a symmetric algorithm is used to exchange bulky machine signals. This can combine the fast performance of a symmetric algorithm and the key distribution of an asymmetric algorithm.

To achieve reasonable security in data transmission, ensuring confidentiality, integrity, and authenticity are needed [b]. However, the use of encryption can only accomplish confidentiality. Hackers can still alter the encrypted message by adding or deleting some of the message content. Moreover, a recipient who obtains the key can only decrypt the message – it is difficult to determine the origin of the message, and the received message may not originate from where the corresponding party claims that it originates. Hence, other security mechanisms are needed to achieve data integrity and authenticity. The combination of encryption, message digest and digital signature is the solution. Message digest is the primary mechanism in achieving message integrity [8]. It is obtained by a hash function, which is a mathematical formula that converts an arbitrary-length input (message) into a fixed-length output (hash value) [9]. The hash value is transferred with the original message to the recipient. After decryption, a recipient carries out the same hash function in relation to the message. We can verify that the received message is not altered if the hash value is the same as the one received. Otherwise, the message has been altered or compromised during transmission. An essential property of hash function is that it is a one-way function. If someone obtains the hash value of a hash function he or she cannot reverse the hash function to retrieve the input. A further property of the hash function is it is collision free. It is assumed that we cannot create the same hash value from two different inputs, while little change of the input will result in a very different hash value. This characteristic helps to increase the difficulty of accessing the original message. While hashing can provide data integrity, it is ineffective if it does not contain origin authentication [10]. When receiving a hash value and its origin message, it is difficult to verify that the message originates from the identified sender. Hence, hashing is needed to include a proof of the sender's identity. A digital signature is needed to provide message authenticity and prevent tampering [d]. A digital signature is a combination of hash function and an asymmetric encryption. A message is first subjected to a hash function. The hash value is then encrypted with the sender's private key to form a digital signature. Once it is received, the receiver can use the sender's public key to decrypt the digital signature. As the public key is the only key with which to decrypt the message that has been encrypted by its corresponding private key, and as the sender's public key can decrypt the digital signature, we can verify whether the message originates from the identified sender.

3 APPLICATION OF SECURITY MECHANISMS IN WEB-BASED MAINTENANCE

The architecture of our Web-based maintenance system is shown in Figure 1. This system can be divided into three main components: local items, server, and remote user. A local computer is used to carry out data acquisition and data publishing. A server is where the analysis and storage of diagnostic programs are performed. To perform a diagnostic test, the server first collects the data from the local computer. At the same time, the collected data and the required diagnostic program are sent to the requested user for analysis. Yet, the Internet is an insecure environment. The security risk cannot be ignored. Figure 2 shows a possible path that a hacker may intercept or through which he or she may alter a machine's signal that is transmitted via the Internet. Consider the case in which a maintenance person wishes to perform an analysis to check the performance of a remotely located machine. The maintenance person must first collect the raw signal of the inspected machine. Once the data has left its origin and has been transferred via the Internet, there is the possibility of a hacker diverting or altering the raw data. The altered raw data thus affects the accuracy of the analysis, which is performed by the maintenance person at a separate location.

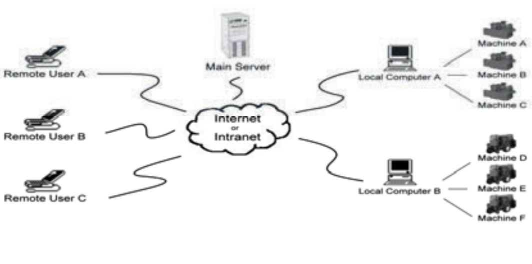

Figure 1: Architecture of Web-based maintenance system

The data protection processes that are used in our Web-based maintenance system are formed by combining symmetric encryption, asymmetric encryption, hashing, and digital signature. As asymmetric encryption does not contain the problem of key distribution, it is used for key exchange. The secret key that is used in symmetric encryption is first exchanged with the aid of asymmetric encryption. Subsequently, bulky machine data can be protected by symmetric encryption that can be performed quickly. This alternative approach can utilise both the advantages of symmetric (fast performance) and asymmetric (key exchange) encryption. The diagram on the left of Figure 3 shows the overall key exchange processes that are used in our system. The secret key is first transferred to a hash function. The hash value is then subject to an asymmetric encryption with the sender's private key to create a digital signature. This digital signature and the original secret key are then combined and transferred to an asymmetric encryption by a receiver's public key to form the final encrypted key block. Once it is obtained, the receiver can decrypt the encrypted key block with a private key to retrieve the secret key and the digital signature. As the sender's public key is openly accessible, the receiver can easily obtain the public key of the sender to decrypt the digital signature. To verify the secret key, it is transferred to the same hash function that is performed by the sender and the result is compared with the one that is obtained in the digital signature. If the two values are exactly the same, then we can verify that the secret key is valid and that it is sent from the local computer it claims to have been sent from.

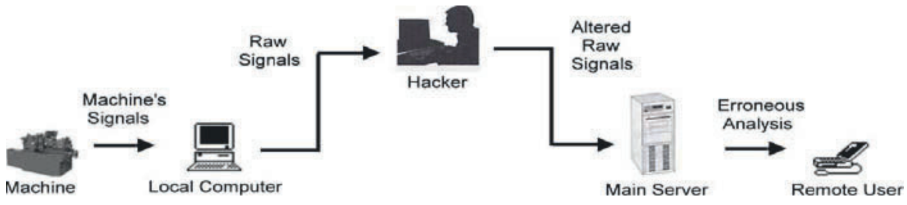

Figure 2: Data security problem in Web-based maintenance system

After the secret key exchange, symmetric encryption is used for further data protection. The right diagram in Figure 3 shows the overall data exchange processes that are used in our system. The operation of data exchange is similar to key exchange. The only difference is that the algorithm that is used for data encryption is changed to a symmetric encryption. Data is first transferred to a hash function to obtain a hash value. This hash value is then encrypted (asymmetric algorithm) with the sender's private key to create a digital signature. The original data and the corresponding digital signature concatenate and carry out a symmetric encryption to create the final encrypted data block. The encrypted data is unreadable by other parties. To retrieve the original data and the corresponding digital signature, the receiver uses the secret key that has already been obtained to decrypt the encrypted data block. The decrypted data is then transferred to the same hash function to produce a new hash value for comparison. If this hash value is the same as the one that is obtained in the digital signature, then the data can be verified as valid and can be used for diagnostic analysis.

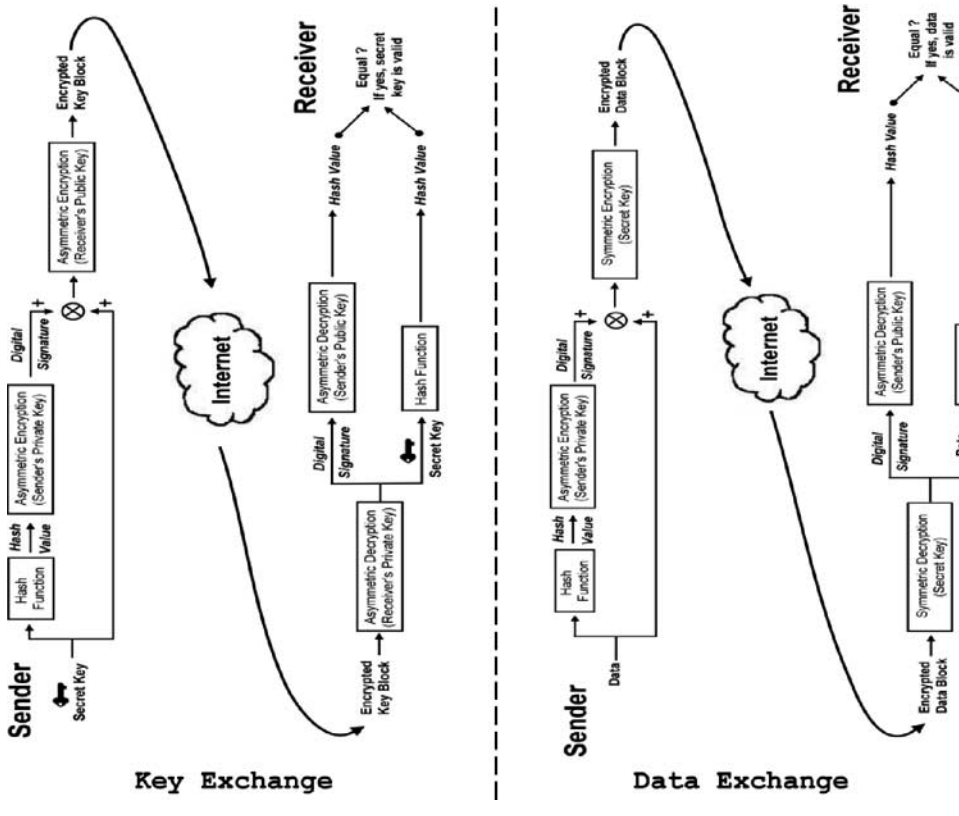

Figure 3: Security processes for key exchange and data exchange

4 SECURITY ALGORITHMS USED IN WEB-BASED MAINTENANCE

The algorithms that are used in our system for symmetric encryption are the Data Encryption Standards (DES) and the Advanced Encryption Standard (AES) [11] and [12]. They are Federal Information Processing Standards (FIPS) that are managed by the National Institute of Standards and Technology (NIST). The NIST is a federal technology agency in the United States that develops and promotes measurement, standards, and technology. The Federal Information Processing Standards Publication (FIPS PUB) is developed by NIST as guidelines for communicating and securing data in information systems. DES is designed for enciphering and deciphering blocks of 64-bits. The key in DES is also 64-bits, but only 56-bits are used (remaining 8-bits are used for parity checks). AES is designed for enciphering and deciphering blocks of 128 bits. The key in AES can have three sizes: 128-bits, 192-bits, and 256-bits. For the point of security, AES is stronger than DES as it is the replacement of DES approved by the US NIST. While DES is less secure than AES, it still has its value in that the processing time of DES is shorter than AES. Thus, our system has implemented both DES and AES as an option for the system user. Users need to determine which they are more concerned about, processing time or protection level, and to select their favourite algorithms.

The algorithm RSA is used for asymmetric encryption. RSA is derived from the first letters of the surnames of its creators (Rivest, Shamir and Adleman). In our Web-based maintenance system, RSA is used to protect the secret key that is used in DES or AES and to produce the digital signature. The basic operation of RSA depends on the factoring problem. Factoring problem is the problem of finding which factors are multiplied to produce a particular number. It is straightforward to multiply several numbers, but it is not easy to figure out what numbers were combined to produced a particular result [13]. RSA contains three main parts: public key e, private key d, and the shared value N (which is often called modulus). The public key e_r and modulus N_r of the receiver are open to the sender. The private key d_r remains undisclosed so that only the receiver knows its value. To encrypt the secret key, the sender makes use of the receiver's public key e_r and modulus N_r. To decrypt it, the receiver can make use of their own private key d_r and modulus N_r. To produce a digital signature, the sender uses their own private key d_s and modulus N_s to encrypt the hash value of the message. The sender's public key e_s and modulus N_s are the components that verify the authentication of the message.

The hash function that is used in our Web-based maintenance system is the Secure Hash Algorithm SHA-1 [14]. SHA-1 conforms to Federal Information Processing Standards (FIPS) for data security and is used in a large variety of security applications to ensure message integrity. Essentially, SHA-1 is similar in structure to another common hash function that is called MD5. The reason for implementing SHA-1, but not MD5, is that SHA-1 produces a larger message digest than MD5. The message digest of MD5 is 128-bits (approximately 3.4 x 10^{38} possible hash values), while the message digest of SHA-1 is 160-bits (approximately 1.4 x 10^{48} possible hash values). As SHA-1 produces a larger message digest, it is less likely to produce the same message digest with two different inputs. Due to the difference in message digest size, SHA-1 seems to be more suitable for our application. Although SHA-1 is 35% slower than MD5, it is a reasonable trade-off to obtain a better security performance. Hence, SHA-1 is selected as the hashing algorithm of our Web-based maintenance system.

In addition to the above algorithms, our Web-based maintenance system also provides another type of protection. As the diagnostic program is sent to remote users to perform diagnostic tests, the first thing we do is restrict the access right of the remote user (viewing, control, or deny). Each remote user is identified by a personal IP address and is given access right. For a remote user who only has viewing privilege, he or she can only view the analysed result in the program but cannot control any function in it. This can prevent an inexperienced user from inputting an invalid parameter into the system. Furthermore, the server can refuse the requests of particular remote users. This helps to prevent overuse of the system. Although unauthorised users can change their IP addresses to pose as authorised users, they must still know the value of a valid IP address. That is, unauthorised users cannot obtain access rights until a valid IP address is matched. The second protection is to restrict the usability of the diagnostic program. As all of the diagnostic programs are stored in the server, it is necessary to specify which programs are accessible to remote users. The server only publishes programs that can be accessed by authorised remote user. Even remote users who satisfy the above requirements (valid access right and valid program) must provide the correct password. To obtain the diagnostic program, remote users must input a URL to link up with the server. Before obtaining the required diagnostic tools, they must input a correct password to prove their identities. Otherwise, they are unable to obtain a diagnostic program.

5 CONCLUSIONS

This paper shows the architecture and the security processes of our Web-based maintenance. With Internet use and the advanced function of diagnostic programs, authorised managers or engineers can determine if machines are faulty without having to be on-site. Security is a prime concern for every Web-based system. To ensure the security of a machine's communication, several security mechanisms have been added to protect the privacy of data communication. The combined use of symmetric encryption and asymmetric encryption provides better encryption performance. The hash function and digital signature facilitate and ensure data integrity and authenticity. In addition, restricting the access right and usability of the program helps to prevent illegal use of our system. Coupled with password protection, Web-based maintenance can achieve reasonable security in data communication. By using our Web-based maintenance, sensory information and the operating conditions of various types of machines can be securely transferred from a factory, for example, to a remotely located office. Managers or engineers can then quickly evaluate the working condition of the equipment. As a result, companies can maximise their manufacturing productivity and customer satisfaction.

ON THE CONDITION MONITORING OF WORM GEARS

Pekka Vähäoja, Sulo Lahdelma and Jaakko Leinonen

University of Oulu, Department of Mechanical Engineering, P. O. Box 4200, FI-90014 Oulu, Finland

Abstract: There has been fairly little research into the condition monitoring of worm gears, although gears of this type have been attached to critical machines in various fields of industry and significant production losses may arise from their breakdowns. Literature has been published on the designing of worm gears but information is rarely provided on fault diagnostics concerning these gears, especially with regard to real-life industrial applications. Some research has been carried out with laboratory-scale test rigs. There is thus an evident need to develop the condition monitoring of worm gears as a basic form of research, but especially to meet the requirements of different fields of industry. This paper gathers together the general information and research reports available on worm gears. Experiences gained from the use of oil analysis and vibration analysis in diagnosing the condition of machines with worm gears are presented in the form of case studies carried in industry. Our experiences of industrial machines with worm gears cover machines employed in cable manufacturing and talc production. We have been monitoring pressers in a cable-manufacturing factory by means of vibration analysis and wear metal analysis of oils for several years now. Condition monitoring data for certain talc agglomerating machines in a talc factory have been gathered during the past few years by means of an oil analysis, and some vibration monitoring data have also been collected. Four similar machines were used here and compared with each other in order to point out similarities and dissimilarities in their behaviour. The aims of this study were to find suitable condition monitoring methods for different machine types all using worm gears and to choose the most sensitive features for routine use in the maintenance of such machines in future. Another aim was to find out if it is possible to propose any common recommendations for the condition monitoring of worm gears.

Key Words: condition monitoring, worm gears, vibration analysis, wear metal analysis

1 INTRODUCTION

A worm gear consists of a worm and a worm wheel, which typically run on crossed axes. The most important part of this gear is the worm, which is usually made of high quality steels. The worm has to be manufactured with high accuracy according to standards. The worm wheel is usually made of different types of bronze mixtures. Due to the high price of bronze, the toothed area is made of bronze and the hub is made of cast iron. By using the worm gear, large gear ratios, even 100:1, can be achieved with only one stage so the relative size and weight of the worm gearbox is usually small. For comparison, helical and conical gears usually have a maximum gear ratio of 5 at one stage in modern applications [1]. Increasing of the gear ratio naturally reduces the diameter of the input shaft, which has a significant influence on the efficiency of the gear. The efficiency of worm gears is usually about 90 %, but it can be as low as 50 % with certain types of worm gears [2]. On the other hand, worm gears damp vibration significantly better than do other types of gears, and run quietly. Worm gears generate a lot of heat, so they have to be cooled, for instance, with a lubricant, ribs of the gear casing or an extra fan. The temperature of the worm gear may not exceed 80 - 90 ^{o}C. Lubrication can be carried out with grease in the case of small and low-speed gears (sliding speed below 4 m/s). Bath lubrication can also be used with low-speed gears (sliding speed below 4 m/s), but splash lubrication is the most common way to lubricate worm gears. Splash lubrication can be used with the sliding speed range from 1.5 to 10 m/s. If the sliding speed exceeds 10 m/s, lubrication has to be carried out under pressure. Lubricating oils for worm gears are usually high-quality, high-viscosity oils with special additives, like EP-additives, to protect or smooth over tooth profiles. Worm gears are often used in machines in which the loading is variable or impact-like. Typical application areas are machines at sawmills and different conveyors. [1-3]

Literature on the condition monitoring of worm gears is relatively scarce. The wearing and surface fatigue of worm gears can easily be detected by means of the wear metal analysis of the gear oil. Wearing of the worm wheel releases bronze particles into the gear oil and correspondingly the worm releases steel particles. The worm wheel usually wears easier because it is made of softer material than the worm. Typical wearing mechanisms are pitting and abrasion [4]. Increased copper and iron concentrations in the gear oil are good failure mode indicators of the wearing of worm wheels and worms in cases where the gear oil only lubricates the gear [5]. Vibration analysis is not used very widely in analysing the condition of worm gears. This may be due to the fact that it is relatively laborious to analyse the vibration signals of worm gears. For instance, impacts at gear mesh frequencies and their sidebands are often followed in the condition monitoring of other types of gears [6], but in worm gears these vibrations are not very informative mostly due to the sliding contact of the gear. Peng *et al.* [7-8] have carried out research where they studied an experimental test rig consisting of a worm gearbox driven by an electric motor in controlled operating conditions. Their focus was an integrated approach to fault diagnosis using both wear debris analysis of gear oil and vibration analysis. The focus was not exactly on the condition monitoring of worm gears, but on comparing the possibilities of these methods in failure detection in more general. They did experiments in different conditions: under the lack of proper lubrication, in normal operating condition and with different contaminant particles in the gear oil, finding out that the wear debris analysis is useful in detecting wear rates and wear mechanisms of the gears, while vibration analysis can provide information on the condition of the bearings. Marshek *et al.* [9] performed a qualitative analysis of the failures of plastic worm gears. They observed that the failure modes for plastic gears were usually quite similar to those of metal gears and differed only in terms of dissimilarities in material properties and processing. Ya-xiong *et al.* [10] studied the wearing of worm gears by analysing the surface shape of the worm tooth flanks. Literature on the usual properties and design of the worm gears is available in the form of machine design textbooks and various articles. For instance, geometric and kinematic factors in worm gear design, tooth contact and stress analysis of worm gears have been discussed in various investigations, and different standards pose requirements that are to be followed. [11-19]

In this study, the condition of certain worm gears was studied by means of a gear oil wear metal analysis and machine vibration analysis. The aim was to find the most suitable features in the failure detection of worm gears and possibly to propose general guidelines for the condition monitoring of worm gears.

2 EXPERIMENTAL PART

The studied machines were used in talc agglomeration in the Mondo Minerals Oy talc factory in Sotkamo, Finland and for copper cable manufacturing in Draka NK Cables Ltd cable factory in Oulu, Finland. Talc agglomerating machines had a worm gear with a worm wheel made of zinc bronze and a worm made of steel. The gears were lubricated with synthetic polyalkyleneglycol oils. The machines had earlier been monitored by means of wear metal analysis and other oil analyses [5]. Cable manufacturing machines had a worm gear with a worm wheel made of tin bronze and a worm made of steel. The machines were lubricated with mineral oils and had formerly been studied by means of wear metal analysis and vibration analysis.

The gear oils were subjected to a wear metal analysis carried out by a microwave-assisted acid digestion and ICP-OES measurement procedure. The gear oil samples (0.4 g) were digested with a 10 ml nitric acid and 2 ml hydrogen peroxide mixture using a two-stage digestion with a Mars 5 microwave oven and HP 500 digestion vessels. The digested samples were diluted with ultra pure water. Typical wear metals were determined by means of Thermo Electron IRIS Intrepid II XDL ICP-OES instrument applying a method described in detail in our other article [20].

Machine vibration measurements were carried out using two different measurement chains. Acceleration signals were detected by means of Brüel & Kjaer Type 4370 and 4370 V accelerometers, amplified using a Brüel & Kjaer Nexus Type 2692 conditioning amplifier and digitized with a NI 9162 Hi-Speed USB carrier, and stored on a lap-top computer with a NI LabVIEW 7.1 software. Acceleration signals were also detected with a Wilcoxon 726 accelerometer and recorded with a Casio DA-7 DAT recorder. Machines were also listened to by means of a SKF TMST2 stethoscope and afterwards from recorded acceleration signals. Effective values of vibration velocity were measured by means of a Mitsol K-94 instrument and peak values of jerk and $x^{(4)}$ by means of a Mitsol D-94 instrument. The same values were also calculated using the LabVIEW 7.1 software. In addition, acceleration, jerk and $x^{(4)}$ time domain signals were analyzed and corresponding spectra were calculated and analyzed with the LabVIEW 7.1 software and also with an Ono Sokki CF 5220 FFT analyzer using an analogue differentiator Mitsol DV-971.

3 RESULTS AND DISCUSSION

3.1 Case Study 1: Talc agglomerating machines

Four similar machines were used in talc agglomeration. Two of them had formerly been studied by means of the wear metal analysis of gear oils. Severe wearing of the worm wheel and the worm of the other machine was detected, while the other was in good condition. Worn machine elements were replaced and the use of both the machines was continued without problems. The detection of the failure at an early stage caused savings of about 200,000 € at diminished repair costs and production losses. The next measurements were carried out ten months after the failure detection, at which point the copper and iron concentrations were at a low level indicating that the repair had been successful. More information on the damaged machine (marked as machine B in this article) is provided in our previous article [5]. At this time, it was decided to monitor the condition of the worm gears of the machines by means of different methods. Gear oil samples were taken from all four machines (machines A-D). In addition, vibration measurements were carried out for two machines (machines C and D).

The analysis results for the two failures, indicating the presence of metals, copper and iron in the gear oils of the machines A-D, are given in Table 1. Copper is the main component in the toothed area of the worm wheels and iron in the worms, which directly indicates the wearing of these machine elements as discussed in our previous article [5].

Table 1

Copper and iron concentrations of the gear oils of talc agglomerating machines

Sample	Cu [mg/kg]	Fe [mg/kg]
Machine A	13	< 2
Machine B	4	< 2
Machine C	94	37
Machine D	< 1.5	5

The concentrations of copper indicating the failure of the worm wheel were at low level in the gear oils of machines A and B and even below the detection limit of the ICP-OES instrument in the gear oil of machine D. However, the copper concentration of the gear oil of machine C is large (94 mg/kg) and indicates that the worm wheel is wearing all the time. It should also be noted that the present gear oil had only been used 14 months. Correspondingly, the iron concentration of the gear oil of machine C has also increased (37 mg/kg) indicating that the worm has also worn slightly. The iron concentrations of the other machines were at a very low level. For comparison, the concentrations of copper and iron in the gear oil in the failure detection of machine B in September 2002 were 106 and 188 mg/kg, respectively. The conclusion is that according to the indicator metal analysis, the teeth of the worm wheel and in a lesser degree also the worm of machine C have worn so their condition should be monitored more intensively.

Vibration measurements were carried out for machines C and D of which the worm gear of machine C was wearing and the worm gear of machine D was in good condition, as indicated by the wear metal analysis. Vibration measurement points are shown in the sketch in Fig. 1 and picture of machine C (machine D is similar) in Fig. 2.

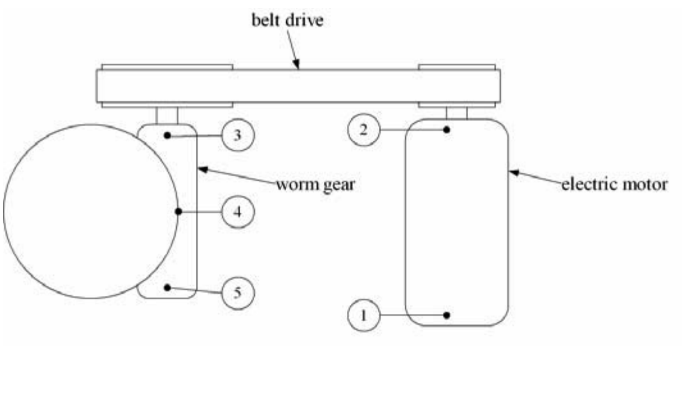

Figure 1. Schematic presentation of machines C and D

Figure 2. Motor (160 kW) and worm gear of machine C.

Excessive vibration at points 3 (vertical), 4 (horizontal) and 5 (vertical) indicates failures in the worm gear, whereas excessive vibration at points 1 (radial) and 2 (radial) indicates the condition of the electric motor. Acceleration signals measured at point 4, i.e. close to the contact point of the worm wheel and the worm, of machines C and D are shown in Fig. 3 and corresponding $x^{(4)}$ signals in Fig 4. More information on the $x^{(4)}$ and other higher order time derivatives of displacement is provided, for instance in [21-22].

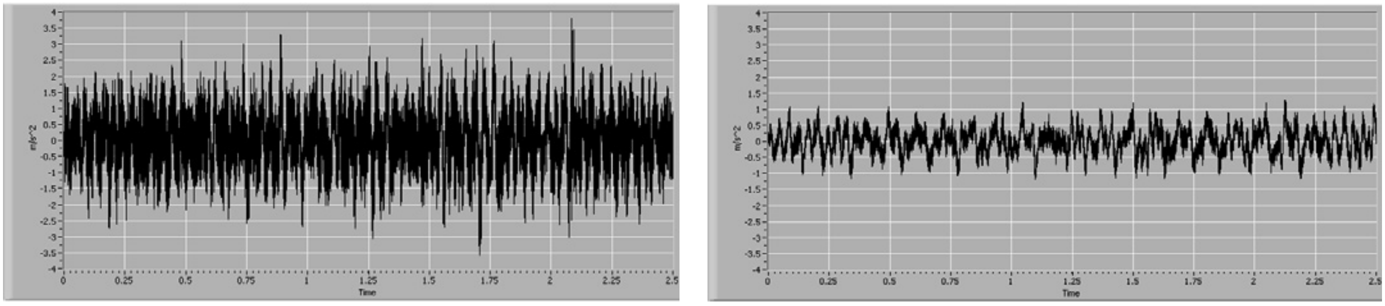

Figure 3. Acceleration signals in the frequency range 3-1000 Hz at point 4 of machines C and D.

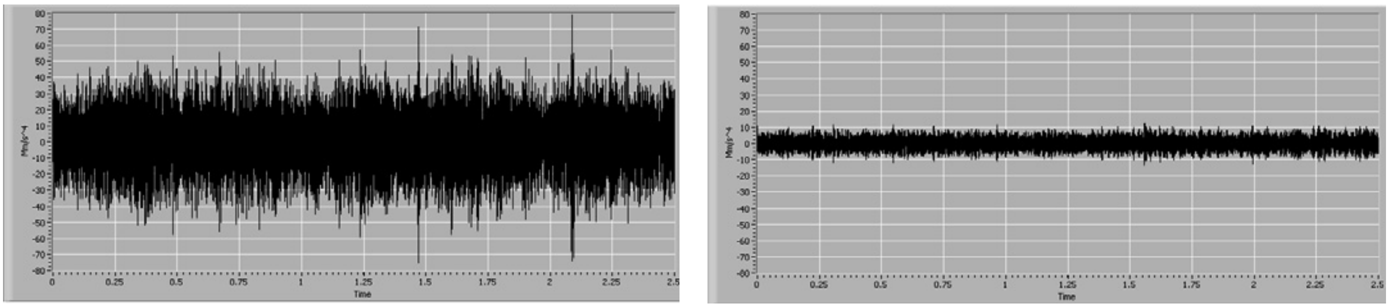

Figure 4. $x^{(4)}$ signals in the frequency range 3-1000 Hz at point 4 of machines C and D.

As indicated in Fig. 3, the levels of acceleration of machine C are larger than the ones of machine D, but there is no clearly distinguishable gear fault. The $x^{(4)}$ signals for machines C and D pointed to a couple of impacts in the signal for machine C. On the other hand, the gear of machine D has no significant impacts. It is easier to detect a gear fault when the frequency range is extended. Similar signals as in Figs 3 and 4 are presented in the frequency range 3-2000 Hz in Figs 5 and 6 and in the frequency range 3-4000 Hz in Figs 7 and 8.

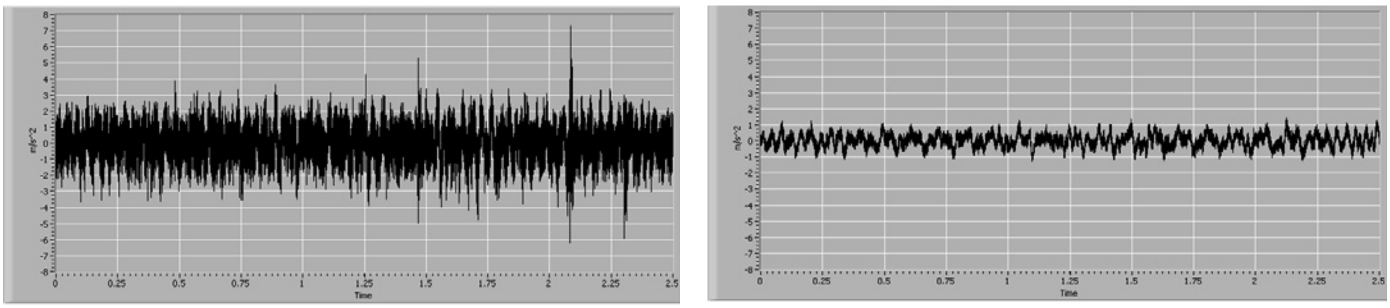

Figure 5. Acceleration signals in the frequency range 3-2000 Hz at point 4 of machines C and D.

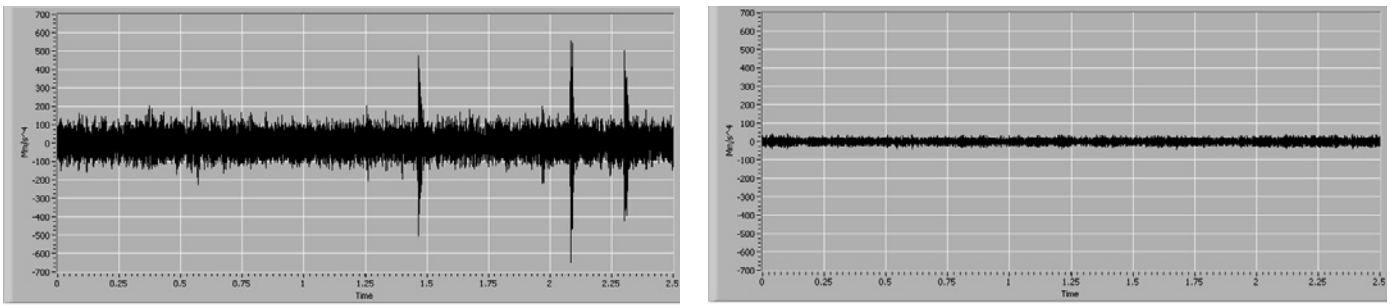

Figure 6. $x^{(4)}$ signals in the frequency range 3-2000 Hz at point 4 of machines C and D.

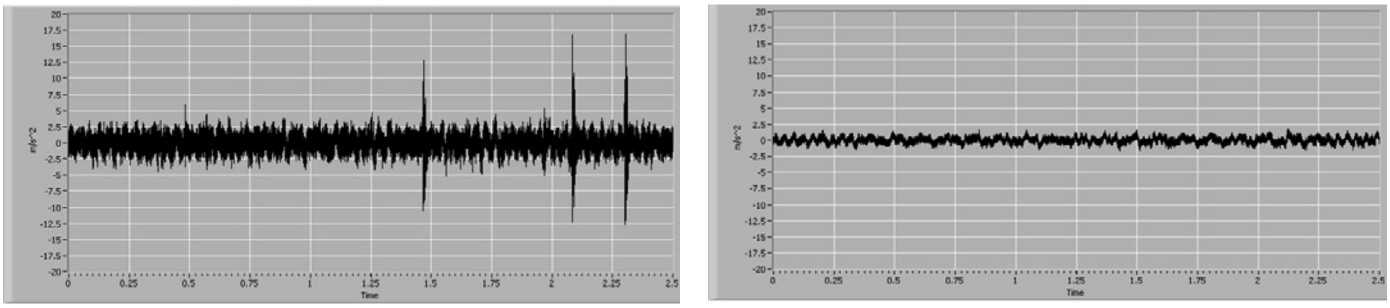

Figure 7. Acceleration signals in the frequency range 3-4000 Hz at point 4 of machines C and D.

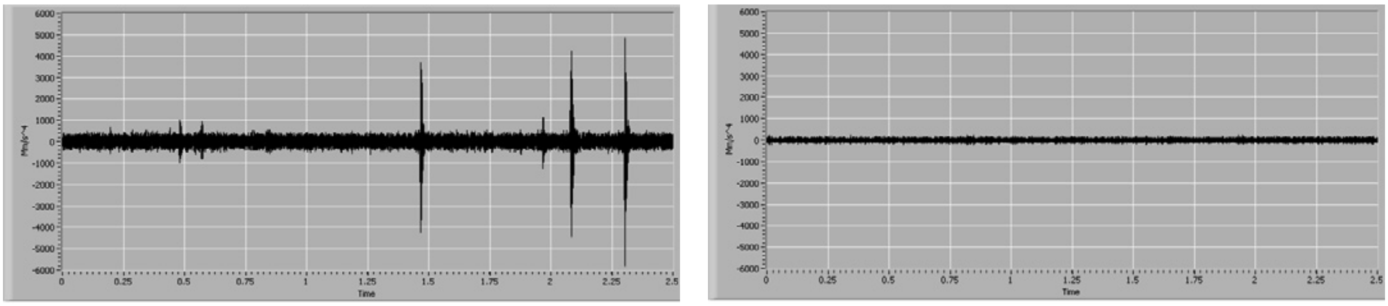

Figure 8. $x^{(4)}$ signals in the frequency range 3-4000 Hz at point 4 of machines C and D.

As seen from Figures 5-6, clear impacts can also be observed from the acceleration signal and very clearly from the $x^{(4)}$ signal in the frequency range 3-2000 Hz. When the frequency range is extended even more, the gear fault can be very easily detected from both the signals. But as stated, it is sufficient to only study the frequency range up to 2000 Hz and the gear fault can still be detected easily. Impacts observed in the time domain signals of machine C could be heard clearly as sharp snaps, when the vibration signals were listened to from DAT tapes and also with a stethoscope. Listening to the signal of machine D only revealed a slight sound of friction, which is typical of worm gears in which the contact between the worm wheel and the worm is sliding. The neighbourhood of the contact point of the worm wheel and the worm, i.e. measurement point 4 in this study, of course tells most about failures and wearing of the worm gear, but the impacts caused by the fault could also be observed easily at the measurement points 3 and 5 on the worm. However, it should be noted that the signals were slightly damped. The reason for the observed impacts is probably the contact of the worm and the failure spots of the worm wheel. The wear metal analysis of the gear oil of machine C already indicated that the worm wheel was wearing, while the gear of machine D had not worn. It was formerly shown in our other publication [5] that the worm wheel of the corresponding talc agglomerating machine (machine B) had worn by pitting, and the pits on the teeth of the worm wheel were large. A finite element analysis made by Su and Qin [23] indicates that certain types of worm gears are sensitive to manufacturing errors. These errors change the contact pattern under loading and increase stress concentration. Simon [24] has indicated that tooth spacing errors and shaft misalignments have influence on tooth contact, so it is possible that slight errors in the tooth profile increase the stress on teeth and finally cause wearing. This wearing can then be observed as excessive vibration in the time domain signals.

One should keep in mind that it seems that the impacts caused by worm gear faults are not necessarily periodical but somewhat stochastic. Because of the behaviour of these gears, it is advantageous to record vibration signals over a relatively long time period. The acceleration and the $x^{(4)}$ signals with a time duration of 50 seconds are shown in Figs 9 and 10.

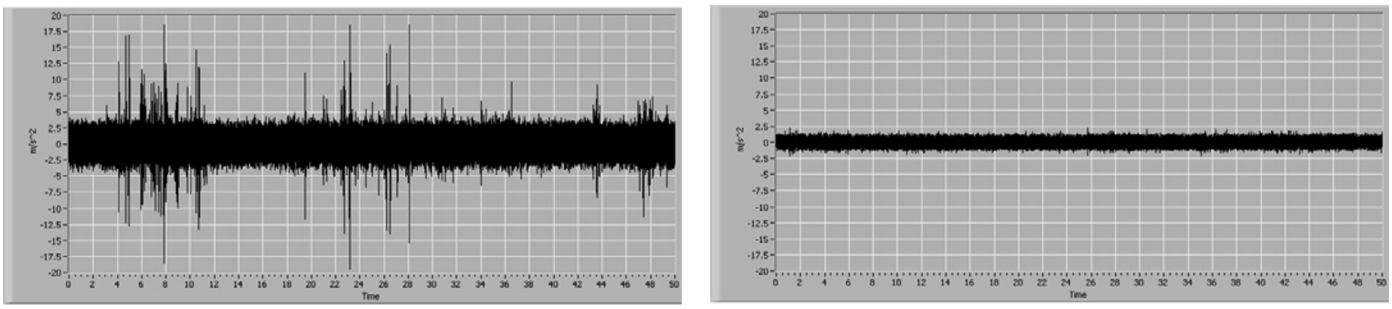

Figure 9. Acceleration signals in the frequency range 3-4000 Hz at point 4 of machines C and D.

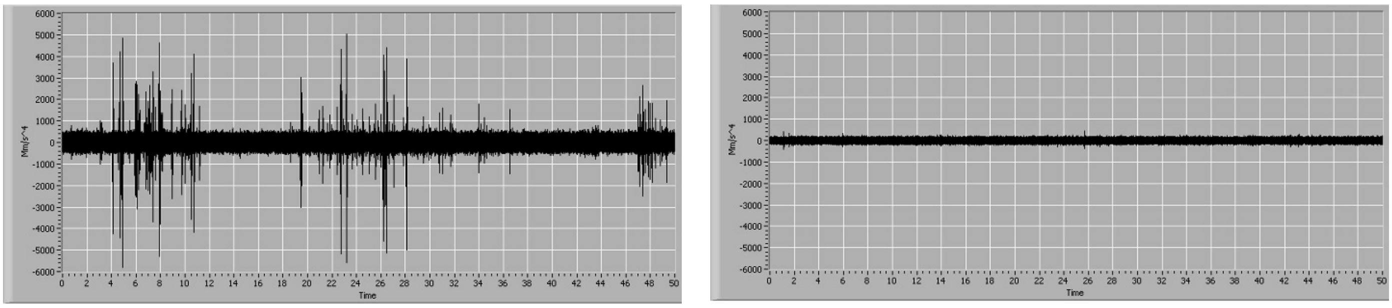

Figure 10. $x^{(4)}$ signals in the frequency range 3-4000 Hz at point 4 of machines C and D.

Figs 9 and 10 show that there is a gear fault in machine C and that machine D is in good condition. The more important observation is that there is no periodic structure in the time domain signals as is usual with faults in other types of gears. The impacts occur almost occasionally. As seen previously, the time domain signals of acceleration and higher order time derivatives of displacement can be very informative, when looking for faults in worm gears. On the other hand, velocity signals were not useful in the failure detection of the worm gears. This is quite obvious, because velocity is seldom sensitive to faults at higher frequencies, like gear failures. The following step after the inspection of the time domain signals is of course to thoroughly study the frequency spectra of the vibration signals. Frequency spectra are usually very informative in detecting failures in other types of gears. If the gear has a fault, increased peaks will occur at the gear mesh frequency, at its multiples and at the sidebands of the gear mesh frequency. Vibration components at the gear mesh frequencies indicate whether or not the gears are in good condition. An example is the acceleration spectrum of an input shaft of a gear in a production crane [25] shown in Fig. 11. All spectra presented in this article are given as rms-values.

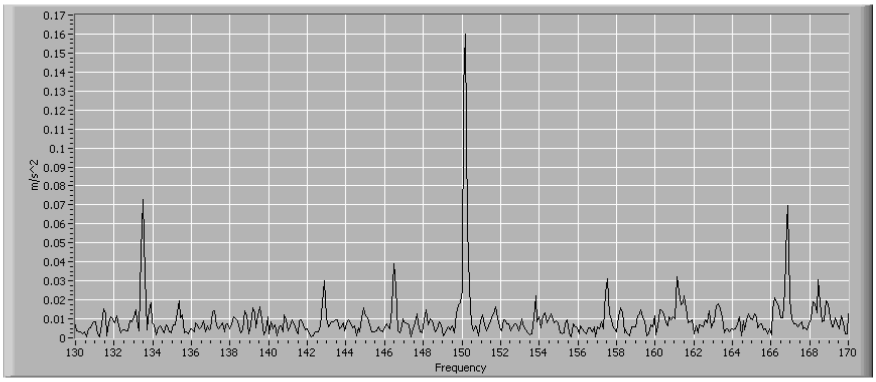

Figure 11. Acceleration spectrum of an input shaft of a gear in a production crane.

An amplitude at the gear mesh frequency of 150.2 Hz and sidebands at 133.5 and 166.9 Hz are observed in this case, although the gear was in good condition. On the other hand, our former study with the copper cable manufacturing machines indicates that a fault in a worm gear cannot necessarily be detected at gear mesh frequencies, but rather as excessive vibration in the higher frequency range caused by increased friction. The frequency range indicating a gear fault was 1350-2250 Hz in that case. Hence it is interesting to see how the frequency spectra can be used in gear fault detection in this case. Acceleration and $x^{(4)}$ spectra of machines C and D are given in Figs 12 and 13, respectively.

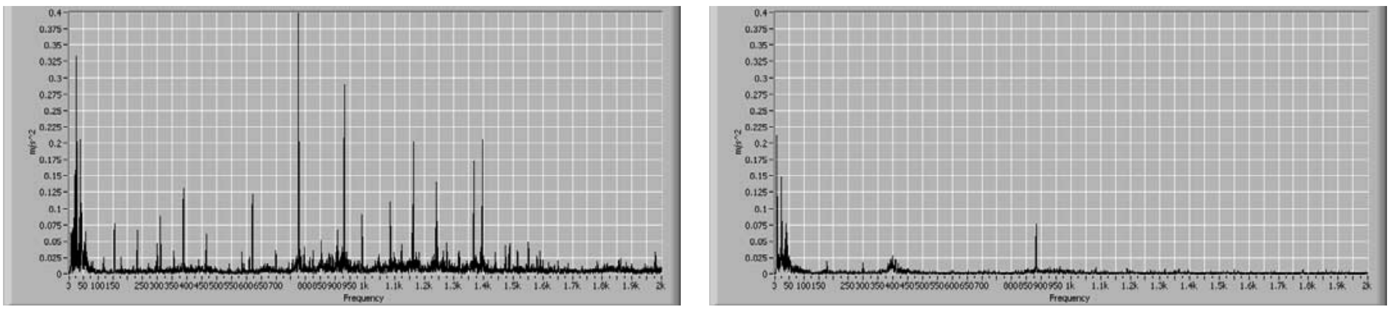

Figure 12. Acceleration spectra in the frequency range 3-2000 Hz of machines C and D at point 4.

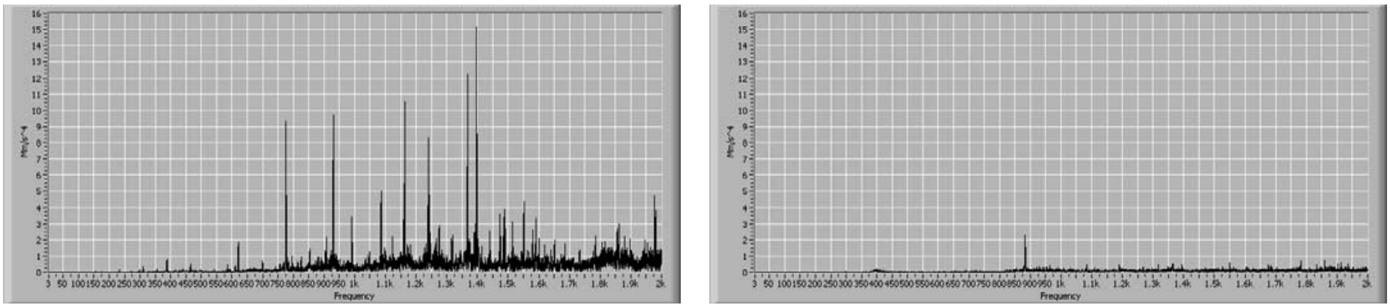

Figure 13. Spectra of $x^{(4)}$ in the frequency range 3-2000 Hz of machines C and D at point 4.

As seen from the frequency spectra of the signals measured near the contact point of the worm wheel and the worm, the amplitudes of acceleration and $x^{(4)}$ are quite low so any exact peak suggesting faults in the gear cannot be observed. Certain peaks at the frequencies of 1000-2000 Hz may be introduced by friction in the worm gear. When the spectrum of either acceleration or $x^{(4)}$ of machine C is compared to the corresponding spectra of machine D, the difference is observable. There are no peaks telling about friction introduced by a fault in the worm gear so the worm gear of machine D is in good condition. The peak at 775 Hz (10 times 77.5 Hz) and other multiples of the frequency 77.5 Hz in the spectrum of machine C suggest an outer race-bearing fault of the electric motor. The vibration caused by this fault is also observed in the worm gear, because the gear and the motor stand on a same foundation *via* which the vibration is transmitted. This fault will be clarified later in this chapter.

One aim of this study was to find out the most sensitive features of worm gear failure detection. Table 2 shows the sensitivities of different features in three different frequency ranges used in failure detection. These sensitivities were calculated from the measurements at point 4. The sensitivities were calculated as averages of twenty values. The sensitivity of a feature is defined as follows:

Sensitivity = (Value of the feature of the machine C) / (Value of the feature of the machine D) (1)

Table 2

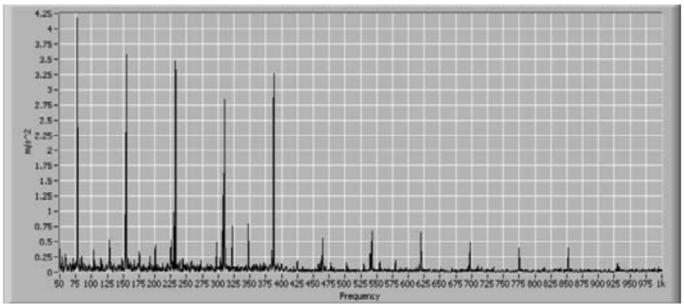
Sensitivities of different features in worm gear failure detection.

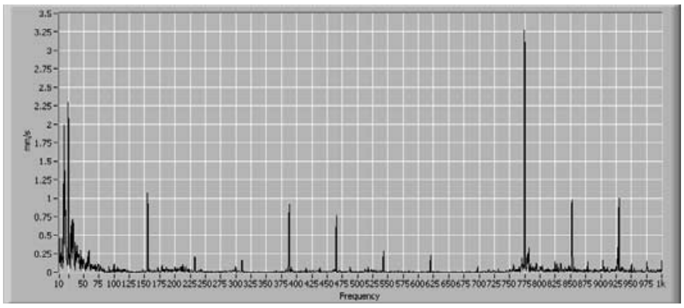
Feature	3-1000 Hz	3-2000 Hz	3-4000 Hz
a_{rms}	2.32	2.77	2.91
$a_{kurtosis}$	1.36	1.27	1.72
a_{peak}	2.93	3.86	5.43
$x^{(3)}_{rms}$	4.18	5.21	3.62
$x^{(3)}_{kurtosis}$	1.14	1.29	4.51
$x^{(3)}_{peak}$	***4.40***	7.06	8.94
$x^{(4)}_{rms}$	4.26	4.98	3.28
$x^{(4)}_{kurtosis}$	1.11	1.65	6.96
$x^{(4)}_{peak}$	4.22	***7.88***	***9.49***

The most sensitive feature in worm gear failure detection in the frequency range 3-1000 Hz was $x^{(3)}_{peak}$, and in the frequency ranges 3-2000 Hz and 3-4000 Hz it was $x^{(4)}_{peak}$. The sensitivity of the peak values in failure detection is very probable, because occasional impacts occur in the vibration signals. The impacts caused by the gear fault are in the higher frequency range and it can also be seen from Table 2 that sensitivities of the features using peak values increase when the frequency range is extended. The rms-values can also be used in failure detection, but they seem to emphasize more the lower frequency range, where e.g. the bearing fault occurs. The sensitivities tend to decrease with $x^{(3)}$ and $x^{(4)}$ using rms-values in the failure detection of the worm gear, when the frequency area is extended from 3-2000 Hz to 3-4000 Hz. Kurtosis seems to be the worst feature in worm gear failure detection in this case. This is in line with our earlier study of worm gears, where kurtosis showed no indication of a worm gear wear [5].

As seen previously in this chapter, wearing of the worm gear could be detected both by means of an analysis of indicator metals (copper and iron) and vibration analysis. Failure in the worm gear might also have been detected by means of other techniques, such as acoustic emission [26]. However, we saw no reason to use acoustic emission in this case, because the failure could be detected with less expensive techniques. It should be noted that the sensors of acoustic emission are more expensive than corresponding acceleration sensors and still vibration analysis should be used to detect faults occurring at the lower frequencies, such as imbalance.

Machine C also had other faults than the wearing of the worm gear. The electric motor has two rolling element bearings and the other of them had an outer race failure and the electric motor also had imbalance. The outer race failure of the bearing could be easily seen from the acceleration envelope spectrum measured at the motor (ball pass frequency of the outer race is 77.5 Hz) given in Fig. 14. Peaks from 77.5 Hz to 10th and even higher multiples can be observed. As a matter of fact, when the acceleration signal was studied by means of an FFT analyzer, 10th and 15th multiples had the highest amplitudes and the amplitudes of these harmonics varied significantly with time. The imbalance of the electric motor was observed at the rotating frequency of 25 Hz. Vibration components occurred also at about 18-19.5 Hz, which is close to the 2nd multiple of the fundamental train frequency of the faulty bearing. The amplitudes of these two frequencies varied randomly when studied by means of an FFT analyzer. This can also explain the variation observed in the effective values of vibration velocity. The velocity spectrum measured at the motor is shown in Fig. 15.





Figures 14 and 15. Acceleration envelope spectrum and velocity spectrum at point 2 of machine C.

3.2 Copper cable manufacturing machines

These two machines had formerly been studied by means of wear metal analysis and vibration analysis [5]. The worm wheel of machine E had worn severely. Both types of analyses detected the failure. More information on this case is given in our other article [5]. The worn worm wheel was replaced and monitoring of the both machines was continued after that. No severe wearing has been detected since and the machines have been working smoothly. An increased amount of copper has been observed in the gear oil of machine E. Before the most recent measurement the wear metal analysis consisted of kerosene dilution of the oil samples and ICP-OES analysis. Now we have developed a new microwave-assisted acid digestion method for degrading oil samples before the ICP-OES analysis. Kerosene does not dissolve solid particles larger than about 10 µm so it is possible that in the case of severe wearing, the results obtained from the wear metal analysis are too small, because particles larger than 10 µm are detached into oil. This is why the new method was developed. As seen from Table 3, the copper concentration of the both machines was quite large in the most recent analysis. The gear oil sample of machine E included solid bronze particles observable with the naked eye, and if analysed, the copper concentration was as much as 120 mg/kg. On the other hand, if the solid particles were ignored, the copper concentration was 41 mg/kg. Which one then is the "right" way to carry out the wear metal analysis? Difficult to say, but it is probable that the value 41 mg/kg represents the copper concentration circulating in the lubrication system. The gear oil sample has to be taken by means of suction from the oil tank, and solid bronze residues from the bottom of the oil tank are also transported into the oil sample. The bronze residues are partly due to a former wearing process of the worm gear and improper flushing of the oil system. Of course, it is evident that the worm wheels of both the machines are wearing, but the situation is not very bad. In any case, monitoring of these machines by means of the wear metal analysis should be continued.

Table 3

Copper and iron concentrations of the gear oils of machines E and F.

Machine	Cu [mg/kg]	Fe [mg/kg]
E (December 2003)	12	< 2
E (November 2004)	28	2
E (November 2005)	41	4
F (October 2003)	36	21
F (November 2004)	22	2
F (November 2005)	45	4

Vibration signals of machines E and F were measured vertically at the bearing of the worm wheel. Acceleration and $x^{(4)}$ spectra of machines E and F in the frequency range 3-2000 Hz are shown in Figs 16 and 17, respectively.

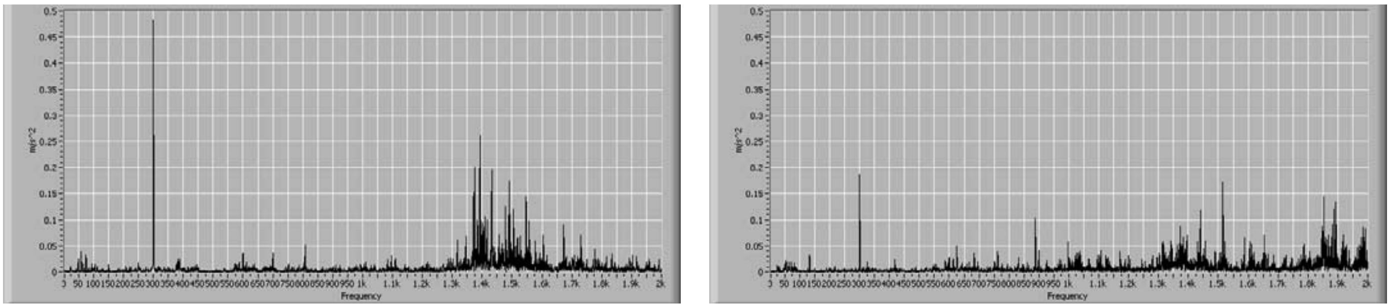


Figure 16. Acceleration spectra in the frequency range 3-2000 Hz at the bearing of the worm wheel of machines E and F.

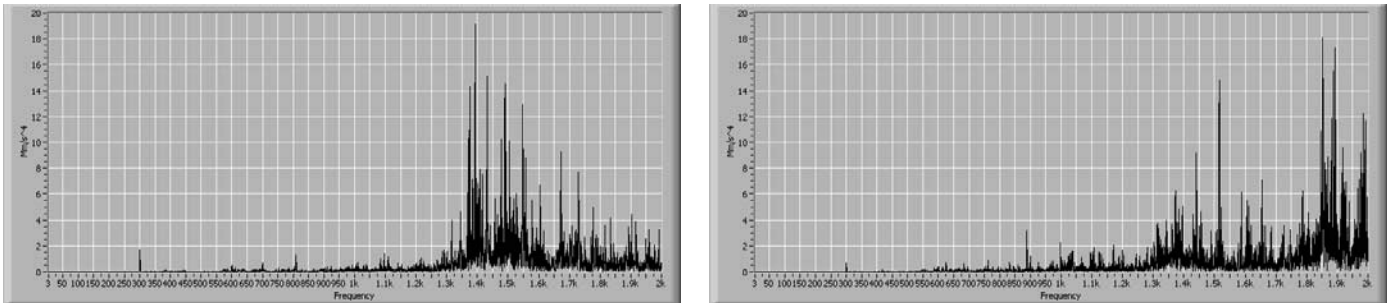

Figure 17. Spectra of $x^{(4)}$ in the frequency range 3-2000 Hz at the bearing of the worm wheel of machines E and F.

When studying the frequency range 1300-2000 Hz in the acceleration and $x^{(4)}$ spectra, numerous peaks can be observed in the spectra of both the machines. When this range was studied by means of an FFT analyzer, significant variation in the amplitudes was observed. This could be an indication of increased friction in the gear. This is in line with our previous study of these machines, in which the wearing of the worm wheel caused vibration in the frequency range 1350-2250 Hz [5]. It is probable that the wearing of the worm wheels, which was observed in the wear metal analysis, will increase friction. The situation may be slightly worse with machine F according to analysing and listening to the signals. A peak at 300 Hz indicates the existence of an electrical fault in the motor of both the machines. The vibration is transmitted in the structure of the machine and seen also at the bearing of the worm wheel. This fault naturally shows well when the measurements are made at the electric motor. The electrical fault is worse with machine E. The v_{rms} measurements in the range 10-1000 Hz do not indicate either the wearing of the worm wheel (the largest values at the output shaft were 0.7 mm/s) or the electrical fault (the largest values at the electric motor were 1.1 mm/s). The most sensitive feature of worm gear failure detection in this case was determined by comparing machines E and F, for which the results are given in Table 4. These sensitivities as averages of twenty values were calculated from the measurements at the bearing of the worm wheel. The sensitivity is defined as follows:

Sensitivity = (Value of the feature of machine F) / (Value of the feature of machine E) (2)

Table 4

Sensitivities of different features in worm gear failure detection.

Feature	3-1000 Hz	3-2000 Hz	3-4000 Hz
a_{rms}	0.58	0.87	1.23
$a_{kurtosis}$	***1.40***	1.04	1.00
a_{peak}	0.77	0.91	1.26
$x^{(3)}_{rms}$	0.98	1.10	1.41
$x^{(3)}_{kurtosis}$	1.12	1.02	1.00
$x^{(3)}_{peak}$	1.08	1.14	1.43
$x^{(4)}_{rms}$	1.25	1.30	1.53
$x^{(4)}_{kurtosis}$	1.16	1.01	1.00
$x^{(4)}_{peak}$	1.33	***1.32***	***1.54***

The most sensitive feature of worm gear failure detection was $x^{(4)}_{peak}$ in the frequency ranges 3-2000 Hz and 3-4000 Hz. This observation is in line with the sensitivities of the same features in detecting worm gear failure in talc agglomerating machines. In the frequency range 3-1000 Hz the most sensitive feature was $a_{kurtosis}$, whereas with the talc agglomerating machines it was $x^{(3)}_{peak}$. The large amplitude at the acceleration spectrum at 300 Hz explains the sensitivity of acceleration in the frequency range 3-1000 Hz. The sensitivity of kurtosis in the frequency range 3-1000 Hz is due to the signal of machine E, which is almost like sine wave having a small value of kurtosis. On the other hand, the signal of machine F has more peaks and therefore a higher value of kurtosis.

4 CONCLUSIONS

Worm gear faults can be identified through the analysis of metals in gear oils and by means of a vibration analysis. Wear metal analysis has been successfully used in detecting the wearing of worm gears in our earlier publication [5]. It is sufficient to measure the concentrations of copper and iron only in order to assure the condition of the worm gear. We have earlier also used vibration analyses in the condition monitoring of worm gears. It is not very easy, though not impossible, to analyse vibration in worm gears The problem is that the impacts caused by faults in the gear do not occur periodically as is usual with other types of gears. Instead they occur almost occasionally so it is beneficial to record the vibration signal over a sufficiently long time period. Measurements should preferably be carried out near the contact point of the worm wheel and the worm, and if this is not possible, at the bearings of the worm or the worm wheel. Vibrations caused by a gear fault could also be observed when measured at the bearings of the worm, but slightly damped in this case. According to our results, worm gear failures can be observed in the frequency range 3-2000 Hz even with acceleration, and the most sensitive one of the studied features of failure detection in this frequency range is $x^{(4)}$ peak value. The rms-values also indicated the gear faults even with acceleration. With the cable manufacturing machines the kurtosis of acceleration was the most sensitive feature in the frequency range 3-1000 Hz, although kurtosis values were not very sensitive with the talc agglomerating machines. When measurements are also carried out at the electric motor, the proper functioning of the whole machine can be assured.

Machines A, B and D at the Mondo Minerals Oy talc factory were in good condition and no wearing of the worm gears was observed. On the other hand, the worm wheel of machine C had worn according to a wear metal analysis. Slight wearing of the worm was also observed. The acceleration and $x^{(4)}$ signals of machine C, which were measured near the contact point of the worm wheel and the worm, revealed intensive impacts that could also be heard when the machine was listened to by means of a stethoscope. These impacts were probably caused by the worm moving over the pits on the worm wheel. In the frequency domain, peaks were observed in 1000-2000 Hz, which could be caused by friction. The electric motor of machine C also had imbalance and a fault on the outer race of one bearing. The bearing had already been replaced and the wearing of the worm gear should be monitored intensively, and the worm wheel should possibly be replaced in future.

The worm wheels of machines E and F in the Draka NK Cables cable factory were wearing, as indicated by the wear metal analysis. Vibration analysis of the machines revealed peaks caused by friction in the frequency range 1300-2000 Hz. The wearing was slightly more prominent with machine F, though both the machines can still be used provided that they are monitored. The electric motors of the both machines had an electrical fault, which was more severe in machine E.

In conclusion, we recommend that worm gears could be monitored as follows.

1. Wear metal analysis and vibration analysis should be combined. The vibration analysis can tell about a fault in the worm gear while the wear metal analysis indicates the wearing machine element.
2. When worm gears are examined, it is enough to only measure the concentrations of copper and iron in gear oil.
3. Vibration measurements should be carried out as near the contact point of the worm wheel and worm as possible.
4. The signal should be recorded over a sufficiently long time period.
5. Time domain signals should be studied carefully and should also be listened to.

Abstract: Much IS literature suggests that various factors play pivotal roles in the implementation of an information system; however, there has been little empirical research about the factors impacting the implementation of business intelligence (BI) systems, particularly in engineering asset management organizations (EAMOs). There is an imperative for a critical success factors (CSFs) approach to enable BI stakeholders to focus on the key issues that leading to successful BI systems implementation. The authors utilised the Delphi method to conduct two rounds of surveys with ten BI system experts of EAMOs domain. Based on the findings, this study identifies ten CSFs that are crucial for implementing BI systems in EAMOs. The paper presents a description and discussion of the CSFs and puts forward recommendations for further research. This study can be valuable to researchers and practitioners who are studying, providing consultancies, planning or implementing BI systems within EAMOs setting.

Key Words: Critical Success Factors, Business Intelligence System, Delphi Study

1 INTRODUCTION

Due to competition resulting from deregulation and from increasingly complex business environments, engineering asset management organisations (EAMOs) such as electricity, gas, water and waste utilities, telecommunications and railway companies are particularly concerned to access timely and high quality information which will enhance decision support and improve the bottom line. Although the computerized transactional systems do provide information to run the daily operations, what EAMOs business executives often need are different kinds of information that can be readily used to make strategic decisions. They need to understand their respective businesses from multiple perspectives, to carry out 'what-if' predictive analysis and to make long-term decisions based on that strategic information. They demand for an easy-to-use intelligent platform and application that is capable of providing strategic information derived from various operational, transactional and legacy systems, spread across multiple platforms and diverse structures. However, these disparate and fragmented operational systems were never designed to support the decision-making process, and hence fail to provide strategic information to the management level. Furthermore, it is impossible to optimise asset lifecycle profits if the management is not provided with a focused approach on asset performance and its interrelationships with other business processes and systems [1]. Yet, with the many millions of dollars of investment in ERP-style systems, EAMOs have been storing vast volumes of transactional data, leading to increased difficulties in analysing, summarising and extracting reliable information. Consequently, in order to solve these problems, EAMOs executives sought to leverage decades-long investments in information systems and data maintenance to improve business decision making. Many progressive EAMOs have turned to implementing BI systems to better manage assets, and this has included transmission and distribution facilities, machines and equipments, supplier and customer relations, and personnel.

A BI system, as Negash [2] explains, is "a strategic information system capable of providing strategic information through a centralised data warehouse, sourced from numerous sources, transformed into meaningful information via analytical and mining tools, to facilitate business insights leading to informed decisions". BI systems come as standardised software packages from such vendors as Business Objects, Cognos, Hyperion Solutions, Information Builders, Oracle and SAS, and they allow customers to adapt them to their specific requirements. A successful BI system implementation presents EAMO with a unified, new and thorough insight across the entire range of its engineering asset management functions. The asset operation management, maintenance management, human resource, inventory control, financial and other business functions are analysed collectively to generate more comprehensive information for better decision support. In other words, critical information from many different sources can be integrated into a coherent body for strategic planning and effective allocation of assets and resources. IDC Research expects that the BI market will enjoy a compound annual growth rate of 23 percent, and report US$3.3 billion dollars turnover in the Asia Pacific region alone [3]. Gartner Research [4] further forecasts that the BI market will continue to grow and flourish through to 2009. This finding is echoed by Darrow's [5] prediction that the worldwide market will reach US$12 billion by 2006.

Despite the increasing interest in, and importance of, BI systems, academic publications relating to this issue are very limited, and this is reflected in the contributions to international conferences and journals. As a BI system is primarily driven by the IT industry, most of the existing BI system literature consists of anecdotal reports or quotations based on hearsay. According to Ang and Teo [6], the implementation of an enterprise-wide information system is a major event and is likely to cause organizational perturbations. This is even more so in the case of BI system implementation. The whole BI project planning and implementation always involves a vast amount of resources and a variety of stakeholders over a period of months, requiring simultaneous attention to a wide variety of organisational, human, budget, technical and cultural variables. Therefore, rigorous academic research to identify the critical success factors for the implementation of BI systems is of great importance. The remainder of this paper has been structured as follows. The next section explains the CSFs approach in information system research, before providing a brief overview of relevant CSFs research in BI systems. The third section then outlines the research methodology for identifying the CSFs of BI systems implementation in EAMOs. In the fourth section the authors analyse and discuss the findings of the study. Then follows the conclusion, and finally proposals for further research initiatives.

2 LITERATURE REVIEW

2.1 Critical Success Factors: Definition and Concepts

The concept of Critical Success Factors (CSFs) was popularised by Rockart [7] as a mechanism to identify the information needs of CEOs. Since then it has become a popular approach in a number of studies linking business and IT [8]. According to Rockart [7], CSFs are those few critical areas where things must go right for the business to flourish. These limited areas are those in which results, if they are satisfactory, will ensure successful competitive performance for the organization. If results in these areas are not adequate, the organisation's effort for the period will be less than desired [9]. The emphasis here is on 'few' and must go 'right'. As the number of CSF is limited, senior management is able to constantly focus on the CSFs until they are successfully achieved [10].

Moreover, Greene and Loughridge [11] add that the identification of CSFs can help to clarify the nature and amount of resources that must be gathered to permit the project team to concentrate their efforts on meeting priority issues, rather than what the available technologies will allow. Evidently, these key areas of activity would need consistent and careful attention from top management if BI system implementation and thus organisational goals were to be attained. In other words, CSFs are high-level management considerations, as distinct from a detailed set of project deliverable specifications. Hence, a set of CSFs identified for the development of any major information system, such as a BI system, is fundamentally different from the set of interlinked detailed tasks which must be accomplished satisfactorily to ensure a project's successful completion [12]. Consequently, the success of BI system implementation may not be fully ensured by meeting the required CSFs, but failure to consider the CSFs will be a major deterrent to success.

Although CSFs was initially introduced to determine the information needs of executives, the approach has been extended to cover other areas of information system research. Despite the limited literature on entire BI system implementation issues, there exists a significant body of CSFs literature about the implementation of information systems, data warehouses, ERP systems and software projects. As a BI system is an enterprise-wide implementation effort similar to ERP and data warehouse, the adoption of CSF approach is therefore considered appropriate in this study of BI system.

2.2 Previous Studies of CSFs for Implementation of BI Systems

The academic literature that explicitly reflects on CSFs for successful BI system implementation is not extensive. The field of BI systems is driven by industry; it takes time for a tradition of academic scrutiny and evaluation to develop into a comprehensive literature. Nevertheless, there have been a number of studies which have sought to identify CSFs for the implementation of an information system, such as a data warehouse and an ERP system. Since data warehouse and ERP system are also involving large IT infrastructure, their CSFs studies are largely applicable to BI systems. The literature forms a basis for the empirical research conducted in this study.

The literature has indicated a number of CSFs for successful systems implementation. In terms of the organisational dimension, support from top management is considered as the most crucial success factor [6, 13, 14]. In particular, Ang and Teo [6] claim that successful implementation completely relies on the strong, persistent commitment of top management. This is because management support can overcome political resistance and encourage proactive participation throughout the organization [13]. Hwang et al [14] further assert that strong executive sponsorship is needed to demonstrate commitment to the BI project, and reinforce the vital linkage of a BI system to business strategy. Additionally, Beath [16] has conducted an extensive study on the importance of a "champion" role in an information system implementation. He indicates that the champion, often the project manager, plays a pivotal role in ensuring the success of a system implementation. Also, Holland and Light [21] note that open communication plays a critical role in ensuring successful implementation. Sarker and Lee [22] confirm through their ERP case study, that systems implementation can only be successful if there is open and honest communication among the stakeholders.

Within the project dimension, Herrmann [17] indicates that project planning and standardisation of activities and documents are needed to minimise the difficulties in collaborating with other organizational units, as well as to reduce coordination and management costs. In addition, the project team needs to ensure that a more complete representation of the entire organisation occurs within the data warehousing project [15], as the BI initiative always involves a variety of organisational stakeholders over a lengthy period. This representation of realities not only applies to the requirement engineering phase, but also to the composition of steering committees to ensure a balanced view of key implementation issues. Furthermore, a balanced multifunctional team is strongly regarded as a key factor for many systems and for the successful implementation of the data warehouse. This team should ideally consist of stakeholders with various skills and solid business backgrounds [13, 18]. Parr et al. [19] indicate that the chosen team members must be fully 'empowered' to achieve their highest possible level of performance. Their assertion is echoed by Levin et al [20], who believe that the empowerment of project team is of great importance to assure faster system roll out. Moreover, the formal and systematic training for end users cannot be taken lightly when aiming for successful system implementation [6, 23].

From the technological perspective, Knox [24] emphasises that management must focus on building BI data environments based on a central data warehouse that allows direct writing of BI applications, constraining datamart creation and introducing standards across data repositories. Ang and Teo [6] recommend that enterprises should start small and plan for continued growth when developing a data warehouse, and that it should be linked to a well-defined BI problem. Otherwise, the value and benefits of the BI project will be difficult to quantify and justify. Watson et al's [15] recent survey suggests that a successful BI deployment must consider scalability requirements from the beginning of the project. Moreover, the project teams are urged to pay significant attention to the transformation of legacy systems and data management tasks [25]. In particular, the transformation and integration of data from EAMO's typically disparate systems is deemed to be the most difficult issue of a BI project. According to Wu [26], a formalised selection plan should also be included to choose the most appropriate tools and technology for the BI system. This plan also provides the project team with a means of checking whether or not the technology was in accordance with business needs. Apart from that, Willcocks and Sykes [27] point out the importance of external consultant support for successful system implementation. They maintain that a qualified consultant must possess knowledge in both business processes and IT, and actively participate in the whole implementation process.

3 RESEARCH METHODOLOGY

The majority of previous studies have used well-established research methods, such as questionnaire surveys and case studies, to examine the key factors for their respective information system research. However, the purpose of present research is not to test hypotheses but rather to identify a set of CSFs for implementation of BI systems, particularly within EAMOs. This study seeks to identify the CSFs that are jointly agreed by a panel of BI system experts who possess substantial experience in EAMOs. The Delphi method was thus deemed to be the most appropriate method for this study [28], because it allows the gathering of subjective judgements which are moderated through group consensus in the absence of rich literature on BI systems. To be specific, a Delphi study is a structured group-communication method for soliciting expert opinion about complex issues, such as CSFs for BI systems implementations, through the use of a series of questionnaires and controlled feedback [29]. Moreover, the method is particularly suitable for this research situation where personal contact between panelists is not desirable because of concerns about the difficulty of ensuring democratic participation.

For data collection, a Delphi panel composed of ten BI systems experts in EAMOs domain was established. Ziglio [30] asserts that useful results can be obtained from small homogeneous groups of 10-15 experts, and that the size and composition of such a panel is thus deemed suitably representative. As shown in Table 1, the panelists have been involved substantially in the implementation of BI systems within EAMOs in Australia and the United States. They consist of senior consultants from BI consultancy firms and BI project managers and system managers within implementation companies. The BI systems included Cognos, Business Objects, Oracle, Hyperion, Microstrategy, SPF Plus, Actuate, Informatica and IBM.

In addition, the range of engineering asset management organizations represented in the implementation by these experts was diverse. The EAMOs include public utilities, such as electricity, gas, water, and waste management, and infrastructure-intensive enterprises such as telecommunications and railway companies. It should be noted that some of the large organisations have had several implementation projects and that they chose to implement the BI systems in a series of phases. Most of the EAMOs are very large companies with engineering assets worth hundreds millions of dollars and have committed immense expenditure to BI projects. So the expertise of the panelists represents 'state of the art' knowledge of BI systems implementation in a broad range of engineering asset-intensive industries.

During the first round of the Delphi study, a semi-structured interview session was conducted separately with each panelist. The interview process followed the focused interview format in which the interviewer followed a set of structured questions derived from literature review. However, the existing literature is not a comprehensive research on an entire BI system, but mainly focuses on data warehousing, which is the core component of a BI system. Therefore, the panellists were allowed - and indeed encouraged - to express their insights into other relevant CSFs. After the interview, further clarifications (if any) were made by follow-up phone calls and email communications. However, the authors were cautious about being over-reliant on panellists, and attempted to seek further evidence to corroborate emerging findings and issues from the documentation and presentation materials provided by the panel. Subsequently, the data gathered from first round of interviews was analysed thoroughly. As a result, a set of candidate CSFs was produced by combining all different factors perceived by the panel to be important.

In the second round of the Delphi study, the combined list of candidate CSFs was surveyed among the panel using a structured questionnaire approach. Specifically, the combined candidate CSFs was tested by elicitation of a Boolean scale in the process of seeking consensus from the BI experts. The purpose of using Boolean response (the factor is/is not critical for successful implementation of a BI system in EAMOs) aims to distinguish important factors from critical success factors. At this round, the majority of the panelists (that is, more than 70 percent of the panel members) shared a common opinion on the short listed CSFs that will be discussed in the following section. Sumsion [31] points out that opinion stability reflects consensus when the panel disagreement is less than 30 percent and that this offers a working definition of a threshold for stability, and hence this round of the Delphi study is considered to have reached a critical point for research termination.

Table 1

Delphi Panellists and their BI Systems Experience in EAMOs

Current Position	Current Company Type	BI System	EAMOs' Industry Sector
Principal Consultant	BI Consultancy	Business Objects, Information Builder, Cognos, Oracle	Electricity utility, Gas utility, Water utility Waste water utility, Power generation, Public transportation authority
Principal Consultant	BI Consultancy	Cognos, Business Objects, Actuate	Telecommunications, Municipal utility, Airlines
Senior Consultant	BI Consultancy	Oracle	Electricity generator and distributor
Business Information System Manager	Implementation company	Informatica, Oracle	Water utility, Waste water utility
Senior Principal consultant	BI Consultancy	Cognos, Hyperion, Microstrategy, Business Objects	Telecommunications, Electricity utility, Gas utility, Water utility
Senior Advisor	Implementation company	Cognos, Oracle	Rail infrastructure and fleets
Consultant	BI Consultancy	IBM, Oracle	Municipal utility, Public transportation authority
System Manager	Implementation company	SPF Plus	Electricity utility
Project Manager	Implementation company	Oracle, Hyperion	Rail infrastructure and fleets
System Support Engineer	BI Vendor	Cognos	Energy utilities

4 DISCUSSION OF FINDINGS

This section discusses the critical success factors perceived by the panel of BI experts in the implementation of BI system within EAMOs. In particular, the panellists were directly drawing on considering their hands-on experience in EAMOs' BI system implementations. Although many factors were elicited in the first round Delphi study, only CSFs which received a panel consensus of more than 70 percent are reported here. These CSFs provide important considerations for relevant stakeholders of EAMOs working on BI system and they help them to avoid costly pitfalls. The details are discussed below.

4.1 Top Management Support and Sponsorship

Top management support was held to be indispensable for successful BI system implementation in EAMOs. The panel asserted that consistent support and sponsorship from top management make it easier to secure the necessary operating resources such as funding, human skills, organisational support, and other requirements throughout the implementation process. The whole BI system implementation effort is a costly, time-consuming, resource-intensive initiative. Hence, the presence of sufficient resources can help the project team to overcome implementation obstacles and deliver on the project milestones. In particular, adequate funding would enable the project team to access the appropriate BI tools and technology. The experts indicate that the selection of BI system components such as ETL tools, data-cleansing software, database management systems, data warehouses, query tools, analytical tools and hardware that are needed for optimized BI application must not be jeopardized because of a lack of funding. Otherwise, the project scope will have to be realigned accordingly and this may present a threat to user expectations. Moreover, without dedicated support from senior executives, the BI project may not receive the proper recognition and hence the support it needs to be successful. This is simply because users tend to conform to the expectations of top management, and they are more likely to accept a system backed by their superiors. Many panellists further indicated that such support was best when it was accompanied by close monitoring of, and interaction with, the BI projects. In this regard, a steering committee was established to provide a balanced check between management needs and project effort. Specifically, senior management set up a structured mechanism for regular monitoring of implementation progress. Apart from these, top management support was deemed critical to solve the organisational resistance and conflicts that may arise for such a complex project.

4.2 Balanced Team skill and Composition

Owing to the immense expense, and the steep learning curve involved in implementing a BI system, the skills, knowledge, experience and aptitude of the development team are perceived to have a major influence on the outcome of the project. The panel stressed that the project team should be composed of those personnel who possess technical expertise and those with a strong business background and knowledge, because BI is a business-driven project to provide enhanced managerial decision support. The panel maintained that these project members must desire to work as a collective team and be able to work and interact well with users, demonstrating excellent interpersonal skills and communication capabilities. In addition, many experts indicated that it is much better off empowering the project leader to choose his or her best team. An effective model has been the small team comprising five to eight people who are knowledgeable, skilled, and dedicated, and who like and respect each other in order to strive for project success. Moreover, these team members should be available full time and released from all other assignments to work on the implementation.

4.3 Project planning and scope definition

According to the panel, for successful BI system implementation it is necessary to carefully take into account the important factors of project planning and scope definition. Proper project planning facilitates flexibility and the adaptability to changing requirements within the given timeframe and resources, especially in implementing a complex EAMO-specific BI system. The panel emphasized that planning provides guidelines which enable the project team to focus on crucial milestones and pertinent issues while shielding them from becoming tapped in unnecessary events. Furthermore, the implementation effort typically requires massive changes in other technologies that are linked to it. Hence, it is critical to expect the project team, and particularly technical members, to provide disciplined preparation for, and completion of, technical aspects to aid in the introduction of changes to existing technologies within the planned timetable and budget. Moreover, the experts strongly recommended that all discussions on key issues should be documented and communicated to relevant BI stakeholders so as to avoid misunderstanding and denial of responsibilities. One consultant pointed out that the "Just do it" philosophy and the excuse of "What a waste of time developing a detailed project plan, yet no one follows exactly to the plan" are warning signs of project failure. In addition, many experts further indicate that it is advisable to start small and adopt an incremental change approach, as large-scale change efforts are always fraught with greater risks given the substantial variables to be managed simultaneously.

4.4 Building a pilot system and incremental change

The panel unanimously agreed that a pilot system is always valuable as proof of a concept; that is, constructing a fairly small BI application for a key area in order to provide tangible evidence for both executive sponsors and general users. They perceive a pilot system that offers clear forms of communication and a better understanding in an important business area would convince organizational stakeholders on the usefulness of BI system implementation. As a result of a successful pilot project, senior management are keen and motivated to support larger scale BI efforts. Moreover, a properly-conducted pilot system is not a wastedproject; for it could be further expanded and enhanced into an enterprise-wide BI system. The pilot system could include additional data sources, attributes and dimensional areas for fact-based analysis and could incorporate external data from suppliers, regulatory bodies and industrial benchmarks. Undoubtedly, a small and highly-focused pilot system may allow an organization to concentrate on crucial issues, so enabling teams to prove that the system implementation is feasible and productive for the enterprise.

4.5 Modeling of Dimensional Data and Metadata

A BI system provides EAMOs users with a dimensional view of data such as engineering assets, and each of the dimensions has measures in terms of throughput or productivity. In order to have consistent dimensions and measures across subject areas, the panel asserted that it is important for users to identify and establish consensus on the dimensions and measures that will be used in the system's data model. Prior to that, many experts stressed that the information needs of organizational key users must be identified to enable the decision regarding the data requirements which will satisfy their expectations and information needs. Consequently, the project team would use those requirements to develop an enterprise-wide data model that is business orientated. Furthermore, it is typical for an EAMO to have hundreds of varying terms, with slightly different meanings, as business units tend to define terms in ways that best serve their purposes. For instance, a maintenance unit might define assets as physical engineering equipment or machine, whereas a financial department might include capital and buildings. Therefore, the development of a metadata model on which to base the logical and physical data warehouse construction for BI system will ease terminology problems. The metadata model, according to the experts, must be sustainable for a long period to provide the consistency upon which end-users rely. More importantly, the metadata model should be flexible enough to enable the scalability of the BI system while consistently providing integrity on which OLAP, data mining and executive information systems depend.

4.6 Formal and Interactive User Involvement

The experts also perceive that with better user participation included in the implementation effort, this can lead to better communication of their needs, which in turn can help ensure the system's successful implementation. This is particularly important when the requirements for a system are initially unclear, as is the case with many of the decision-support applications that a BI system is designed to sustain. Significant numbers of panellists explained that user participation can help meet the demands and expectations from various end users, and one panellist asked, "How can the project team design and implement a BI system to meet the users' needs without their involvement?" Hence, the data dimensions, business rules, metadata and data context that are needed by business users must be consulted and incorporated into the system. Another panellist mentioned that "…if the BI project does not involve adequate user participation, then the project is not likely to be successful because the BI application will not satisfy the end users." Besides that, when users are actively involved in the project, they have a better understanding of the potential benefits and this makes them more likely to accept the system on completion.

4.7 Data Quality and Reliable Sources

The Delphi study indicates that the quality of data is crucial if a BI system is to be implemented successfully. This can be anticipated, as data quality will affect the quality of management reports, which in turn impact the decision outcomes. A primary purpose of the BI system is to integrate disparate data in the organisation for further analysis via BI analytical tools. However, most EAMOs face great difficulties if it is found that the data in their source systems are of poor quality. These problems may be due to the lack of concern on the part of field maintenance workers and a lack of enforcement by managers. Thus, the combined efforts of the project team and business units are required to assess the quality of the data and to put appropriate data-cleansing processes in place, especially during the ETL process Furthermore, the EAMO should initiate efforts to improve the quality of the data in such source systems as operational, maintenance, procurement, contract management, work management, finance and human resource, because limitations will have a ripple effect on the BI applications and subsequently the decision outcomes.

4.8 Formal Selection of Development Tools and Technology

The panel further confirmed that the selection of development tools and technology impacts the efficiency and effectiveness of BI development efforts as much as other factors, particularly if the tools are not well understood by the project team. In fact, the tools and technologies involved in BI systems within EAMOs are different from those used with operational systems because the BI effort requires advanced data extraction, transformation and loading software, data-cleansing programs, database software, and multidimensional analysis tools. Many experts assert that the whole implementation effort will suffer if the development technologies do not meet the requirements of strategic asset management for EAMOs. Therefore, the selection of these important development technologies and tools must meet the needs and expectations of asset managers and users. Some consultants suggested that using a formal business-based methodology approach to select against defined goals can significantly increase the success rate of getting most optimised tools and technology. This business-driven approach builds upon consensus and therefore is more likely to meet user requirements. Furthermore, one panellist advised that the project team should not let an external consultant make important decisions on matters such as software selection. The skills and experience of the consultant may hinder the individual's judgment from offering an independent recommendation.

4.9 Formal and Adequate User Training

The panel also agreed that the formal and systematic training for end users must not be ignored when aiming for successful BI system implementation. Many experts indicated that adequate training can help users to speed up the system adoption and to explore the required information in a more effective manner. One expert posed the following question, "Will the users of BI system know how to use it? If not, how are they going to make use of the BI application?" Furthermore, panellists emphasized that training should focus on the technology itself as well as on the associated management and maintenance issues. This training is important to equip users to understand and experience the features and functions and to learn about the configured environment and business rules of the BI applications. In order to facilitate more conducive training sessions, it is also critical to separate power users from casual one because individuals may have different needs and expectations. Moreover, the experts stressed that companies that view training as an investment rather than a cost, reap greater benefits from the project implementation because users are accountable for making the system produce timely and accurate information.

4.10 Presence of a Champion

Apart from the above CSFs, the panel agreed that getting the right person to lead the project is critical for implementation success. The project leader, or so-called 'champion', must not only be technically-knowledgeable, but possess in-depth business acumen as well as excellent interpersonal skills to deal with organisational conflicts. He or she must be committed to the success of the project, must be unswerving in promoting the benefits of the new BI system, and must help resolve any internal disputes that are impacting the project. Also, the champion must be able to motivate his team to channel their energies into overcoming both technical and organisational obstacles to better meet project objectives. Consequently, the selection of a champion may determine the cohesion and success of BI system implementation.

5 CONCLUSION AND FURTHER RESEARCH

This paper has reported the results of a Delphi study that aimed to critically identify the CSFs for the implementation of BI systems in EAMOs. Since this research topic is a relatively new area, the approach drew upon a collection of expert opinions through interviews with 10 BI practitioners who have been involved extensively in implementing BI system within EAMOs. Based on the first round interview findings, the authors then conducted a questionnaire survey with the panel in order to seek consensus on the candidate CSFs. Finally, a list of CSFs was produced from the Delphi survey result that met the minimal 70 percent panel agreement. An analysis of the findings demonstrated that there is a combination of CSFs peculiar to successful BI system implementation in EAMOs. Senior management, project sponsors, project leaders, project members, end-users and external consultants all play critical roles in respective CSF. While the specific CSFs vary somewhat among BI systems and general IS studies, it appears that there is a new understanding of factors associated with infrastructure projects like BI systems which can be used in future research. Many CSFs of BI system implementation are probably the same as the IS development. However, there is a great difference with the technical CSFs like data modeling issue because the technical issues vary with the nature of the infrastructure system.

From a practical standpoint, the findings of this study help BI project stakeholders both to identify and to concentrate on the CSFs, especially in the planning of a BI system. Such outcomes will help them to improve the effectiveness and efficiency of their implementation activities by obtaining a better understanding of possible obstacles that might hinder the successful BI system implementation. It is also believed that by understanding the CSFs for their system the organisation is more likely to have a more reliable BI system after its implementation. For further research, it is planned that a survey with multiple EAMOs will be conducted using a structured questionnaire based on this Delphi result. As it stands, this research was exploratory in nature and further empirical research in other industries may shed light on where and how the research findings can influence the success of BI system implementation.

FEATURE GROUP OPTIMIZATION FOR MACHINERY FAULT DIAGNOSIS BASED ON FUZZY MEASURES

Xiaofeng Liu, Lin Ma, Sheng Zhang and Joseph Mathew

CRC for Integrated Engineering Asset Management, School of Engineering Systems,

Queensland University of Technology, Brisbane, QLD 4001, Australia

Abstract: With the development of modern multi-sensor based data acquisition technology often used with advanced signal processing techniques, more and more features are being extracted for the purposes of fault diagnostics and prognostics of machinery integrity. Applying multiple features can enhance the condition monitoring capability and improve the fault diagnosis accuracy. However, an excessive number of features also increases the complexity of the data analysis task and often increases the time associated with the analysis process. A method of bringing some efficiency into this process is to choose the most sensitive feature subset instead. Fuzzy measures are helpful in this regard and have the ability to represent the importance and interactions among different criteria. Based on fuzzy measure theory, a novel feature selection approach for machinery fault diagnosis is proposed in this paper. A heuristic least mean square algorithm is adopted to identify the fuzzy measures using training data set. Shapley values with respect to the fuzzy measures are applied as importance indexes to help choose the most sensitive features from a set of features. Interaction indexes with respect to the fuzzy measures are then employed to remove the redundant features. Vibration signals from rolling element bearing test rig are used to validate the method. The results show that the proposed feature selection approach based on fuzzy measures is effective for fault diagnosis.

Key Word: Fault diagnosis, Feature selection, Fuzzy measures, Importance index; Interaction index

1 INTRODUCTION

The task of condition monitoring and fault diagnosis for modern machinery is becoming increasingly complex as the machines become more automated and complicated. Fortunately, with the development of modern multi-sensor technology and advanced signal processing techniques, the increasing complexity of the tasks of diagnostics and prognostics of these machines can now be managed more meaningfully.

The task of condition monitoring and fault diagnosis usually results in a probabilistic result with a level of uncertainty. According to information fusion theory, information uncertainty can be reduced by applying multi-source information [1]. Hence, condition monitoring and fault diagnosis capability can be enhanced by applying multiple features. However, an excessive number of features on the other hand also increases the difficulties of data analysis and usually escalates maintenance cost. In fact, using all the features for monitoring and diagnosis purposes is also unnecessary as the contribution of each feature varies in a range. Some of them may be of little use to a specific troubleshooting process. Thus, selecting the most valuable feature subset is extremely important.

Various methods have been applied for feature selection purposes. Sub-optimal methods are more widely used than optimal methods. Although sub-optimal methods can generally produce optimal or near-optimal results in most real application cases, they cannot guarantee optimal results. The most frequently used sub-optimal feature selection algorithms are sequential forward search, sequential backward search, plus-L-minus-R and floating search, etc [2].

The exhaustive search is a universal optimal method. It produces an optimal solution by testing all the possible feature combinations. However, as the number of feature combinations increases exponentially with the number of features, this method becomes difficult to implement for high dimension feature space [3] [4] [5]. The only method other than exhaustive search still capable of yielding an optimal result is the branch and bound (BB) based algorithm. However, its application is also conditional. This method is only limited to monotonic criteria. Furthermore, its converging speed is highly dependent on the data sets [3]. To enhance its performance, BB algorithms have been improved by some researchers [6, 7].

Classical set theory and probability theory have been widely applied for dealing with uncertainty problems. Fuzzy set theory and fuzzy measure theory are two more general mathematical methods. Fuzzy methods are more effective than traditional clustering methods in handling fault features which are imprecise, with the boundaries among different failure modes usually being ambiguous in their mapping space. Fuzzy methods describe fault patterns in a non-dichotomous way which is similar to the manner in which human beings process vague information. As an outgrowth of classical measure theory, Fuzzy Measure (FM) and Fuzzy Integral (FI) theory has been applied to pattern recognition [8] [9] [10], image processing [11] [12] [13] and information fusion [14] and have the advantage that they are able to represent importance of criteria and certain interactions among them.

This paper presents a novel optimal feature selection approach for machinery fault diagnosis based on the fuzzy measure theory. It is suitable for low feature space problems. A heuristic least mean square algorithm (HLMS) is adopted to identify the fuzzy measures from training data set. Shapley values with respect to the fuzzy measures are computed and applied as importance indexes to choose the most sensitive features from a number of features. Interaction indexes with respect to the fuzzy measures are then employed to remove the redundant features. Vibration signals from rolling element bearings are used to validate this method. The results show that the proposed feature selection approach based on fuzzy measures is effective for fault diagnosis and is agreeable with feature subset obtained through other method.

The rest part of this paper is organised as follows. In section 2, the definition of fuzzy measures and related concepts, such as Shapley value and interaction index, are briefly introduced. In Section 3 a heuristic least mean square algorithm for identifying 2-additive fuzzy measures is introduced. A novel approach for fault diagnosis feature optimisation based on fuzzy measures is proposed in section 4. Section 5 presents the results of the experimental evaluation. Discussions based on the results are presented in Section 6, and Section 7 draws the conclusion.

2 FUZZY MEASURE, CHOQUET FUZZY INTEGRAL, IMPORTANCE INDEX AND INTERACTION INDEX

A fuzzy measure on the set X of criteria is a set function

$$\mu : P(X) \rightarrow [0,1]$$

satisfying the following axioms:

1) $\mu(\Phi) = 0, \mu(X) = 1$
2) $A \subset B \subset X$ implies $\mu(A) \leq \mu(B)$

where $X = \{x_1, \ldots, x_n\}$ is the set of criteria, $P(X)$ is the power set of X, i.e. the set of all subsets of X. Here $\mu(A)$ represents the weight of importance of the set of criteria A. Φ denotes the empty set.

The 2-additive fuzzy measure is a special kind of fuzzy measure. It is defined by

$$\mu(K) = \sum_{i=1}^{n} a_i x_i + \sum_{\{i,j\} \subseteq X} a_{ij} x_i x_j \text{ ,} \qquad (1)$$

where $K \subseteq X$. For any $K \subseteq X$ and $|K| \geq 2$ with x_i=1 if $i \in K$, otherwise x_i=0.

As $\mu_i = a_i$ for all i, the general form for the 2-additive fuzzy measure can be formulated as

$$\mu(K) = \sum_{\{i,j\} \subseteq K} \mu_{ij} - (|K| - 2) \sum_{i \in K} \mu_i \qquad (2)$$

for any $K \subseteq X$ and $|K| \geq 2$. It can be seen from the expression that the 2-additive fuzzy measure is determined by the coefficients μ_i and μ_{ij}.

The 2-additive fuzzy measures need $n(n+1)/2$ coefficients to be defined. The general number of coefficients required to be defined for k-order additive fuzzy measures is $\sum_{j=1}^{k} \binom{n}{j}$.

Fuzzy measures can describe any of the three interactions between two criteria A and B:

3 Synergetic interaction, which can be represented by

$$\mu(A \cup B) > \mu(A) + \mu(B) \text{,} \qquad (3)$$

3 Inhibitory interaction, which can be represented by

$$\mu(A \cup B) < \mu(A) + \mu(B), \tag{4}$$

3 Non-interaction, which can be represented by

$$\mu(A \cup B) = \mu(A) + \mu(B). \tag{5}$$

Classical probability theory can only be applied to the third situation when there is no interaction between two criteria [15].

The Choquet fuzzy integral of a function $f : X \to [0,1]$ with respect to μ is defined by

$$C_\mu(f(x_1),\ldots,f(x_n)) := \sum_{i=1}^{n} (f(x_i) - f(x_{i-1}))\mu(A_i), \tag{6}$$

where $X = \{x_1,\ldots,x_n\}$ is the set of criteria; $P(X)$ is the power set of X, i.e. the set of all subsets of X; $\mu(A)$ is the fuzzy measure representing the importance of the set of criteria A, and $A_i = \{x_i, x_{i+1},\ldots,x_n\}$

The importance index (Shapley value) [16] v_i of element i with respect to a fuzzy measure μ is defined by

$$v_i = \sum_{k=0}^{n-1} \gamma_k \sum_{K \subset X \setminus i, |K|=k} [\mu(K \cup \{i\}) - \mu(K)], \tag{7}$$

where $\gamma_k = (n-k-1)!k!/n!$, X is a set of n elements, $K \subset X$.

Shapley value describes the global importance of each element. It has the property

$$\sum_{i=1}^{n} v_i = 1. \tag{8}$$

Scaled by n, a Shapley value greater than 1 indicates that the element is more important than the average. The Shapley values can also be converted into a percentage to represent the importance of each element

The importance index demonstrates the contributions of individual features to the recognition of a specific class. Based on the importance index, we can determine feature i is more important than feature j if importance index v_i of feature i is great than importance index v_j of feature j.

The interaction index [17] I_{ji} between two elements i and j with respect to a fuzzy measure μ is defined by

$$I_{ij} = \sum_{k=0}^{n-2} \zeta_k \sum_{K \subset X \setminus \{i,j\}, |K|=k} [\mu(K \cup \{i,j\}) - \mu(K \cup \{i\}) - \mu(K \cup \{j\}) + \mu(K)], \tag{9}$$

where $\xi_k = (n-k-2)!k!/(n-1)!$.

The interaction index describes the degree of redundancy of two features to the recognition of a specific class. Feature i and feature j are complementary for recognition of a class from others if the interaction index I_{ji} between two elements i and j is positive. Both the two features should be employed as their combination will enhance the recognition capability. Feature i and feature j are redundant for the recognition of a class from others if the interaction index I_{ji} between two elements i and j is negative. Choosing of either feature i or feature j will have the same effect on final recognition result.

Feature i and feature j are independent for the recognition of a class from others if the interaction index I_{ji} between two elements i and j is zero. In this case, both features have their contributions.

Based on the concept of importance index and interaction index, a feature selection approach for machinery fault diagnosis is proposed. The importance index is used to choose the most important feature set from a number of features. The interaction index is then applied to remove the redundant feature form the set. This approach is expected to optimise the feature group selection for machinery fault diagnosis in different aspects.

3 IDENTIFYING FUZZY MEASURES USING TRAINING DATA SET

As discussed before, the bases of this feature selection method depends on calculation of the importance index and the interaction index with respect to the fuzzy measure μ. This research uses the 2-additive fuzzy measure as it is relatively simple and easy to implement. However, identification of the fuzzy measures is not easy. Here we present a data-driven algorithm for identifying the fuzzy measures.

Identifying fuzzy measures using training data set is an inverse problem of defining fuzzy integrals. Normally the training data set are obtained according to a field expert's knowledge. Here the overall assessment was regarded as Choquet fuzzy integral. The local assessments *f* are based on individual features, see Table 1. In this case, according to the definition of the Choquet integral, identifying the fuzzy integrals means to solve the equation

$$\sum_{i=1}^{n}(f(x_i)-f(x_{i-1}))\mu(A_i)=a_l \quad (l=1,\ldots,m) \tag{10}$$

Table 1

Training data for identifying fuzzy measures

Data point	Local assessments				Overall assessment
1	$f_1(x_1)$	$f_1(x_2)$	...	$f_1(x_n)$	$C_{\mu 1}$
2	$f_2(x_1)$	$f_2(x_2)$	...	$f_2(x_n)$	$C_{\mu 2}$
⋮	⋮	⋮	⋮	⋮	⋮
m	$f_m(x_1)$	$f_m(x_2)$	...	$f_m(x_n)$	$C_{\mu m}$

A heuristic least mean square algorithm (HLMS) is employed to provide an approximate optimal solution of the equation by minimizing the error between the actual Choquet fuzzy integral and the expected Choquet fuzzy integral output

$$E=[C_\mu(f)-y]^2. \tag{11}$$

Conditions such as monotonicity and normalization should also be satisfied when implementing the algorithm. The monotonicity condition can be formulated as

$$\sum_{j\in K}\mu_{ij}-\sum_{j\in K}\mu_j-(n-2)\mu_i\geq 0 \tag{12}$$

for $\forall i\in X$, $K\subseteq X\setminus i$, where $|X|=n$.

The normalization condition can be formulated as

$$\sum_{\{i,j\}\subseteq X}\mu_{ij}-(n-2)\sum_{i\in X}\mu_i=1 \tag{13}$$

4 FEATURE GROUP OPTIMISATION BASED ON FUZZY MEASURES

The proposed optimisation method for feature group optimization can be implemented in four steps (Figure 1). First we need to obtain the fault knowledge, which is represented by a training data set. Based on the training data set, a specific kind of fuzzy measure is extracted. The interaction index with respect to the fuzzy measures, which is used to remove redundant features from a group of feature set, is then computed. The last step of the approach is to compute the importance index to choose the most important features from a number of features. Sometimes we can change the order of the last two steps.

To obtain the fault knowledge, fuzzy *c*-means (FCM) clustering analysis is employed. It is used by inputting both individual and combinations of fault features to acquire both the local and overall assessment of an object. The overall assessment is used as Choquet fuzzy integrals and the local assessment is used as function f to describe the contributions of individual features to the object.

The core part of the heuristic least mean square algorithm (HLMS) for the 2-additive fuzzy measure identification adopts the gradient descent theory

$$\mu_{new} = \mu_{old} - \alpha \frac{E}{E_{\max}} (x_{n-i} - x_{n-i-1}) \qquad (14)$$

where i denotes the ith element of feature vector in ascending order; $\alpha \in [0,1]$ is a constant, which is known as learning rate; E is the error between actual and expected output.

Once the fuzzy measures are determined, the interaction index of every pair of features and importance index of each feature can be computed. Based on the importance index and interaction index, the less important and redundant features will be eliminated.

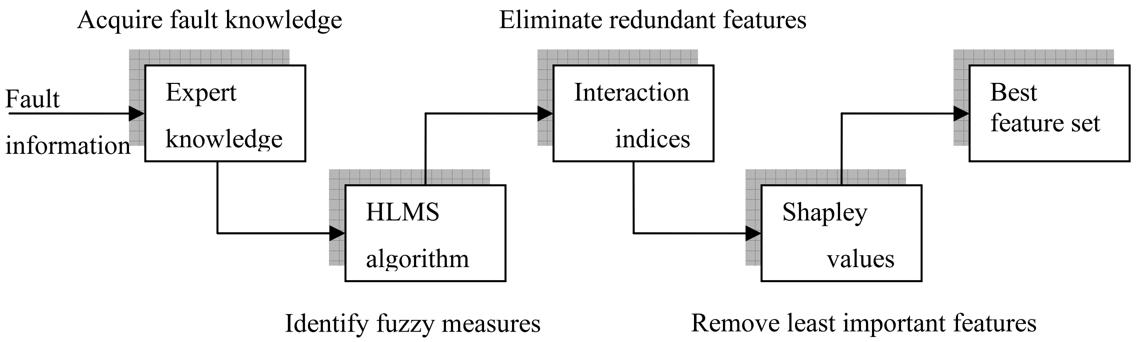

Figure 1 Feature group optimization based on fuzzy measures

5 EXPERIMENT RESULTS

An experiment on rolling element bearing faults was conducted using a machinery fault simulator made by SpectraQuest Inc to evaluate the proposed fault diagnostic method. The data acquisition system included an amplifier PCB 482A20, a filter KROHN-HITE 3202, a NI A/D card Daq6062E with a connector BNC2120, two vibration sensors IMI 608A11 and a Toshiba laptop computer. The software used was LabView. The cutoff frequency was 5k Hz and the sampling rate 20k Hz. Simulated defects included inner race fault, outer race fault, ball fault, looseness of the bearing housing and different fault combinations under different loads and rotating speeds.

Four time-domain features were extracted from the vibration signals, including Root Mean Square (RMS), maximum value, kurtosis and crest factor. The feature values were normalized into range [0, 1] to meet the requirement of the employed fuzzy method input.

For machinery fault diagnosis, although quite a few features are available, their degrees of contribution to the diagnostic process are usually different. The purpose of this research is to keep the minimum number of features while still maintain the diagnostic accuracy. In this specific scenario, we managed to choose two most suitable features from the group of four to validate our proposed method. Here we used x_1, x_2, x_3, and x_4 to denote RMS, maximum value, kurtosis and crest factor, respectively.

The fault knowledge is normally obtained empirically or according to expert field knowledge. This research used fuzzy *c*-means clustering algorithm as an expert system to acquire the fault knowledge from the original signal. The fault knowledge included local and overall assessment of a specific fault based on different features.

Once the fault knowledge extracted, the 2-additive fuzzy measure was identified. Table 2 shows the identified fuzzy measures for bearing outer race fault. Table 3 shows the Shapley values of each feature for bearing outer race fault.

Table 2

The 2-additive fuzzy measures on the power set of features

Subset	$\{x_1\}$	$\{x_2\}$	$\{x_3\}$	$\{x_4\}$		
Fuzzy measure	0.2975	0.2623	0.3350	0.3268		
Subset	$\{x_1,x_2\}$	$\{x_1,x_3\}$	$\{x_1,x_4\}$	$\{x_2,x_3\}$	$\{x_2,x_4\}$	$\{x_3,x_4\}$
Fuzzy measure	0.5680	0.6375	0.5000	0.5784	0.5310	0.5987
Subset	$\{x_1,x_2,x_3\}$	$\{x_1,x_2,x_4\}$	$\{x_1,x_3,x_4\}$	$\{x_2,x_3,x_4\}$		
Fuzzy measure	0.8890	0.7124	0.7769	0.7840		

It can be seen from Table 3 that all the interaction index involving feature x_4 are negative. This indicates that Crest factor is a redundant feature. It can also be seen from Table 4 that Crest factor plays the least important role in diagnosing bearing fault in this case. As such, this feature should be removed from the feature group. Table 4 shows that the second least important feature is the Maximum value. Although it is complementary with other features, it was eliminated from the set, as a feature subset of only two elements was pursued in this case.

Table 3

Interaction index

Feature set	$\{x_1,x_2\}$	$\{x_1,x_3\}$	$\{x_1,x_4\}$	$\{x_2,x_3\}$	$\{x_2,x_4\}$	$\{x_3,x_4\}$
Interaction index	0.0720	0.0706	-0.0425	0.0187	-0.0837	-0.0532

Table 4

Importance index of different feature

Feature	x_1 (RMS)	x_2 (Maximum)	x_3(Kurtosis)	x_4(Crest factor)
Importance index	0.2493	0.2353	0.3039	0.2115

As a result, the two features of Crest factor and Maximum value were eliminated from the original feature set {*RMS, maximum value, kurtosis, crest factor*} based on important index and interaction index with respect to the 2-additive fuzzy measures. The best feature subset for diagnosing the bearing fault, {*RMS, kurtosis*} was eventually obtained.

6 DISCUSSIONS

Fuzzy measure and fuzzy integral techniques are able to represent importance of criteria and certain interactions among them. Based on this concept, a feature group optimization approach for machinery fault diagnosis is proposed. For rolling element bearing fault diagnosis, the feature subset {*RMS, kurtosis*} was selected from a feature set of four {*RMS, maximum value, kurtosis, crest factor*}. To validate the result, fuzzy *c*-means clustering was used for comparison. Table 5 illustrates the average values of the membership degree of all features of the bearing fault. By comparing Table 4 with Table 5, it can be seen that the two results are in full agreement with each other.

Table 3

Average value of membership degree of features

Feature	RMS	Maximum	Kurtosis	Crest factor
Average value	0.9523	0.9118	0.9524	0.1729

Even from the 2-additive fuzzy measures, some initial signs can be observed. The fuzzy measure for $\{x_1, x_3\}$ is greater than other fuzzy measures of the two-element subset. The fuzzy measure of a three element set which contains x_1 and x_3 is also greater than other fuzzy measures of the three-element subset. The initial assumption was further proven by using the importance index and the interaction index.

7 CONCLUSION

This paper presents a novel fuzzy measure based feature optimization approach for machinery fault diagnosis. This method can produce an optimal feature set in terms of the importance index and the interaction index. In the case study, a two feature subset {*RMS, kurtosis*} was selected from a feature set of four {*RMS, maximum value, kurtosis, crest factor*} for rolling element bearing fault diagnosis. Experimental results show that the proposed feature selection approach has great potential in efficient and effective fault diagnosis.

ABSTRACT:Many of the rail infrastructure owners take ad-hoc decisions in inspection, lubrication and grinding strategies for controlling rolling contact fatigue (RCF) and wear. Limited research has been conducted in this area for economic effectiveness combining above rail and below rail assets. There is need to focus on damage of rail caused due to wheel and damage of wheel caused due to rail and total cost of rail and wheel for optimal replacements, maintenance and penalty costs to rail or train owners. This paper focuses on techniques in developing integrated economic decision model combining above rail and below rail assets for operational and maintenance strategies. These techniques able to analyse the effectiveness of operational and maintenance related decisions combining rail and wheel considering various scenarios.

KEYWORDS: Wear-Fatigue-Lubrication-interaction, Grinding, Inspection and Rail-wheel replacements

1 1. INTRODUCTION

Many of the rail infrastructure owners take ad-hoc decisions in inspection, lubrication and grinding strategies for controlling rolling contact fatigue (RCF) and wear. Rail and wheels deteriorate due to rail-wheel interaction in the form of wear, plastic deformation and fatigue. This includes rolling contact fatigue cracks, loss of profile and development of corrugations. Rail grinding is widely used to control some of these problems. The appropriate rail-grinding interval depends on the rail metallurgy, track curvature, axle loads. Magel and Kalousek (2002) recommended an interval of 8-12 MGT (280-300 BHN standard carbon rail) and 12-25 MGT (360-380 BHN premium rail) for sharp curves. Decisions on rail grinding to reduce rolling contact fatigue (RCF), lubrication to reduce wear and rail replacements to reduce risk of derailments are taken on the basis of rail life data. Similar decisions are taken for rolling stock based on rate of degradation and actual condition at the time of inspection. Ishida et al., (2003) studied rail grinding in practice to determine grinding interval (how frequently the grinding should be conducted) and grinding depth (how much surface material should be removed). Rail players around the world take decisions based on Visual Qualitative Checks (VQC), Non Destructive Testing (NDT), assumed Million Gross Tonnes (MGT) for axle loads and Traffic Density (TD). This is a slow, time consuming and costly process of decision making leading to a risky operating condition in between inspections.

Rail-wheel lubrication reduces wear rates for rail infrastructure owners and increases fuel savings for rail operators. Three lubrication systems used generally are hi-rail, wayside and on-board lubrication systems. Hi-rail lubrication system uses a specially designed mobile truck for the grease application from the nozzle as a thin bead along the rail gauge face. Wayside lubrication system grease is applied at track when the lubricator is activated either mechanically or electronically by passing wheels. On board lubrication system, the lubricator is mounted on the locomotive and the lubricant is applied using a spray system to the locomotive wheel flanges. By using one or a combination of the above systems, railroads are able to achieve significant savings in fuel and cost of wheel/track maintenance. However, there are some adverse effects of using excessive lubricant. These are wastage, loss of locomotive traction due to presence of lubricant on the top of rail and environmental concerns due to underground water contamination (Pandey et. al., 2000).

MTR Corporation in conjunction with BHP Research developed an economic/technical Rail Management Model to optimise the rail maintenance and replacement strategies for the MTR system under specific operating conditions (Keefe and Soleiman, 1994). The improved rail-wheel contact conditions significantly reduced rail replacements due to gauge corner shelling. It is found that rail replaced during the year 2000 was approximately 85% less than the rail replaced in the year 1992 whilst the annual gross tonnage has increased approximately by 10% (Keefe and Ravitharan, 2001). Achieving optimised rail and wheel profiles influence the contact mechanics and significantly affect wheelset and steering dynamics. It has helped rail infrastructure owners in reducing cracking and shelling defects and excessive wear and corrugation, and improving vehicle performance. A worn wheel profile is the result of all the rail profiles it encounters on a particular route and a worn rail is the result of all of the wheel profiles that pass over it.

This paper focuses on techniques in developing integrated economic decision model combining above rail and below rail assets for operational and maintenance strategies. Outline of this paper as follows: Section 1 provides introduction with an overview of existing rail-wheel inspection and maintenance. Section 2 focuses on comparative evaluation of these techniques. Section 3 proposes economic model combining above rail and below rail assets for operational and maintenance decisions. The concluding section discusses summary and scope for future work.

2 COMPARATIVE EVALUATION OF EXISTING TECHNIQUES

2.1 Rail and wheel wear

Wear is loss of material from the surface of rail and wheel due to rolling and sliding contact. MiniProf Rail profile system is used to measure the profiles just before and after preventive rail grinding as shown in Figure 1. Further information on the MINIPROF system can be found in Esveld and Gronskov (1996). The accuracy of the MINIPROF system is in the order of ± 0.015mm.

Figure 1: Rail Profile Measurement using MINIPROF Rail profile system [MINIPROF, Greenwood, Denmark]

Kalousek and Magel (1997) introduced magic wear rate. The boundary between sufficient and insufficient wear – the optimal, or "magic", wear rate – represents a state of balance in which the development of fatigue is arrested by wear or metal removal. The magic wear rate is achieved when the surface material wears just enough to prevent surface fatigue cracks from propagating and causing fatigue failures. Rail owners are still looking for better wear measurement to determine wear rate for rail and wheel to reduce cost of replacements and risk of derailments. Epp and Mutton (2002) explains that optimisation of wheel-rail interface is a continuous process. Ongoing review and refinement of wheel and rail profiles are required as long as there are changes in vehicle types and traffic conditions.

2.2 Rolling Contact Fatigue (RCF)

There are different approaches to analyse fatigue crack initiation such as, the defect-tolerant approach and the total-life approach. The total-life approach estimates the resistance to fatigue crack initiation based on nominally defect-free materials/ components (Ringsberg, 2001). The strain-life approach together with the elastic-plastic FE model is used to predict:

- The position for greatest fatigue damage
- The orientation of crack planes
- The fatigue life to crack initiation due to both low-cycle fatigue and ratchetting.

Yokoyama et al., (2002) investigated rolling contact behaviour in pearlitic and bainitic steel rails with various angle of attack in the twin-disc type RCF test machines.

2.3 Rail-Wheel Lubrication Strategies

Railway flange lubrication is used to reduce wear of the rail and wheel which is particularly severe at curves. The American Association of Railroads (AAR) estimated that the wear and friction occurring at the wheel/rail interface of trains due to ineffective lubrication costs American Railways in excess of US $ 2 billion each year. Currently, the largest expenditure faced by the railroad industry is the rail maintenance and replacement. Application of lubricants at the wheel rail interface dramatically reduces the rail track degradation and fuel consumption (Sid and Wolf, 2002). Rail life has been increased by factor of two and wheel life by factor of five (Queensland Rail, Australia) using appropriate lubrication. Spoornet (South Africa) has reported that rail life was increased from 27 MGT to up to 350 MGT depending on curve radius. Canadian Pacific (CP) rail indicated that rail life improvement by 110% using effective lubrication. Experiments on the Olympic park loop, NSW (Australia) on a 200 m radius curve indicated that flange wear rate is reduced from 0.36 mm/day (life of 0.2 year) to 0.006 mm/day (life 3.5 years). HKMTRC (Hong Kong) reported a cost saving of £ 783,000 per year on wheel and rail maintenance on the solid lubricant lines. Eurostar conservatively estimates that this saves £ 1,000,000 per year on maintenance and wheel replacement costs with effective lubrications (Larke, 2003). ERL/Malaysia has recorded data on lubrication shown in Table 1.

Table 1

Cost of Lubrication strategies (Larke, 2003)

Track/Vehicle condition	Wheel life in km	Wheel life in weeks	*Annual wheel cost in (£)*
No lubrication	170,000	20	*1.6 million*
Rail lubrication	300,000	35	*825,000*
Vehicle lubrication	1,000,000	118	*250,000*
Target	*1,500,000*	*177*	*170,000*

Typical lubricant costs in the UK are between £ 2.50/kg to £ 6/kg. In the filed measurement Norfolk Southern, the electric lubricators achieved 107% improvement in lubricant dispersion along the track, a 67% reduction in lubricant usage and a 57% of reduction in wastage (Larke, 2003). Typical grease usage data, lubricant costs and maintenance costs are shown in the Table 2.

Table 2

Lubrication costs to rail players (Larke, 2003)

Railway	Quantity(tonnes/yr)	Lubricator(£/yr)	Lubricant(£/yr)	Costs (£/yr)
Spoornet	200	125,000	134,000	259,000
IBCV	Not known	325,000	279,000	604,000
HKMTR	0.3 (depots)	5,600	550	6,150
Eurostar	1.1	Not known	Not known	70,000
Banverket	20	Not known	31000 - 62000	Not known
DSB	25	95,000	100,000	195,000
SNCB	40	1,000,000	479,000	1,479,000

Magel and Kalousek (2002) discussed the optimal rail wheel profiles. Ishida et al., (2003) discussed about wheel rail interface problems such as rolling contact fatigue (RCF), squat defects, grinding, corrugations, and lubrication of Japanese Railways (JR). Preventive grinding is currently most reliable and effective method of reducing the occurrence of RCF defects. In Japan grinding started in the 1970s and only about 100 km of affected track was ground every year. In 1995 two rail grinding cars were introduced. Since that time rail grinding has been carried out more than 1000 km of track per year (Tada, 1999). It is found that the number of squats has been steadily decreasing as a result of grinding. The target has been a grinding thickness of 0.08 mm/pass and a grinding interval of 40 MGT, which is similar to 0.1 mm/50 MGT. In this study it is found that the effect of preventive grinding has not been scientifically evaluated. It is essential to obtain optimal grinding period and grinding amount (the thickness of material removed from the rail surface) to control such defects.

3 ECONOMIC MODEL COMBINING ABOVE RAIL AND BELOW RAIL

The rail and wheel interface produces wear and fatigue. Unbalanced or damaged wheels have adverse effect on rails. Similarly, uneven wear rate of rails or worn out rails have adverse effect on wheels. Achieving balance and charging damage caused by rails to rail infrastructure operators or caused be wheels to train operators is a big challenge. It is important to predict wear and fatigue in both rails and wheels to maintain the balance. Wheel-rail interaction model proposed by Mutton (2001) found that 12 m of rail (head hardened) track length is required to wear out one wheel for a worn wheel but approximately 17.5 m is required to wear out one wheel for a new (head hardened) rail. Similarly 20 m standard carbon rail is required to wear out one worn wheel and approximately 25 m required to wear out one new wheel. The values changes with the curve radius increase of axle loads and train speed and traffic density.

A conceptual rail wheel damage interaction could be any of the following ones:

$$y_i(w) = a_i e^{-b_i r} \tag{1}$$

Where w is wheel wear loss, r rail wear loss,

a and b are parameters based on rail-wheel materials and conditions.

$$y_i(w) = a_i + b_i r^1 + c_i r^2 + d_i r^3 \tag{2}$$

Where a, b, c, and d are parameters based on rail-wheel materials and conditions.

r is rail wear loss for different rail materials (such as head hardened and standard carbon), rail size, and condition (new and worn rail and wheels)

$$y_i(w) = a_i(r)^{b_i} \qquad (3)$$

Where w is wheel wear loss, r rail wear loss,

a and b are parameters based on rail-wheel materials and conditions

It is also possible to model rail loss for known wheel material and condition for certain operating conditions.

Table 3

Rail-wheel damage interaction data

Serial No	Scenario	Rail wear loss (mm^2)	Rail track length (m)
1	Head hardened (HH) rail and worn-n-wheels	10	12
		20	6
		30	4
		40	3
		50	2.5
2	Head hardened (HH) rail and new wheels	10	17
		20	8.5
		30	5.5
		40	4.25
		50	3.25
3	Standard Carbon (SC) rail and worn-n-wheels	10	20.5
		20	10.5
		30	7
		40	5.25
		50	4
4	Standard Carbon (SC) rail and new wheels	10	26
		20	14.10
		30	9.75
		40	7
		50	5.75

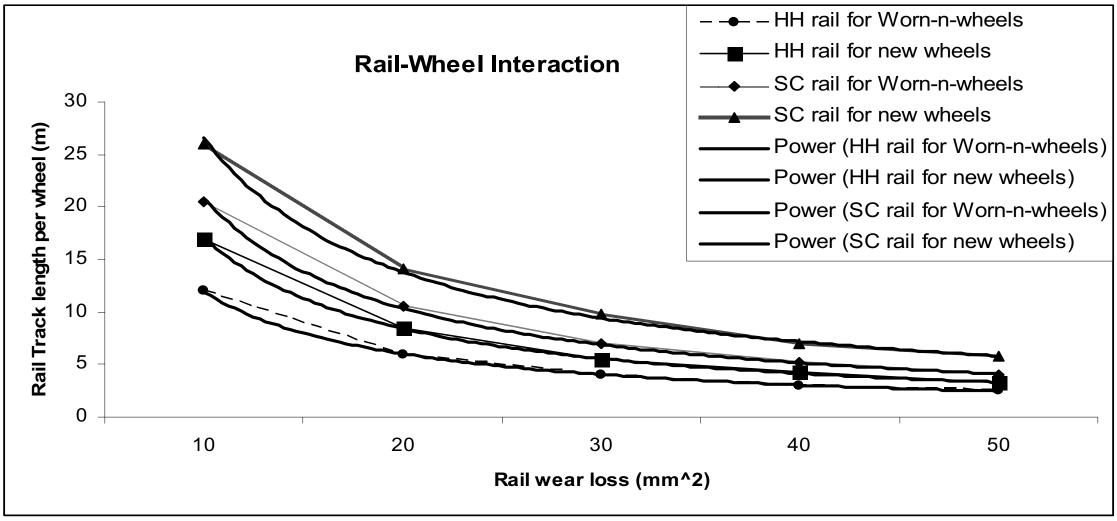

Figure 2: Above rail and below rail damage interaction.

Figure 2 shows the analysis of above rail and below rail model for rail wheel interaction. It is found from the analysis that Figure 2 better captures the real life case. It is also found that standard carbon (SC) rails have less adverse effect on wheel life damage compared to head hardened rails. Figure 3 shows the event tree analysis of rail-wheel degradation.

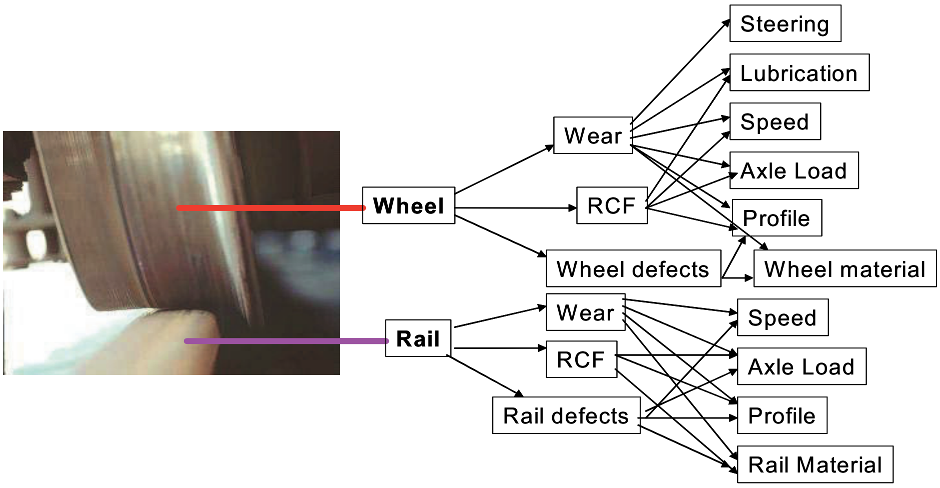

Figure 3: Factors influencing rail-wheel degradation (Chattopadhyay et al., 2004)

There is a need for development of rail-wheel interaction models for reducing risk of derailment and to improve safety and reliability of rail life. Figure 4 shows proposed rail-wheel damage interaction model. This model can be used to estimate the costs due to rail wear loss and wheel wear loss as a result of rail-wheel damage interaction.

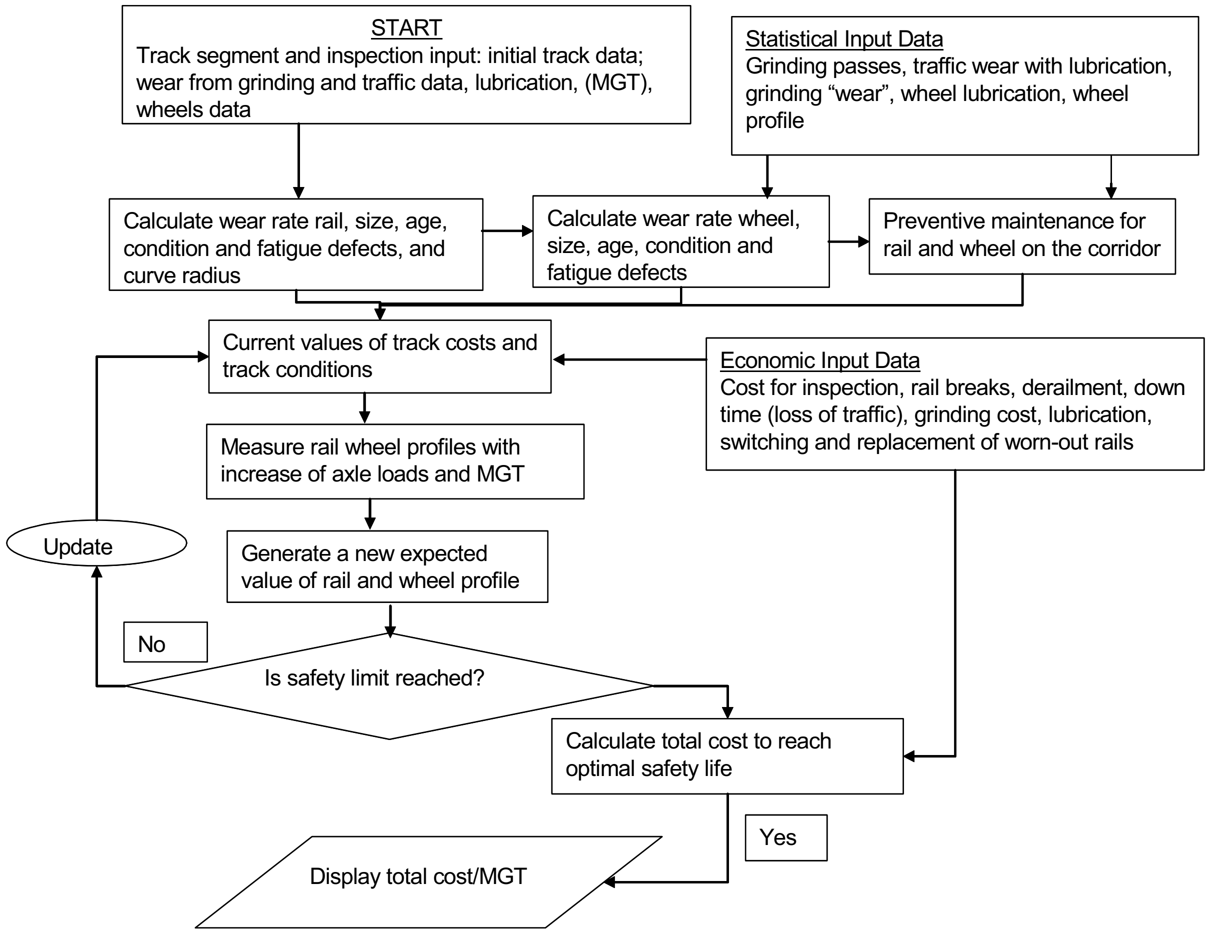

Figure 4: Proposed model for rail-wheel damage interaction model

4 SUMMARIES AND SCOPE FOR FUTURE WORK

This paper focused on techniques in developing integrated economic decision model combining above rail and below rail assets. Rail-wheel damage interaction models proposed based on rail wear loss and wheel wear loss considering new and worn wheels for various rail materials and wheel conditions. Proposed models were developed based on Queensland Rail (QR) internal report. Further these models could be illustrated and validated with laboratory and real life data. There is scope for future work in development of rail-wheel damage interaction model under various operating conditions and traffic types. This model can be used as a framework for penalty costs related to rails damaging wheels or wheels damaging rails and who pays for what. Authors are currently working in this area and results would be published in the future.

Abstract: Prediction of operational risk and enhancement of reliability and safety for rail network are important to rail infrastructure providers and train operators. Rail defects leading to rail breaks and derailments cost huge amount due to cancelled / delayed traffic, emergency maintenance, loss of assets, loss of revenues and liability compensations due to down times. Wear occurring at the wheel/rail interface as a result of ineffective lubrication costs huge amount to rail infrastructure providers per year. Cost of rail-wheel maintenance and replacements are reduced significantly with effective lubrication. Studies on interaction of factors behind wear, fatigue, lubrication and grinding problems are required to monitor those factors and finding out cost effective technological solutions in predicting and reducing operational risks. This paper focuses on development of wear-fatigue-lubrication-interaction model for cost effective rail maintenance decisions.

Key Words: Wear-Fatigue-Lubrication-interaction, Grinding, Inspection and Operational risks

1 INTRODUCTION

Wear and fatigue of rail and wheel are growing concerns to rail infrastructure players. These are main concerns of heavy haul operators and on heavy traffic density lines. Material loss in wear occurs in the form of debris, transfer of material from one surface to another by adhesion or by local plastic deformation. In the rail-wheel contact three wear regimes are identified: they are mild, sever and catastrophic wear [1]. Rolling contact fatigue (RCF) occurs due to repetitive load of wheels on track. Some of the adverse effects are squats, shelling and head checks. Problems at curves and switches due to frequent contacts near gauge corners occurs due to reduced contact area and high slip resulting severe contact stresses [2]. Rail grinding is used to remove fatigue cracks on rail surface and to optimise rail profile. Literature shows that increase in rail grinding interval frequency has substantially increased rail maintenance costs. Rail infrastructure owners around the world have been using lubricant routinely to reduce noise, wear and friction. Effective application of lubrication reduces energy consumption and also extended rail life up to two to three years even in heavy traffic areas. Lubrication commonly used by rail infrastructure providers and rail operators are way side lubrication, on board lubrication and hi-rail lubrication [3]. Lubrication has influence on accelerating fatigue cracks on rail surface under increased axle loads and speed in heavy traffic areas. Lubricant entrapment has adverse effect on initiation and propagation of fatigue cracks leading to rail breaks and catastrophic derailments. Wear can be used to reduce the initiation and propagation of rolling contact fatigue (RCF) cracks. The severe or catastrophic (increase in material loss) wear has significant reduction in rail life. Therefore, understanding wear-fatigue-lubrication interaction is important for cost effective maintenance decisions which results in reduced operational risks and costs.

The outline of this paper: Section 1 introduces rail wear-fatigue-lubrication interaction. Section 2 focuses on overview of wear-fatigue-lubrication interaction. In Section 3 Integrated model is proposed for wear-fatigue-lubrication interaction. Section 4 proposes cost model for effective maintenance decisions. The concluding section discusses summary and scope for future work.

2 OVERVIEW WEAR-FATIGUE-LUBRICATION INTERACTION

Rail wear rate depends on increase of million gross tonnes (MGT), axle loads, train speed, direction, and curve radius and traffic density. Wear limit varies with rail operating and environmental conditions. Many rail infrastructure owners have developed their own wear limit standards based on experience with these factors to control rail wear rate and to reduce risk of low rail derailments. Effective application of lubrication reduces slip and creep force regime between flange and gauge corner. It also reduces traction, material wear and flow and fatigue effects [4].

Wear-fatigue-lubrication interaction has currently received attention from rail infrastructure owners. Recent study shows that huge amount of lubrication are wasted annually in the effort to control wear. The American Association of Railroads estimates that the wear occurring at the wheel/rail interface as a result of ineffective lubrication costs in excess of $US 2 billion per year. Eurostar estimated saving of £ 1,000,000 per year on maintenance and wheel replacement with effective lubrication [5]. The largest expenditure is rail maintenance and replacement [6]. Lubrication reduces traction stress on rail gauge face and on the gauge corners. This increases the wheel loading cycles which influences rolling contact fatigue (RCF) defects. Preventive rail grinding reduces fatigue initiated surface cracks. However, RCF in combination with lubrication influences rail life significantly. When lubrication is applied at rail gauge face, the top of the high rail and low rail remain dry. This increases angles of attack compared to that for dry gauge face. It results in increased lateral forces and contact stress on the gauge corner of the high rail leading to gauge corner shelling of the high rail [7].

Cannon and Pradier [8] analysed various surface initiated cracks in railheads. Head checks (HC) occur near the (rail) gauge corners of the curves and crossings due to repeated plastic deformation and consecutive accumulated damage at the surface of railhead due to rolling contact fatigue (RCF). These accumulated head checks can cause gauge corner break up to a depth of several millimetres. In rare cases, the cracks propagate in a transverse direction with a complete fracture of the rail, known as rail break. Existing theories have limitations in accurately predicting rolling contact fatigue (RCF) and initiation of crack leading to rail breaks [9]. Sawley and Kristan [10] conducted small- and full scale tests to potential resistance of rolling contact fatigue damage. It was found that wear performance of bainitic rail steel depends considerably on test conditions, the indication was that bainitic steel rails can have significantly better rolling contact fatigue performance compared to pearlitic rails. Lubrication has adverse effect on the pressure distribution along surface crack and helps to propagate influencing rail break and risk of derailment. Operational risks are further influenced by number of axle passes, curve radius, rail-wheel profile and material, hardness of material, rail/wheel interaction, rail-wheel grinding intervals, and lubrication at rail-wheel interface and maintenance decisions. If not monitored and controlled properly these can lead to rail defects, rail breaks and derailments. These problems can cause huge loss of revenue, disruption of service, resulting damage of assets, and loss of lives. In 2000, the cost of the Hatfield, UK accident was £730 million for repairs and compensation payments. The main cause was RCF [11].

3 INTEGRATED MODEL FOR RAIL WEAR-FATIGUE-LUBRICATION-INTERACTION

Lubrication has a substantial impact on rail life by reducing wear at sharp curves resulting in improvement of reliability and safety of railroads. However, fluid lubricants contribute to the development of rolling contact fatigue (RCF) cracks by mechanisms, e.g. crack face friction modification and fluid entrapment shown in Figure 1. The possibility therefore exists that while application of a fluid lubricant may reduce rail and wheel wear, the lubricant may lead to rail RCF failures. Dry solid lubricants have advantage to avoid this problem [12].

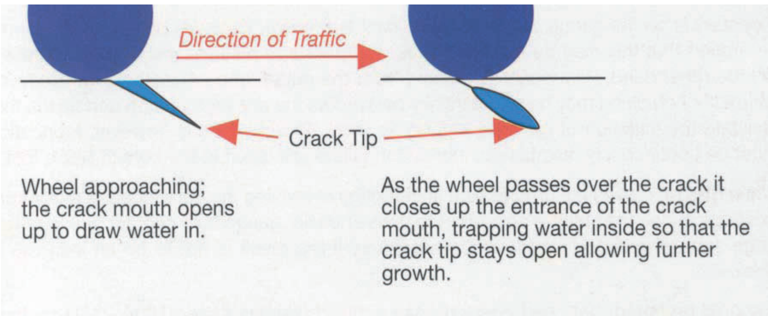

Figure 1: Fluid entrapment in rolling contact fatigue cracks of rail surface [13]

Effective lubrication can be achieved only with

- suitable weather and environmental friendly and improved efficient lubricant
- appropriate position of way side lubricators
- effective maintenance of lubricators
- effective application (distribution) of lubricant along the rail and wheel surface
- balanced (even) distribution of lubricant throughout the curve length of rail
- cut-off point for curve radius that need to be to lubricated above recommended curve radii
- dismantling of blades from the track before grinding and reinstalling after grinding can lead to additional maintenance costs
- exploring the possibilities of hi-rail and on-board lubrication for cost effectiveness application of lubrication
- applying cheap lubricant may not be an effective (optimal) solution, which inturn lead to additional maintenance costs of lubricators.

A lubricated wheel/rail contact operates with boundary or mixed film lubrication. The difference between these regimes is shown in Figure 2.

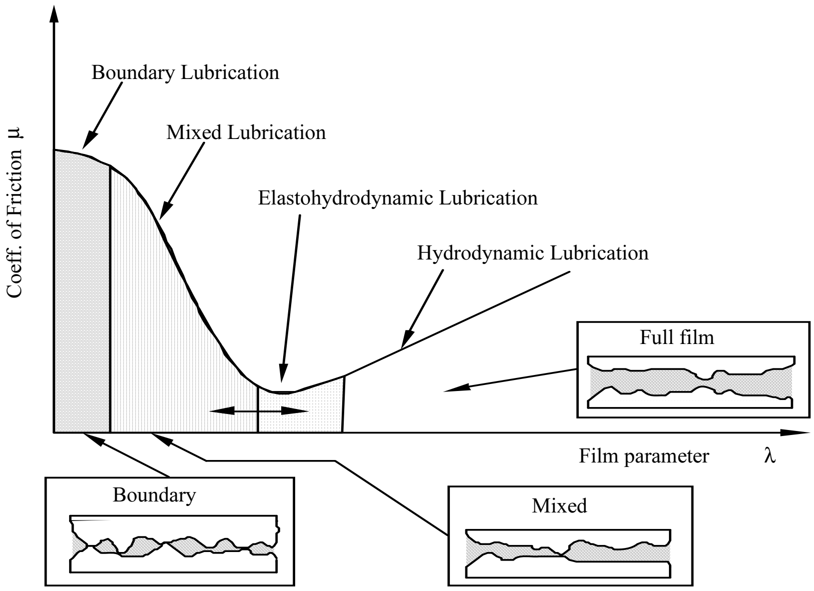

Figure 2: Coefficient of friction varies with the film thickness parameters [14]

Therefore, there is a need to develop a lubrication decision model for benchmarking lubrication for various curve radii considering extreme environmental conditions. Rail grinding has been effective solution to reduce rolling contact fatigue cracks and to correct rail profile. Rail grinding is a costly maintenance activity used to prevent fatigue cracks, rail breaks, failures and catastrophic derailments. Rail players around the world also using balanced (sufficient) wear to control rolling contact fatigue. Figure 3 shows the twin disc test rig developed at QUT and was being used to conduct wear and lubrications tests.

Figure 3: Twin disc test rig developed at QUT

Besuner et al., [15] pointed out limitations of rail life prediction models using MGT because it does not differentiate between following two cases

1. a certain number (say *m*) of heavy wheel loads of magnitude P and
2. twice this number (2*m*) of smaller wheel loads of magnitude p/2.

For most wear-out phenomenon, including fatigue crack propagation and initiation the heavier wheel load of case (1) is more damaging to the rail compare to the larger number of lighter loads of case (2). Johnson and Besuner [16] proposed that the crack propagation rate *da/dN* is proportional approximately to the 4th power of stress leading to an effective usage parameter, *MGT-Effective* given by

$$\textit{MGT-Effective} = \left[\sum_{i=1}^{n} (MGT_i)^4\right]^{1/4} \qquad (1)$$

where n = total number of wheels passing through the curve section.

Kalousek and Magel [17] introduced the magic wear. It is the boundary between sufficient and insufficient wear – the optimal, or "magic", wear rate – represents a state of balance in which the development of fatigue is arrested by wear or metal removal. The magic wear rate is achieved when the surface material wears just enough to prevent surface fatigue cracks from propagating and causing fatigue failures. A combination of lubrication and light, but frequent, profile grinding is generally required to obtain the optimal condition. While every wheel/rail system has an optimal, or magic, wear rate, the rate is not constant. The optimal value changes with the hardness of the materials, the average contact stresses, the wheelset-steering performance, and coefficient of friction, or the effectiveness of the lubrication. Magel and Kalousek [18] recommended an interval of 8-12 MGT (280-300 BHN standard carbon rail) and 12-25 MGT (360-380 BHN premium rail) for sharp curves in most environments. It is important to scientifically determine grinding interval (how frequently the grinding should be conducted) and grinding depth (how much surface material should be removed). This knowledge is useful to improve the efficiency of grinding work and decrease in the maintenance cost. It is a big challenge for rail players to best utilize the available grinding power (and grinding budget) to maximise the effectiveness of the rail grinding program. Currently rail players around the world take decisions based on Visual Qualitative Checks (VQC), Non Destructive Testing (NDT), assumed Million Gross Tonnes (MGT) for axle loads and Traffic Density (TD). This is a slow, time consuming and costly process of decision making leading to a risky operating condition in between inspections. An ongoing cost effective data acquisition for condition monitoring of rail track would be able to overcome risks between periodic checks. Inspection is the key in reducing rail breaks, defects and catastrophic failures. There are three aspects to rail inspection, (1) technology used, (2) frequency of inspection, and (3) actions specified when a defect is detected. Inspection is generally based on line speed, track conditions, traffic tonnage and axle load and traffic type. Sawley and Reiff [19] show that broken rails are generally result from the following major factors:

- Poor inspection procedures. This may be due to poor operator training, out-of calibration equipment.
- Surface conditions interfering with the ultrasonic signal. It is known that surface damage, such as cracks, spalls, and flakes can hinder ultrasonic inspection by affecting transmission of ultrasound into the out of the rail. Figure 4 shows detection undetected fatigue cracks on rail surface.

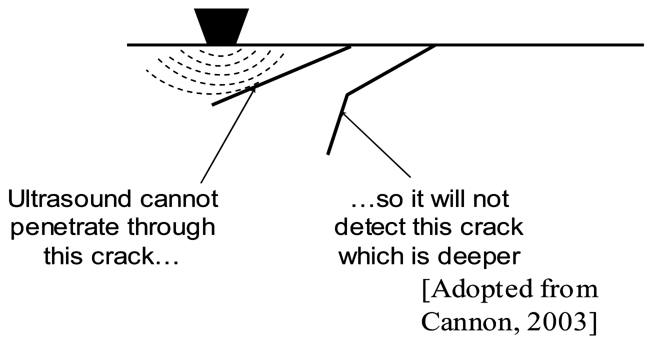

Figure 4: Detection undetected fatigue cracks on rail surface [20]

- Defects those are inherently difficult to detect using existing technologies. Ultrasonic signals enter the head of rail and, though they travel down the web section, they are not able to find defects in the outer edges of the foot. Cracks towards, the outer edges of the head are also difficult to locate, as are vertical/transverse crack such as those found in thermite welds.
- Inspection intervals that are longer than optimum. If inspection interval is too long, defects can grow from non-detectable to critical sizes between inspections.

Rails are regularly inspected by ultrasonic techniques using inspection vehicles with manual methods (including walking stick) used mainly for verification tests and tests at special areas such as switches and crossing. However, ultrasonic can only inspect the core of materials; that is, the method cannot check for surface and near-surface cracking where many of the faults are located. Because of this, some other techniques other than the ultrasonic method are used. Four main types inspection methods commonly used are [21]:

1. Visual inspection.
2. Dye penetrant inspection and magnetic particle inspection.
3. Eddy current testing.
4. Radiography

All of the above techniques could not able to detect surface and near-surface cracking defects accurately. In many cases an investigation will be performed to try and identify the cause of the failure. On many occasions the defect may be classified as undetectable at the time of test because it may have been too small or the surface condition of the rail may have presented additional ‘noise’ that may have masked the defect. Also, the cause of the broken rail may have been something such as a wheel flat. In these instances a latent defect likely to be found at the next test may become a catastrophe when subjected to the impact of a train wheel with flats. Cannon et al., [20] estimated annual vehicle inspections followed by manual verifications of detected defects, inspection costs are about €70 million per year for 0.5 million kilometres. This indicates the importance of the inspection technology, frequency interval and the detection of undetected defects. Therefore, there is need for detail study and analysis of inspection techniques to detect rail defects. Inspection before grinding, after grinding and inspection of lubricators, their performance, application and effectiveness of lubricant need to be studied for better understanding and for effective maintenance decisions to reduce operational risks and costs.

Rail replacement is most expensive operation in rail maintenance system. Rail infrastructure owners are trying to rectify the detected defects with various maintenance procedures. If the defect is at the initial stage then rectification could be postponed until it reaches to critical stage. If the rail defect is critical, immediate overhaul could be done to reduce risk of rail breaks and catastrophic failures. It is an expensive maintenance procedure even to rectify or to replace a small segment of rail defect during winter (below -25^0 Centigrade). This can be reduced only through accurate inspection frequency intervals during summer and in spring before the winter to reduce maintenance costs.

3.1 COST MODEL FOR RAIL MAINTENANCE DECISIONS

3.1.1 Modelling Lubrication and Wear rate

Wear rate *(I)* can be estimated as a linear function of $T\lambda/A$ parameter, where T is tangential force, λ is the relative slippage, and A is the Hertzian contact area.

$$I=T\lambda/A \tag{2}$$

Zakharov et al., (1998) [22] has conducted laboratory simulated tests of wheel flange and rail gauge face wear particularly for severe and catastrophic wear modes in unlubricated conditions and at a relatively stable coefficient of friction the specific volume wear rate *(I)* can be expressed as

$$I=kp\lambda^2 \tag{3}$$

where p is contact pressure at the contact patch and λ relative slippage varying from 0 to 1 and k is the coefficient of friction rail-wheel interaction. The relative slippage depends on the angle of wheel to rail attack and curve radius. It is important to evaluate the gauge face friction before positioning lubricators in order to determine the point of contact between rail-wheel interaction. Coefficient of friction is the classification of surface roughness which reduces wear on rail surface. The co-efficient of friction μ together with film parameter, Λ is shown in Figure 4. Coefficient of friction is expressed as:

$$\mu = f/w_z \tag{4}$$

Where f is tangential friction force and w_z is the normal applied load. It is found that film thickness parameter, Λ influence the co efficient of the friction, μ. The pressure builds up in moving surface separate the asperities from the boundary lubrication to the mixed film lubrication. Lubrication cost can be estimated assuming cost of lubricant (C_l) selected for application of particular curve section *(r)* of rail segment *(s)* under known weather and environmental conditions. Let C_{mirs} be the cost of maintenance of each lubricator. It includes lubricator servicing, checking and filling of lubricator tanks, evaluating the performance of lubricators and checking the blades and plungers for each lubricator.

C'_{mirs} = cost of emergency repair during the failure of i^{th} lubricator or lubricant leak or spilling of lubricant.

C_{pirs} = cost of the personnel involved in maintenance of i^{th} lubricator.

Differential Wear loss (W_{irs}) = Total rail wear before lubrication – Loss of material after lubrication for i^{th} lubricator of curve section r of rail segment s.

Where i is the index.

C_r = *Cost of rail material per meter per kg*

Therefore, the total cost of differential wear loss for particular curve section *(r)* of rail segment *(s)* can be expressed as

$$TC_{W_{irs}} = W_{irs} * C_r \tag{5}$$

Total cost of lubrication for i^{th} lubricator at curve section r and rail segment *(s)* can be expressed as

$$TC_{l_{irs}} = C_L + C_{mirs} + C'_{mirs} + C_{pirs} \tag{6}$$

If

$$TC_{l_{irs}} \leq TC_{W_{irs}} \text{ then the lubrication is effective} \tag{7}$$

This is individual comparison of total cost of each lubricator and total wear cost for particular curve section (r) and rail segment *(s).* Some places it is difficult to compare these costs due to different curve radius and rail size, age and condition of rail. The results will be more appropriate if we consider average total cost of n number of lubricators for curve section for a rail segment. Therefore, the total average cost of n number of lubricators for curve section (r) and rail segment (s) can be expressed as:

$$TC_{nlrs} = \sum_{i=1}^{n} TC_{l_{irs}} \tag{8}$$

The total average wear cost for n lubricators of curve section (r) and rail segment (s) can be expressed as:

$$TC_{wnrs} = \sum_{i=1}^{n} TC_{W_{irs}} \tag{9}$$

The ratio of Equation (8) and (9) can be used to determine the percentage of average costs of wear and lubrication for particular curve section at a rail segment under consideration. Therefore, the ratio can be expressed as,

$$\text{\% of average costs} = \frac{TC_{nlrs}}{TC_{wnrs}} \times 100 \tag{10}$$

The average costs can be compared to determine the effectiveness of lubrication and differential wear costs. The ratio of these costs would be used to determine the percentage of savings in terms of lubrication costs and also for evaluation of lubricator's performance. Then the total cost of maintaining n lubricators for particular curve section (r_i) of rail segment (s_i) per year

$$T_c = \sum_{i=1}^{n} T_{Cl_{irs}} \tag{11}$$

3.1.2 Modelling Rail grinding cost

Let G be the cost of grinding per pass per meter and n_i be the number of grinding pass for i^{th} grinding, L be the length of rail segments (0-300, 300-450, 450-600, 600-800 meters of curve radius sections) under consideration, N be the total number of periods up to safety limit for renewal, and r be the discounting rate per period. It is assumed that payments are made to subcontractors after each of the (N-1) grinding.

Therefore the annuity cost for rail grinding is given by:

$$c_g = \{\sum_{i=1}^{N-1} (G * n_i * L)/(1+r)^i\} * r_y /(1-(1/(1+r_y)^Y)) \quad (12)$$

3.1.3 Modelling Rectification and Replacement costs

Once rail defect is detected it is important to decide what type of maintenance activity is required to reduce risk of rail breaks and derailments. Currently rail infrastructure owners are following three types of maintenance activities. They are

- Minimal repair
- Overhaul and
- Replacement (for details see [23])

Let c_{re} be the expected cost of replacement for segment L and consists of labour, material, and equipment, consumable and down time cost for rail replacement. Let I be the cost of current investment in new rail. In this model the cost of replacement is assumed to be occurring at the beginning of each year and is simplifies as the annual spread over of investment of new rail. Then c_{re} is given by:

$$c_{re} = I * (1-(1/(1+r)))/(1-(1/(1+r_y)^y)) \quad (13)$$

where r is discount rate.

3.2 Modelling Operational Risks due to Wear-Fatigue-Lubrication Interaction

Let cost per rectification of rail breaks on emergency basis, C_r be modelled through $G(c)$, and is given by

$$G(c) = P[C_r \le c] \quad (14)$$

For an example, if $G(c)$ follows exponential distribution [24], then it is given by

$$G(c) = 1 - e^{-\rho c} \quad (15)$$

where $\bar{c}$ denote the expected cost of each rail break repair on emergency basis and is given by:

$$\bar{c} = [1/\rho] \quad (16)$$

Let k be the expected cost of repairing potential rail breaks based on NDT in a planned way and a be the expected cost per derailment. Then k and a could be modelled in similar manner. The risk cost associated with rail break and derailment is based on the probability of NDT detecting potential rail breaks, rail breaks not detected by NDT, derailments and associated costs. It also depends on lubrication, grinding, and rectification and replacement maintenance activities of rail. Let $P_i(A, Fatigue, s)$ be the probability of undetected potential rail breaks leading to derailments based on rail head area, RCF, speed of train. Let $P_i(B)$ be the probability of detecting potential rail breaks based on rail head area, fatigue and speed of train. Rolling contact fatigue is given by Million Gross Tonnes (MGT). Railhead area is determined by wear and preventive rail grinding based on MGT [25]. When expected number of failures are modelled as Non Homogeneous Poisson process and is given by $E[N(M_i+1, M_i)$ then the risk cost is given by:

$$C_r = \left\{ \sum_{i=0}^{N} \frac{E[N(M_{i+1}, M_i)] * [P_i(B) * k + (1 - P_i(B)) * (P_i(A, Fatigues)) * a + (1 - P_i(A, Fatigues)) * \overline{C}]}{r/(1-(1/(1+r)^N))} \right\} \quad (17)$$

Where r is discount rate.

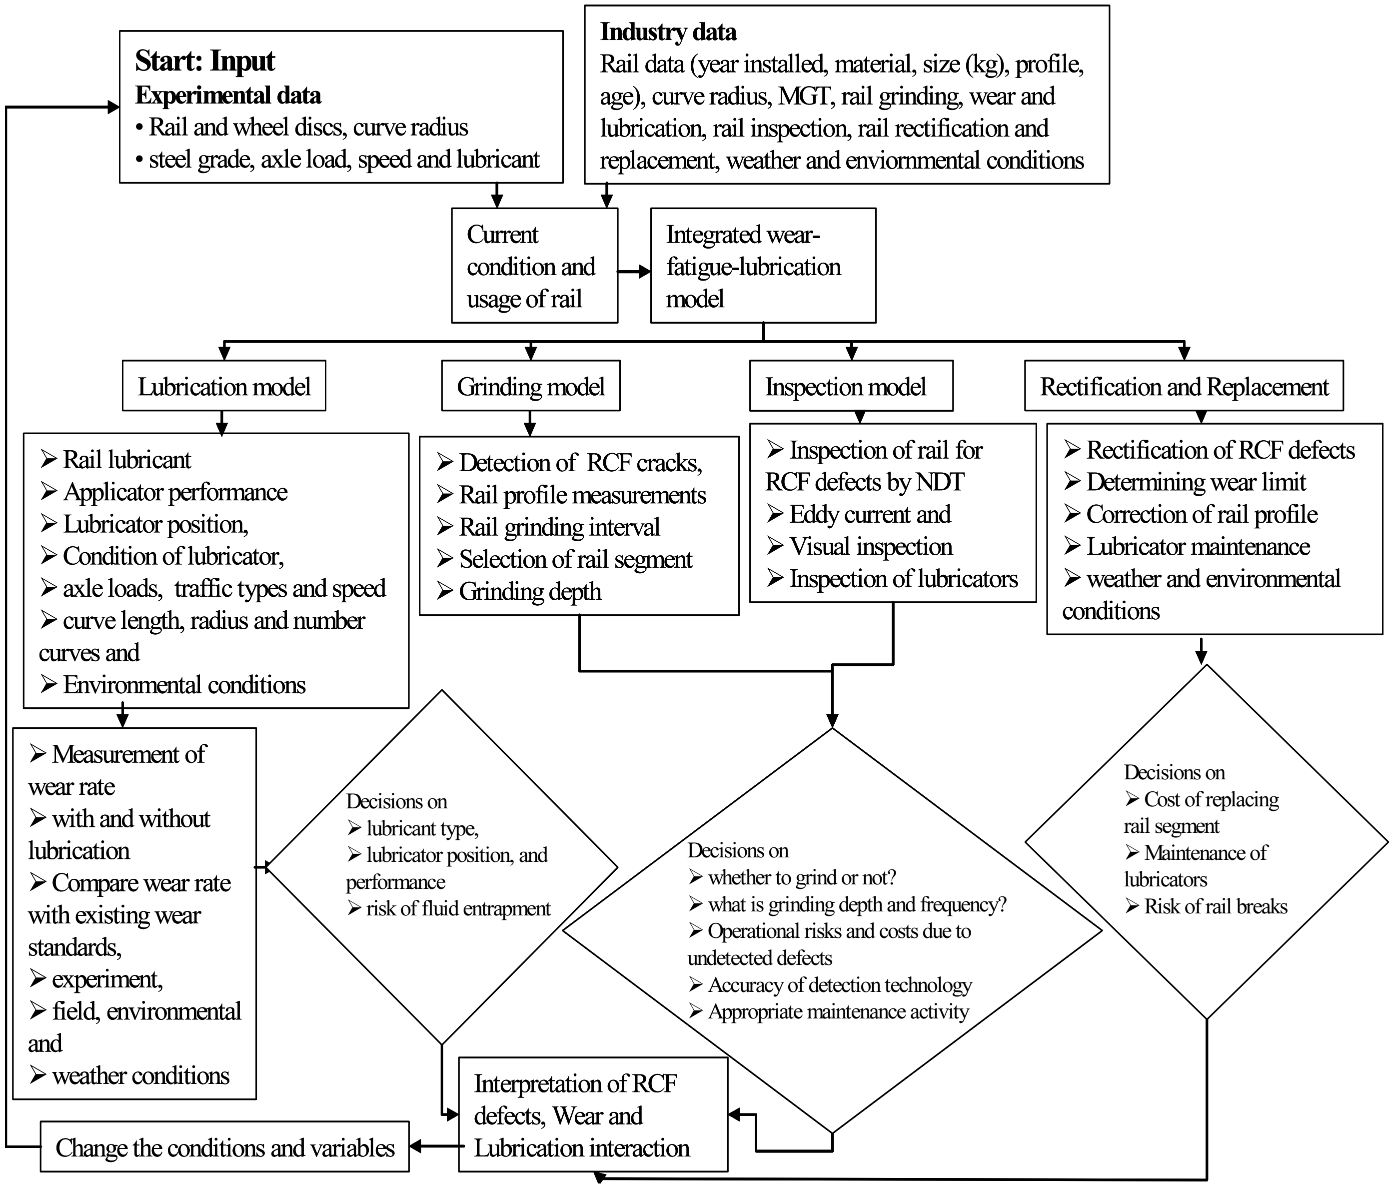

Figure 5: Proposed integrated model for wear-fatigue-lubrication and grinding

Figure 5 shows proposed model for wear-fatigue-lubrication interaction, grinding and inspection maintenance activities. The model can be used for effective maintenance decisions on lubricators, type of lubricant, effectiveness of lubricant, grinding death and interval, inspection techniques accuracy and interval, defect rectification and replacement of rails to minimise operational risks and costs.

4 SUMMARY AND CONCLUSION

In this paper an integrated model proposed for wear-fatigue-lubrication interaction. It also covers grinding and inspection activities. The proposed model would be useful for analysing wear-fatigue-lubrication interaction considering grinding, lubrication, inspection, rectification and replacement decisions. Cost models proposed here could be used for rail-wheel maintenance and replacements decisions. It is able to evaluate performance of lubricators and grinding and inspection. Authors are currently working in this area and results will be published in the near future.

Abstract: The paper proposes a computational strategy for discovering trends of changes and gradual performance deterioration of construction machines and other complex systems. If a significant change in the machine performance is detected, it further activates a fault diagnosis procedure in order to find the possible faulty condition. In order to send the information from various sensors of the construction machine to the maintenance center in an efficient form, a special information compression method is proposed in the paper. It uses original unsupervised learning algorithm to locate the given number of neurons from the parameter space in the densest data areas. These neurons are considered as information granules, which are later on sent in a wireless way to the maintenance center to represent the current machine operation. Two information recovery procedures are also proposed in the paper for analyzing the compressed information from the neurons. The first one is a specialized version of the moving window method, while the other is fuzzy inference-based approach for discovering possible machine deterioration. Results based on real experimental data from a hydraulic excavator are used to explain the proposed computational strategy and its merits.

Key Words: Information Compression, Information Recovery, Unsupervised Learning, Neurons, Fuzzy Inference, Maintenance, Deterioration, Information Granules

1 INTRODUCTION

Construction machines, such as excavators, wheel loaders and others are complex systems that use many different sensors to provide adequate information for their control, monitoring, fault diagnosis and maintenance. As a result, a big number of data, taken by regular sampling over the daily operation of the machine are collected on-board and should be dispatched to the Maintenance Center for evaluation and analysis of a possible deterioration or abnormality in the machine operation.

The real problem in such analysis and detection of changes and deterioration trends is the high dimensionality of the data space and the large number of the obtained data, which makes any direct human decision quite subjective and ambiguous. The first and the simplest question to be answered, when looking at the multidimensional collected data set is whether the current machine operation condition is similar or differs significantly from the standard “normal operation” mode. In other words detecting the changes in system performance in automatic way is an important task which, if properly solved can provide a basis for solution of the next fault diagnosis problem.

There is a big interest in the literature on the problems related to the fault detection, diagnosis and performance evaluation in industrial and other complex systems, as shown in [1-5]. The widely used methods here involve different modifications of neural models [3], fuzzy models [4] or knowledge-based clustering [5]. The authors interest in this area and some of their latest results can be also found in [6,7].

In this paper we propose an efficient computational strategy for automated analysis and detection of changes and deterioration trends in operation of construction machines. It is based on the concept of information compression of the original large number of “raw data” into a smaller portion of “information granules” [5] in the form of neurons in the multidimensional space. Thus a very economical information transfer between the construction machine and the maintenance center is achieved. Finally, two additional methods are proposed as tools for recovering and further analysis of the information.

The following Fig. 1. is a graphical illustration of how complex and ambiguous is the problem for detection of similarities (or differences) between various operations of a construction machine. It displays four different operations of a hydraulic excavator. By just observing visually the *raw normalized* data in Fig. 1., it would be difficult for the human operator to properly judge which operations are “similar”, as well as which of them are “normal” and which belong to “abnormal” operation of the machine. All the human operator can do is to compare the shapes of the “data clouds” in the respective pairs of two-dimensional spaces.

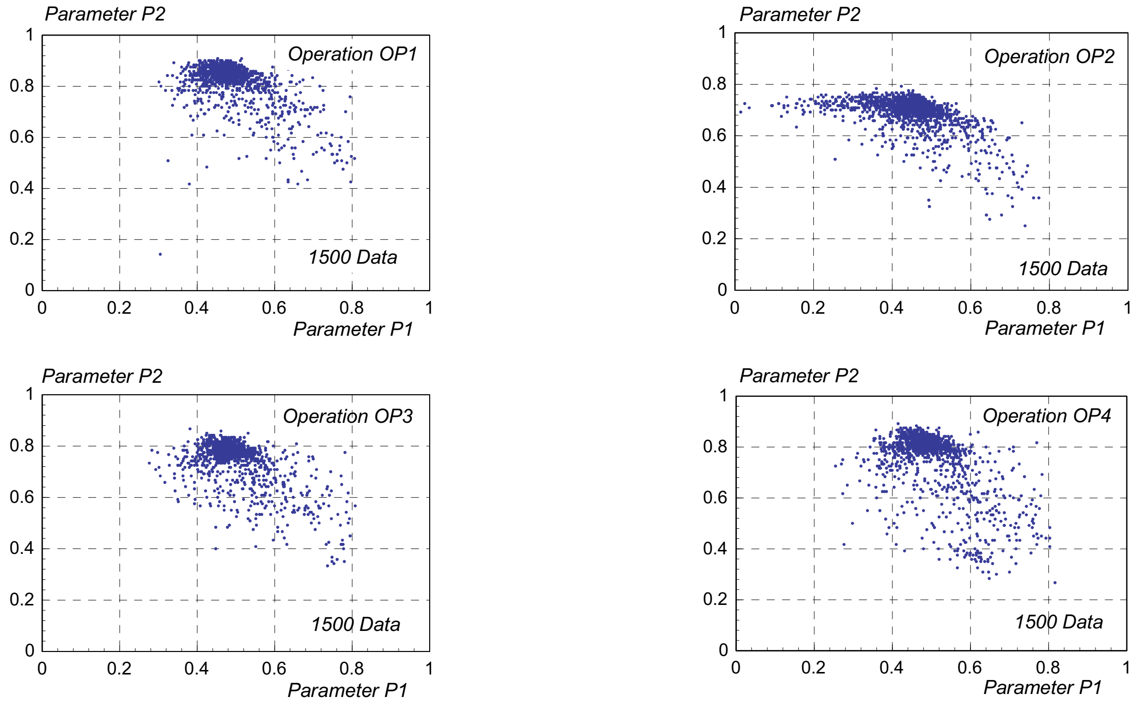

Figure 1. Example of four different operations of a construction machine, shown as plots of normalized “raw data”.

The remaining part of this paper is organized as follows. The proposed system for information compression and information recovery is explained in the next section *2*. Section *3* deals with the method for information compression, while section *4* presents two methods for information recovery. In section *5* different (normal and abnormal) operations of a hydraulic excavator are analysed by the proposed methods and system. Finally section *6* concludes the paper.

2 THE PROPOSED IC-IR SYSTEM FOR INFORMATION COMPRESION AND INFORMATION RECOVERY

Our basic assumption is that the *Operating Site* (OS) of the construction machine and the *Maintenance Center* (MC) are remotely located at a big distance from each other. Therefore an economically efficient system for transmitting the most relevant information for the current (daily) operation of the machine to the maintenance center is needed. This information is then processed and analysed in the MC in order to make an appropriate conclusion about the current state (normal, abnormal, faulty) of the machine and to take appropriate measures for correction (repair), if needed.

Since many thousands of data from different parameters are usually measured by the respective sensors during the daily operation of the machine, it s not practical to send all these “raw data” directly the maintenance center (MC) for a further analysis. Here there could be at least two different approaches to alleviate this high dimensionality problem.

One approach is to make an “on-board” pre-processing (simplified analysis) of the data and then to send the results of this analysis in a wireless way to the MC for final decision making. The merit of this method is that it is economical (a small number of data are transmitted between OS and MC), but at the same time it has two demerits, as follows. The first one is that the usually small “on-board” computing power puts limitations on the complexity of the analysis, which results in a simple (not sufficient) data analysis being done “on-board”. The second demerit is that in this way we are losing “on the spot” a big portion of information which cannot be further recovered at the MC.

Another approach, which we propose in this paper, is to make a kind of "information compression" (IC) based on the all measured raw data "on-board" and to transmit this compressed (highly reduced) information to the MC in a wireless way. Then, at the MC a respective "information recovery" (IR) procedure is run which is followed by information analysis and appropriate decision making step. In such way, the current daily operation of the construction machine can be analysed, evaluated, classified (as normal, deteriorated or faulty) at the maintenance center, as well as to be compared to other operations of the same machine in different (past) time periods.

The proposed system, based on the IC-IR approach for analysis of the deterioration trends has two clear merits. The first one is that the compressed information "on-board" is recoverable (to a high extend) at the MC. This means that we are not losing a lot of useful information, as in the previous mentioned approach. The second merit is that the compressed information can be efficiently transmitted to the MC, which makes the whole hardware system, based on this approach very practical.

The block-diagram of the IC-IR system for information compression and information recovery, based on the above proposed approach is shown in Fig. 2.

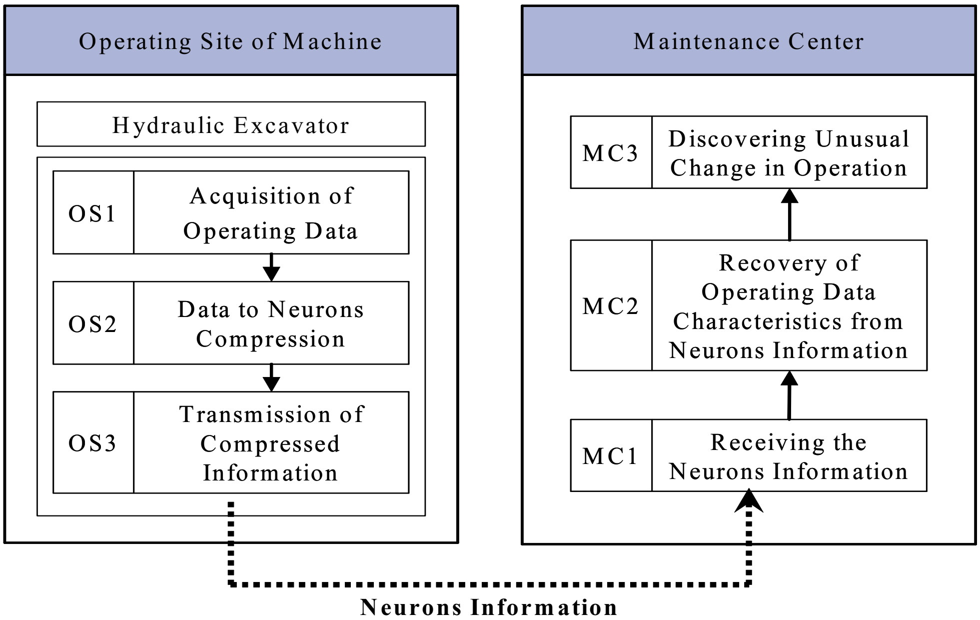

Figure 2. The Proposed IC-IR System for Information Compression and Information Recovery.

As seen from the figure, there are three main steps to be performed at the Operation Site of the construction machine, denoted as OS1, OS2 and OS3 and three other computation steps at the Maintenance Center, denoted as MC1, MC2 and MC3.

Step OS1 is dealing with the real-time data measuring of a fixed number of parameters and data acquisition. Normally the data are measured with a sampling period of *1 sec* in order to represent the dynamical behavior of the machine during its operation. As a result, several thousands of data are accumulated in the "on-borad" computer memory.

Step OS2 is the essential part of the whole IC-IR system, because it performs the information compression, which is explained in details in the next Section of the paper. In short, this step creates a kind of "information granules" in the form of preliminary fixed number of neurons, appropriately trained in the parameter space, so that to best represent the data structure of the "raw data".

Step OS3 is a wireless transmission of the compressed information from the OS to the MC, i.e. transmission of the information granules (neurons) with all the related information about their parameters.

Once the compressed information is transferred and received at the Maintenance Center (step MC1 in Fig. 2.), then step MC2 performs some computational methods and algorithms for information recovery. In Section 4 of the paper we suggest and explain two methods and algorithms, which represent two different aspects of the information recovery. The first one is based on the window moving average and the second one is an original fuzzy inference method for analysis of the relationship between the parameters.

The results from the information recovery at step MC2 are further on used in the last step MC3, which is a final decision making procedure for confirmation (or rejection) of a possible deterioration (or faulty) state of the machine. This step includes also a possible automatic fault diagnosis, which is not a research subject in this paper.

The whole proposed IC-IR system in Fig. 2. is currently in a status of implementation for performance analysis and evaluation of the operations of hydraulic excavators, including detection of abnormal operations.

3 THE METHOD FOR INFORMATION COMPRESSION

Further on we suppose that a big number (usually many thousands) of M "raw data" $\mathbf{x}_s, s=1,2,...,M$ have been collected at the Operating Site during the current operation of a construction machine. Each data point $\mathbf{x}_s$ represents the measurements from K parameters, which are dynamically changing during the operation, i.e. $\mathbf{x}_s = [x_{s1}, x_{s2}, ..., x_{sK}]$, $s = 1,2,...,M$.

The general concept of the information compression method proposed in this paper is to replace the complete data set of M data with a much smaller set of N ($N \quad M$) *information granules* that carry as much as possible of the original amount of information given by the "raw data".

The most important part of the information that should not be lost in the process of information compression is the original *data structure* for the current operation of the machine. This structure is best represented by the overall *data shape* (in the form of "cloud" in the K-dimensional space); as well by the *data density distribution* in the different areas of the data "cloud". These two characteristics of the data play important role in the final procedure (Step MC3 in Fig. 2.) for detection of deterioration trends in the machine performance as well as for fault diagnosis purposes.

Further on we consider all N information granules obtained by the information compression method as a kind of *neurons* in the K-dimensional parameter space, which carry the following three types of information:

Neuron *centers*: $\mathbf{C} = \{\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_N\}$; Neuron *weights*: $\mathbf{G} = \{G_1, G_2, ..., G_N\}$ and Neuron w*idths*: $\mathbf{W} = \{\mathbf{w}_1, \mathbf{w}_2, ..., \mathbf{w}_N\}$. Please note that the centers in $\mathbf{C}$ and the widths in $\mathbf{W}$ are K-dimensional vectors, while the weights in $\mathbf{G}$ are scalars.

Neuron *centers* $\mathbf{c}_i = [c_{i1}, c_{i2}, ..., c_{iK}]$, $i = 1,2,...,N$ show the place (position) of each neuron in the K-dimensional space: Generally neurons should be surrounded by as much as possible "raw data" points, in order to represent (compress) the information in a suitable way. In other words these centers serve as prototypes of local clusters in the space [5,8].

Neuron *weights*: G_i, $i = 1,2,...,N$ can be viewed as *strengths* of the neurons, in a sense of number of the data points that are represented (managed) by each neuron.

Finally, neuron *widths* $\mathbf{w}_i = [w_{i1}, w_{i2}, ..., w_{iK}]$, $i = 1,2,...,N$ are a kind of measure for the neuron *activities,* which indicate *how large* is the area around each neuron center for which it is "responsible".

The proposed information compression method first locates the neuron centers by appropriate unsupervised learning algorithm and then defines the other two parameters, namely the neuron weights and neuron widths. The computational details and illustrations are given in the next sub-sections.

3.1 Location of the Neuron Centers by Unsupervised Learning.

The main goal of this computational procedure is to train the centers of the neurons in the most appropriate way, so that to locate all the neurons at the "best" places in the K-dimensional parameter space. A natural way to do this is to use the information about the density distribution of all available data points $\mathbf{x}_s, s=1,2,...,M$ in the space.

Basically, the learning methods in this case belong to the group of the competitive unsupervised learning methods and algorithms [8,9]. Among them are the well known and widely used clustering algorithms [5,8], the Self-Organized (*Kohonen*) Maps [9], Neural Gas Algorithms [10] etc. Because of their unsupervised nature, these methods are considered as pure "data-driven learning" (DDL) methods which tend to locate the neurons in the densest (the most "crowded") area of the input space.

We use in this paper the well known and popular Neural-Gas unsupervised learning algorithm, first reported in [10], with some minor algorithmic improvements and simplifications, which make it more suitable for our problem.

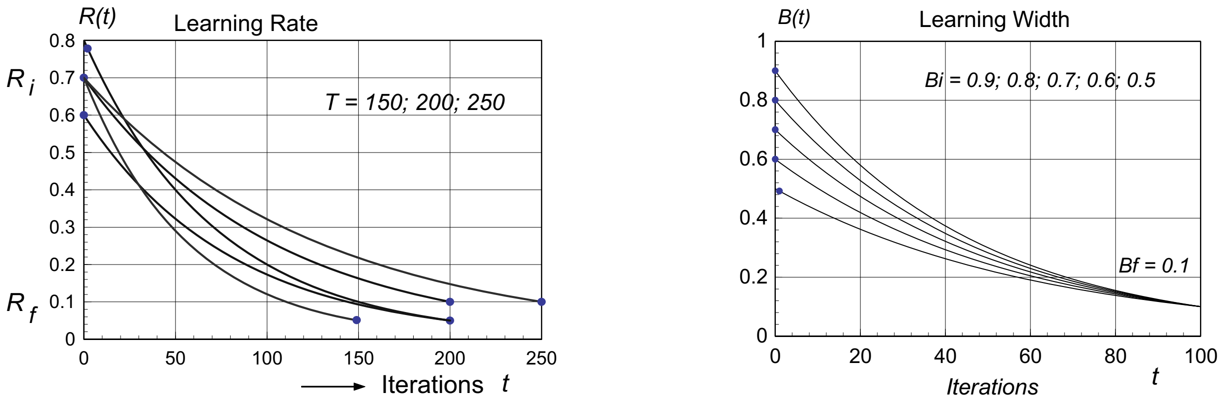
Initialization Step: There are some parameters that have to be set in advance, before the unsupervised learning starts. First of all a preliminary fixed number of N neurons ($N \quad M$) is assumed and their initial locations (centers) are set randomly in the K-dimensional space as follows: $\mathbf{c}_i^{\,0} = [c_{i1}^{\,0}, c_{i2}^{\,0}, ..., c_{iK}^{\,0}]$, $i = 1,2,...,N$. The maximum number of iterations T for the unsupervised learning is also set in advance and usually varies between several hundreds and several thousands. Another tuning parameter is the *learning rate* $R(t)$, $0 \le R(t) \le 1$, $t = 0,1,2,...,T$ which controls the speed and convergence of the learning process. It is defined by two initial parameters: R_i and R_f representing the initial and final learning rate, respectively. The learning rate depends also on the current number of iteration, as shown by the following exponentially decreasing function:

$$R(t) = R_i (R_f / R_i)^{t/T}, \; t = 0,1,2,...,T \tag{1}$$

Another tuning parameter in the unsupervised learning is the *learning width* $B(t)$ which controls the size of the "neighbourhood" of the neurons (explained later). In a similar way as in $R(t)$, the learning width $B(t)$ is defined by two initial parameters: B_i and B_f that represent the *initial* and *final* width respectively. It also decreases exponentially with the number of iterations, as follows:

$$B(t) = B_i (B_f / B_i)^{t/T}, \ t = 0,1,2,...,T \tag{2}$$

The following Fig. 3a) and Fig.3b) is an illustration of the learning rate and learning width evolutions during the iterations under different initial and final settings.



a)Exponentially Decreasing Learning Rate b)Exponentially Decreasing Learning Width

Figure 3. Evolution of *Learning Rate* and *Learning Width* under different initial and final settings.

<u>Learning Step:</u> This step is repeated for each iteration $t = 1,2,...,T$ and for all available data $\mathbf{x}_s$, $s = 1,2,...,M$. The purpose is to gradually move the centers $\mathbf{c}_i, i = 1,2,...,N$ of all N neurons into the areas in the parameter space with a bigger data density. This is done by the following general incremental learning rule:

$$\mathbf{c}_i(t) = \mathbf{c}_i(t-1) + \Delta\mathbf{c}_i(t), \ i = 1,2,...,N. \tag{3}$$

The increment $\Delta\mathbf{c}_i(t)$ for the movement of each neuron's center is computed as:

$$\Delta\mathbf{c}_i(t) = R(t) H_s(t,r) \left[\mathbf{x}_s - \mathbf{c}_i(t-1) \right], \ i = 1,2,...,N. \tag{4}$$

It is seen from (4) that the amount of learning (movement) of the *i*-th neuron in the *K*-dimensional parameter space depends on the following three factors:

- the current learning rate $R(t)$, computed by (1);
- the current *neighborhood* of the *i*-th neuron in respect to the *s*-th data point $\mathbf{x}_s$, computed by the *neighborhood function* $H_s(t,r)$;
- the current distance between the *s*-th data point and the *i*-th neuron (taken separately for each of all *K* parameters).

The *neighborhood function* $H_s(t,r)$ is an exponentially decreasing function, which is important and specific part of the Neural-Gas unsupervised learning algorithm. It can be viewed as a variable scaling factor for the *amount* of the update for each neuron, which depends on the relative closeness of the *i*-th neuron to the current s-th data point $\mathbf{x}_s$. This relative closeness is taken as the *ranking position* $r = 1,2,3,...$ of this neuron compared with all other neurons in the space. Finally the neighborhood function is computed as:

$$H_s(t,r) = \exp\left(-\frac{(r-1)^2}{B(t)} \right) \tag{5}$$

where $B(t)$ is the current learning width of the neighborhood function, computed by (2).

For a given data point $\mathbf{x}_s$, the ranking positions $r = 1, 2, 3, \dots, N$ for all N neurons are computed through a sorting procedure in ascending order of the *Euclidean distances* $D_S(n)$ between all the neurons n, $n = 1, 2, \dots, N$ and this data point:

$$D_S(n) = \sqrt{\sum_{j=1}^{K} \left(x_{s\,j} - c_{n\,j} \right)^2} \tag{6}$$

The neuron with the minimum distance to $\mathbf{x}_s$ (the closest neuron to this data point) is called "winning neuron" and gets the ranking position $r = 1$. The second closest neuron to the same data point gets position $r = 2$ and so on until certain neuron is ranked as the last one ($r = N$) being the furthest neuron to the data point $\mathbf{x}_s$.

Figure 4. shows the evolution of the neighborhood function during a learning with *T = 100* iterations. Since the learning width $B(t)$ in (5) is a monotonically decreasing function of the iterations, the neighborhood function (5) is gradually becoming narrower, which results in a smaller amount of update for a neuron with the same ranking position r. From (5) it is clear that the "winning neuron" gets always the full amount of update (4) that is $H_s(t,r) = 1.0$ for $r = 1$. Other neurons get smaller updates, according to their ranking, as seen from Fig. 4.

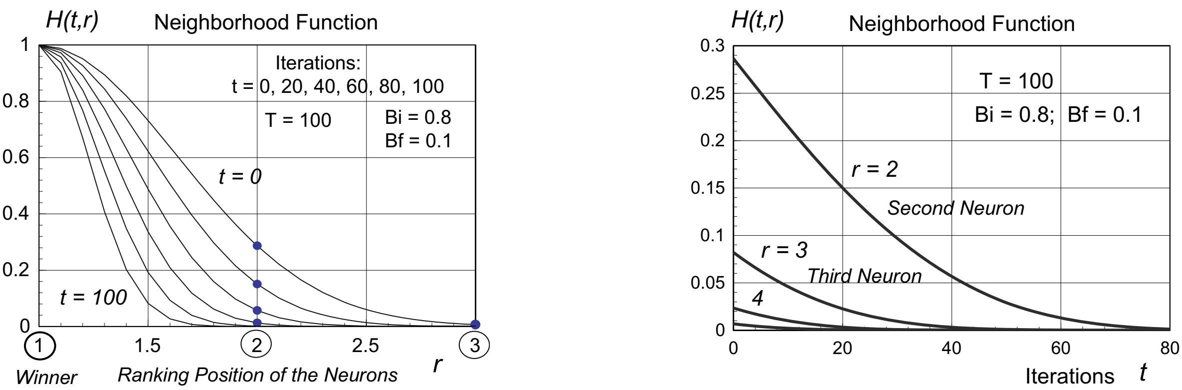


Figure 4. Evolution of the Neighbourhood Function during iterations and updates of the neurons.

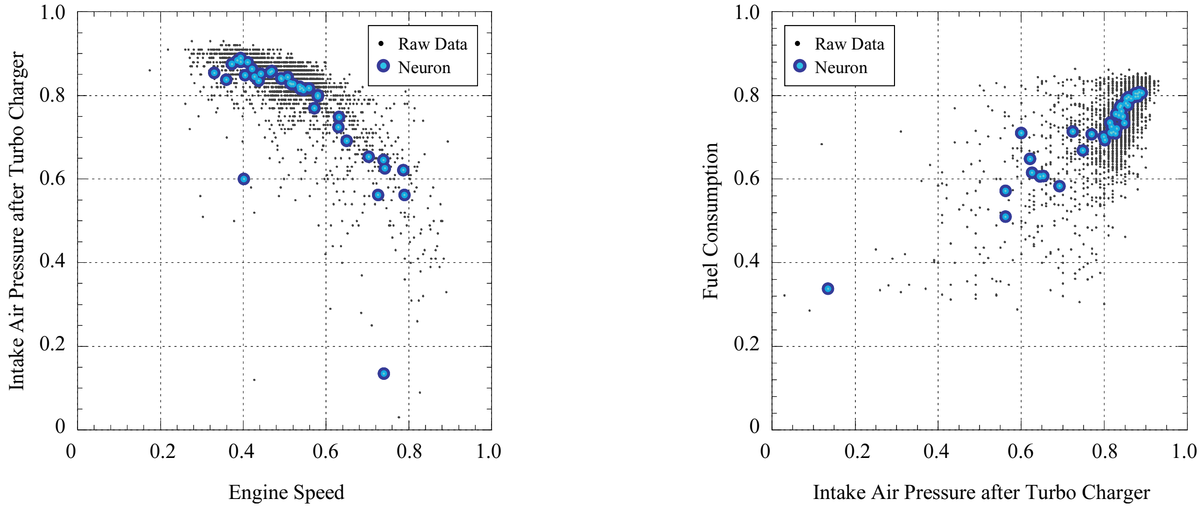
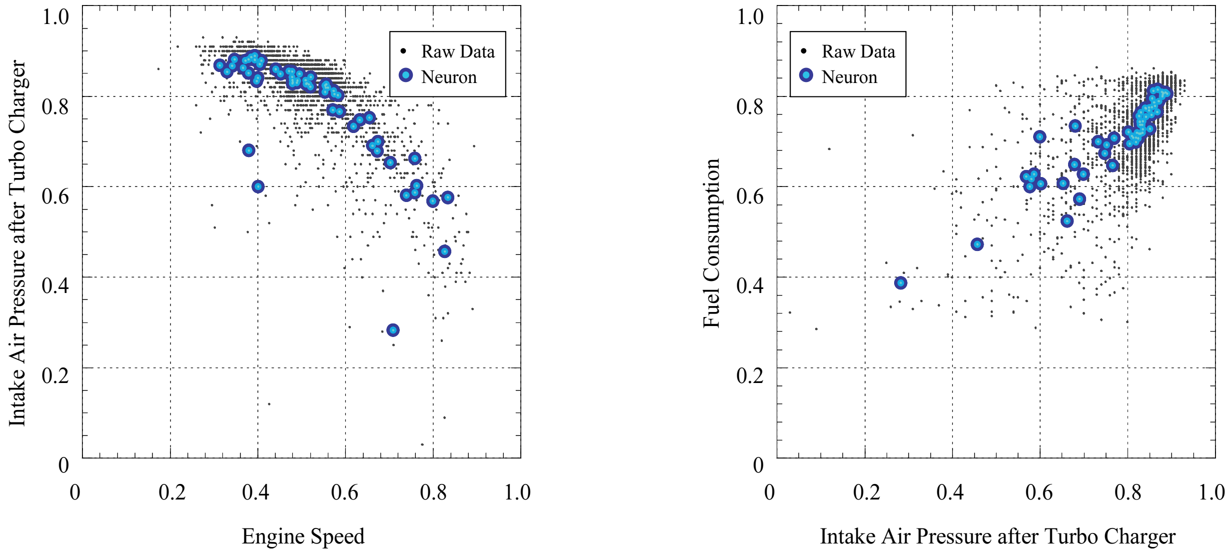
3.2 Illustration of the Information Compression by the Unsupervised Neural-Gas Learning

The next two figures, Fig. 5. and Fig. 6. serve as illustration of how the Neural-Gas unsupervised learning algorithm compresses the information carried by a set of *2515* raw data with three different parameters (*K = 3*), taken from a hydraulic excavator with a sampling period of *1 sec*. Figure 5 shows the case of compression by using a set of *40* neurons (*N = 40*), while Figure 6 is a compression of the same data set by using *N = 60* neurons. In both cases the learning is done with the following learning parameters: $T = 300$; $R_i = 0.5$; $R_f = 0.05$; $B_i = 0.7$; $B_f = 0.1$. It is visually understood that even if there is not a big difference between the two figures, the bigger number of neurons in Fig. 6. allows a better preservation of the structure (shape) of the original raw data set. Therefore the neuron set from Fig. 6.can serve as a set of information granules for transmitting the compressed information to the Maintenance Center for further recovery and information analysis. The problem of a proper selection of the number of neurons for a minimum loss of information is empirically solved in this paper, but could be done in more rigorous way by setting an appropriate criterion.



(a) (b)

Figure 5. Information Compression of $M = 2515$ raw data from a normal operation, by using $N = 40$ neurons.



(a) (b)

Figure 6. Information Compression of $M = 2515$ raw data from normal operation, by using $N = 60$ neurons.

3.3 Computing the Neuron Weights $\mathbf{G}$

As mentioned above in the section, the neuron weights $\mathbf{G}=\{G_1, G_2, ..., G_N\}$ are scalar values, which serve as *strength levels* for each neuron, evaluated by the number of data points that are represented by (or "belong" to) this neuron. In order to find the number of data, "belonging" to each neuron we use again the notion of "wining neuron" from the Neural-Gas learning algorithm.

First of all, for each data point $\mathbf{x}_s$, $s=1,2,...,M$ we find the respective "winning neuron" n_s, $1 \le n_s \le N$ as the closest neuron to this data, i.e. the neuron with a minimum Euclidean distance (4) to $\mathbf{x}_s$:

$$D_s(n_s) = \min_{1 \le n \le N} \{D_s(n)\} \tag{7}$$

Then this information is used for splitting all M data into N subsets: $\mathbf{M}_n$, $n=1,2,...,N$, each of them containing the data points m_n, $n=1,2,...,N$ for which the same n-th neuron has been "winning neuron". Speaking more precisely, the following conditions hold:

$$m_n = |\mathbf{M}_n|;\ 1 \le m_n \le M,\ n=1,2,...,N;\quad \sum_{n=1}^{N} m_n = M = |\mathbf{M}|,\ \text{where}\ \ \mathbf{M} = \bigcup_{n=1}^{N} \mathbf{M}_n \tag{8}$$

The normalized weights of the neurons are computed simply as follows:

$$G_n = m_n / M;\ 0 < G_n \le 1,\ n=1,2,...,N,\ \ \text{with}\ \ \sum_{n=1}^{N} G_n = 1. \tag{9}$$

It is worth to note that each subset of data $\mathbf{M}_n, n=1,2,...,N$ forms the so called "*Voronoi polygon"* [9,10] in the K-dimensional space.

Illustration of a *rough* information compression of a set with $M = 759$ data by a set of $N = 6$ neurons, trained with the Neural-Gas algorithm, is presented in the following Fig. 7. It shows also the shape of all 6 "*Voronoi polygons*" and their respective number of data points m_n, $n=1,2,...,6$.

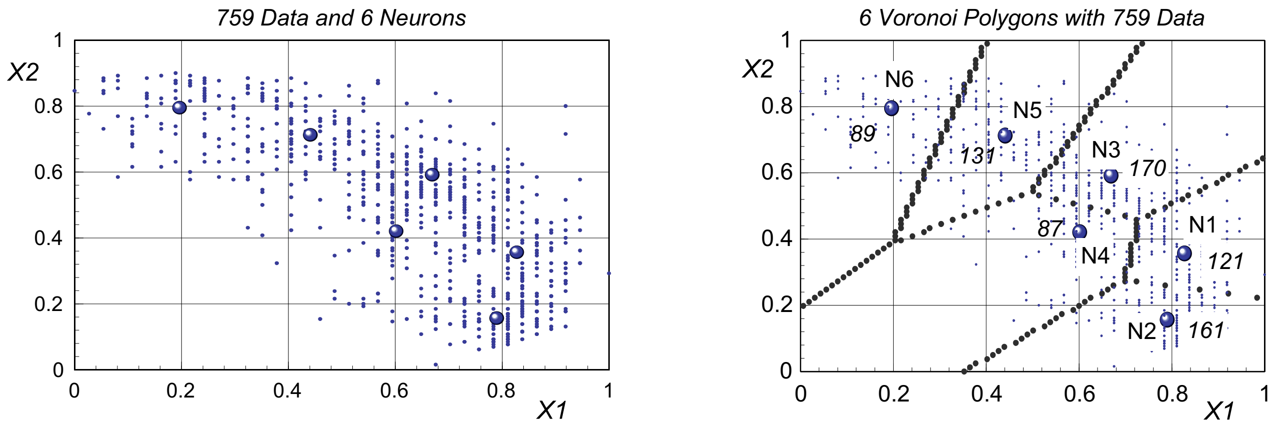


Figure 7. Information compression of *759* data with *6* Neurons and respective "*Voronoi polygons"*.

3.4 Computing the Neuron Widths W

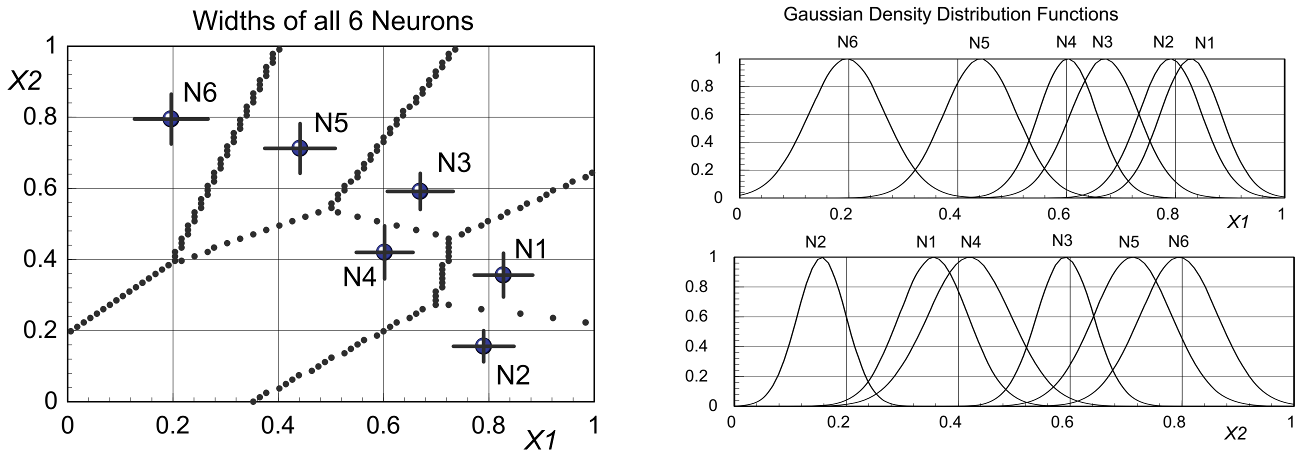
The size of the area covered by each "*Voronoi polygon*" does not reflect directly the data distribution in this area, since a part of it could be empty. This is clearly seen from the above Fig. 7. However, the neuron widths $\mathbf{W} = \{\mathbf{w}_1, \mathbf{w}_2, ..., \mathbf{w}_N\}$ should provide a kind of evaluation of the data density distribution, which is important for the further step: information recovery (IR). Therefore, a plausible measure of such data distribution could be the average distance between the neuron center and all the data points in its "*Voronoi polygon*".

Computation of all the vectors for neuron widths $\mathbf{w}_n = [w_{n1}, w_{n2}, ..., w_{nK}],\ n=1,2,...,N$ is done by the following equation:

$$w_{nj} = \frac{1}{m_n} \sum_{s=1}^{m_n} |x_{sj} - c_{nj}|,\ j=1,2,...,K;\ n=1,2,...,N. \tag{10}$$

The following Fig. 8*a* is a scaled illustration of the widths of all 6 neurons, named as *N1, N2, ..., N6* from the example, shown in the previous Fig. 7. The bold horizontal and vertical lines around each neuron show their respective widths: $\{w_{n1}, w_{n2}\}$, $n = 1,2,...,6$ in the 2-dimensional parameter space $\{X1, X2\}$.

The computed neuron widths can be further regarded as widths of respective Gaussian density distribution functions, as shown in Fig. 8*b*. These functions are useful for approximate recovery of the density distribution of all *M* data over the whole range of the parameters, as it is shown in the following sections.



(a) (b)

Figure 8. Illustration of the neuron widths and the respective Gaussian density distribution functions.

4 METHODS FOR INFORMATION RECOVERY AND ANALYSIS OF DETERIORATION

The compressed information, consisting of the neuron centers $\mathbf{C}$, weights $\mathbf{G}$ and widths $\mathbf{W}$, as explained in the previous section are further transmitted to the Maintenance Center MC for information recovery (IR). There could be different methods for such recovery with their own merits and demerits, measured by the amount of the lost (unrecoverable) information. In this paper we propose and explain two relatively simple IR methods which can be used in the process of analysing the deterioration trends in the construction machines.

4.1 The Moving Window Average (MWA) Method

This simple method is used for recovering an important part of the information in the form of relationship between a given (predefined) *pair* of parameters, for example *P1 = X* and *P2 = Y*, selected from the group of all *K* parameters. The relationship can be drawn as a curve from a preliminary computed number of M_w points in the two-dimensional space $\{X, Y\}$, $\mathbf{V}_j = \{V_{jX}, V_{jY}\}$, $j = 1,2,...,M_w$. The number of these points coincides with the total of the windows M_w with a predefined size (length) *WL*, which are moved gradually from the left to the right boundary of the parameter *X* with a predefined overlapping *WO*. A graphical explanation of this Moving Window Average (*MWA*) method is given in Fig. 9*a* while Fig. 9*b* depicts an example based on real experimental data, taken from a hydraulic excavator.

The following abbreviations and notations are assumed in Fig. 10: *LB* – left boundary of the range of all neurons; *RB* – right boundary of this range; *B1* – left boundary of the current *j*-th window; *B2* – right boundary of the current *j*-th window (***W4*** in this case); *WL = B1 – B1*: window length; *WO* – window overlapping.

The most plausible way to evaluate the coordinates of the point $\mathbf{V}_j$ in the *j*-th window $(j = 1,2,...,M_w)$ is to compute the "*center-of-gravity*" of all N_j neurons that are "captured" in this window, as follows:

$$V_X = \sum_{i=1}^{N_j} C_{iX}^j G_i \Big/ N_j ; \;\; V_Y = \sum_{i=1}^{N_j} C_{iY}^j G_i \Big/ N_j ; \quad j = 1,2,...,M_w , \tag{11}$$

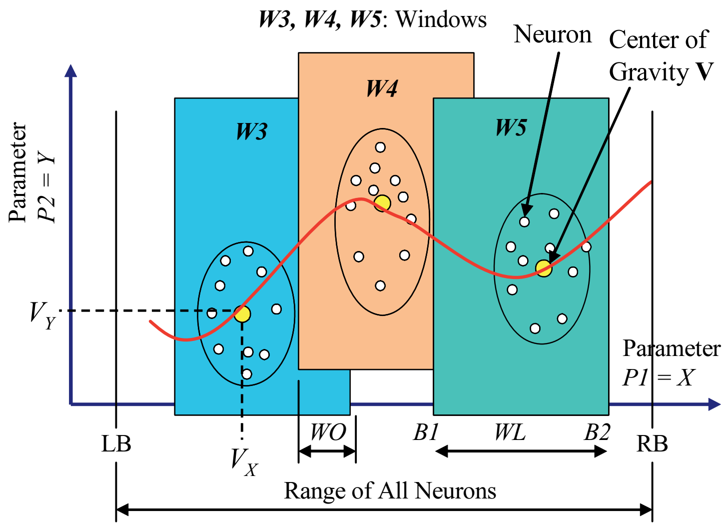
where C_{iX}^j and C_{iY}^j denote the center of the *i*-th neuron $(i = 1,2,...,N_j)$ and G_i is the relative weight of this neuron, computed by (9). Please note that as a result of this weighted computation of the coordinates (11), the point $\mathbf{V}_j$ does not fall in the geometrical center of the j-th window, but in its "*center-of-gravity*". Also, because of the overlapping between the windows, the following inequality holds: $\sum_{j=1}^{M_W} N_j > N$, where N is the total number of neurons.

The resolution of the computed relationship curve for the selected pair $\{X, Y\}$ of parameters depends on the window length *WL* as well as on the overlapping range *WO*. Generally, a bigger number of windows M_w and a moderate overlapping *WO* (less that *70 - 80*% between the neighbour windows) produce a better (smoother) curve without significant loss of information, compared with the performance of the Moving Window Average method on the original "raw data". The two close curves in Fig. 9*b* demonstrate such a good information recovery.

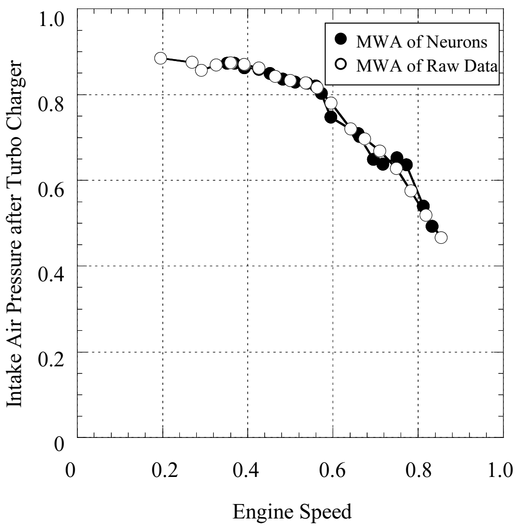
The MWA method could be used as an easy tool to discover differences between two or more operations of a machine, by visually comparing the relationships (curves) between certain pairs of parameters. Such example is provided in the last section of the paper.

4.2 The Method of Fuzzy Inference-based Relationship Analysis (FIRA)

The MWA method does not recover any information about the data density distribution, which could be quite important for discovering potential abnormalities in operation of the machine. The reason for this is that MWA method does not utilize the information about the data distribution, implicitly given by the neuron widths $\mathbf{W}$. Therefore here we propose another method, which is able to approximately evaluate (recover) the density distribution information. This method uses a fuzzy inference procedure to smoothly interpolate the density distribution along all parameters and will be referred to as FIRA method.



a) Graphical Illustration of the Moving Window Average Method;



b) MWA Performance, based on neurons and raw data.

Figure 9. Illustration of the MWA method and performance analysis of the method, based on "raw data" and on neurons.

The FIRA method tries to recover in the most plausible and smooth way the relative data density distribution along each parameter. Then a curve (in relative units) of the density distribution could be drawn for each parameter, for visualisation purposes, as shown in the next Fig. 10. It is worth to mention that the bold gray lines in Fig. 10., connecting the weights *G1, G2,…, G6* of the neurons for the two parameters *X1* and *X2* separately, do not represent in a true way the density distribution along the parameters, because they simply make a "piece-wise" linearization, which often causes "big jumps" between the far located (but neighbour) neurons, if there is a big difference in their weights (9).

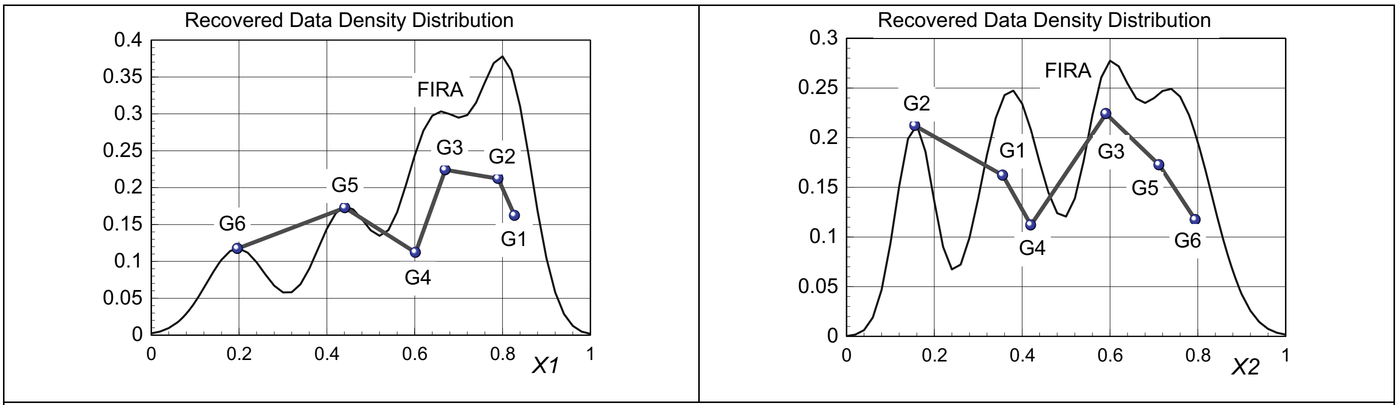


Figure 10. The recovered Data Density Distribution for the example in Figs. 7/8 by using FIRA method

Another way of using the FIRA method is to compute the so called "*Generalized Operating Point*" (GOP) which is one point $GOP = [x_o^1, x_o^2, ..., x_o^N]$ in the *K*-dimensional parameter space that shows the vicinity of the most frequent operation of the machine. Then a large number of GOPs in the parameter space can be computed from the compressed information for respective operations of one machine. The obtained "image" (shape, line) produced by the plotted GOPs (in each 2-dimensional plain) can be used for a simple visual detection of the existence of abnormal operations in this machine. Such operations will be represented by points (GOPs) being far from the general tendency (line) of the normal operations.

In the followings a brief explanation of the computational procedure for the FIRA method is given. As it will be seen, this method utilizes all parameters, obtained by the information compression procedure, namely neuron centers, weights and widths.

First of all, for each separate coordinate (parameter) r, $r=1,2,...,K$ we generate artificially (by scanning) *m* equidistant points, as follows: $x_j^r \in [P_{r\min}, P_{r\max}]$, $j=1,2,...,m.$ Then a "fuzzification" $0 \leq f_i(x_j^r) \leq 1$ of all points x_j^r for the current *r*-th parameter is made, as in the fuzzy sets theory and applications [4,5,7], by using *N* Gaussian membership functions (equal to the number of neurons) with their respective centers and widths:

$$f_i(x_j^r) = \exp\left[-\frac{(c_{ir} - x_i)^2}{2 w_{ir}^{\ 2}}\right], i=1,2,...,N; \ j=1,2,...,m. \tag{12}$$

The next step is to compute the *weighted density distribution* z_j^r in the *j*-th point x_j^r of the *r*-th parameter by using the fuzzified values from (12) and the weights of all *N* neurons , as follows:

$$z_j^r = \sum_{i=1}^{N} f_i(x_j^r) G_i, \ \ j=1,2,...,m. \tag{13}$$

Finally, each local coordinate of the GOP is computed as "weighted average", known also as "defuzzification" in the fuzzy sets theory in the following way:

$$x_o^r = \sum_{j=1}^{m} z_j^r x_j^r \Big/ \sum_{j=1}^{m} z_j^r, \ r=1,2,...,K, \tag{14}$$

The density distributions (the smooth curves) in Fig. 10 are computed by the above computation procedure. Some application examples for computing the GOP based on the FIRA method are given in the next section.

5 ANALYSIS OF DIFFERENT OPERATIONS OF A HYDRAULIC EXCAVATOR

In this section, the above presented methods for information recovery, namely MWA and FIRA methods, as well as the whole IC-IR technology for information compression and information recovery are illustrated and analysed by using real data from different operations of a hydraulic excavator, in order to detect possible deteriorations and abnormalities.

Six operations (considered as *normal*) of the excavator were available, taken during daily operation of the machine at different seasons of the year. In addition, data from seven other (*abnormal*) operations of the excavator, working on a special proving land, were also obtained. The abnormal operations were performed by emulating different types of faults in the diesel turbo-engine, by respective human intervention (special changes in the tuning of the engine parts and parameters). Among them are the following (most distinct) four faults: *F1* - Fuel Spray Nozzle of one cylinder is deactivated; *F2* – Deterioration in the Turbo-charger efficiency; *F3* – Air Filter Obstruction (*Big*) and *F4* - Air Filter Obstruction (*Small*). In order to achieve a fair comparison of the different operations, similar number of data points has been collected from each operation, in the range of *2000 - 2500* data with information compression made by using $N = 80$ neurons.

The following Fig. 11. depicts the case of the abnormal operation (fault *F1*). As seen from the comparison, based on the MWA method and shown in Fig. 12., this faulty operation can be easily detected, as the relationships between the pairs of parameters are quite different from those obtained from the normal operation with data, shown in the above Fig. 5. and Fig.6.

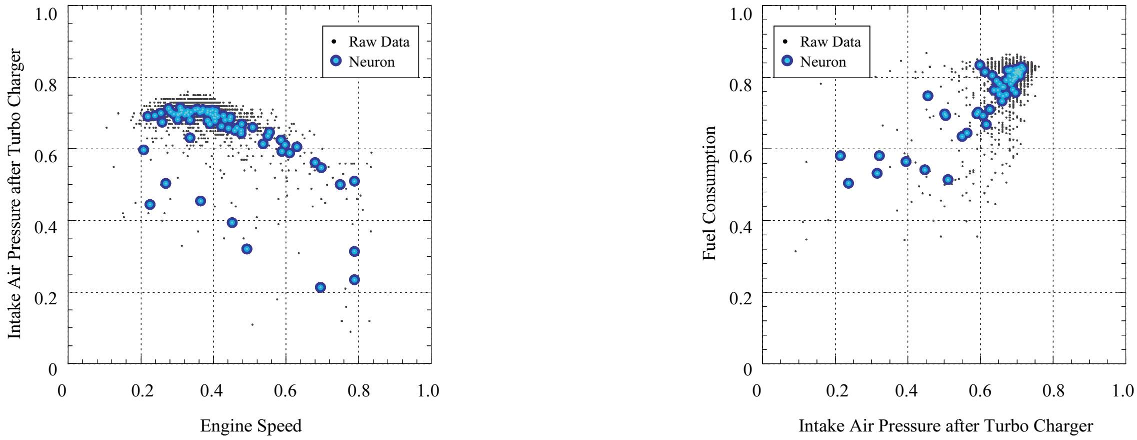

Figure 11. Plots of raw data and neurons in the case of abnormal operation (fault F1).

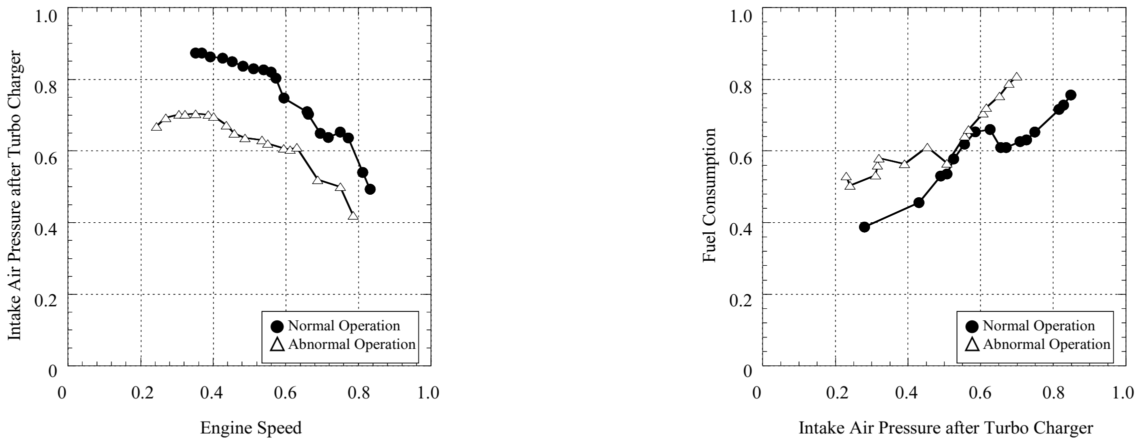

Figure 12. Detection of abnormal operation (fault *F1*) by using the MWA method

Finally, the FIRA method was used for all *6* normal and *7* abnormal operation data in order to create the plots of the *13* generalized operating points (GOPs), shown in the next Fig. 13. The abnormal operations are shown as diamond curve symbols, while the normal operations and denoted by bold circles.

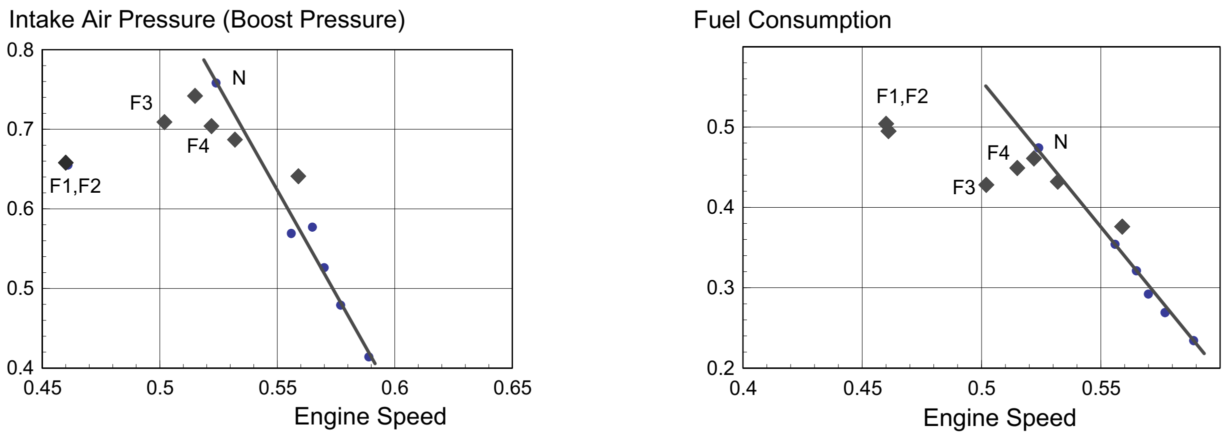

Figure 13. Detection of abnormal operations by using FIRA method, based on *6* normal and *7* faulty operations.

It is easy to notice from Fig. 13. that all *six* normal operations (including the operation denoted by *N*, which corresponds to the data from Fig. 5. and Fig.6.) are characterized by a straight line in the *2*-dimensional parameter space, which means that the working regime (performance) of the machine is not changed. The big distances between some of the operating points GOPs are explained with the *different load,* under which the machine was normally operating on that day.

It is also seen from te above Fig. 13. that most of the faulty operations (including the "strong" faults *F1,F2,F3* and *F4*) stay apart from this "normal operation line". The remaining four faults are considered as "mild" faults, i.e. they are very similar to the normal operation of the machine, because their GOPs are close to the "normal operation line".

6 CONCLUSIONS

The IC-IR technology and system for information compression and information recovery, proposed and analysed in this paper is an efficient tool for processing and dealing with large amount of data taken from the daily operation of the construction machines for the purpose of their performance evaluation, fault detection, diagnosis and maintenance. The real data used from different (normal and faulty) operations of a hydraulic excavator and their successful analysis prove the system applicability. Currently the whole system and the algorithms are under further refinements in order to improve the resolution level of the IC-IR process, as well as to make it more practical for early automatic detection of abnormal and faulty states in machines.

A STATISTICAL ACTIVITY COST ANALYSIS OF THE RELATIONSHIP BETWEEN PHYSICAL AND FINANCIAL ASPECTS OF FIXED ASSETS[1]

A. Colin[†] M. Falta[†2] S. Su[†], L. Turner[‡] R. Willett[†] & R Wolff[‡]

School of Accountancy[†] & School of Economics and Finance[‡] Queensland University of Technology, Brisbane QLD 4001, Australia

Abstract: In this paper, Statistical Activity Cost Analysis (SACA) is used to identify the interaction of mutually dependent physical and financial aspects of a fixed asset-like system configuration. The novelty of the approach is, having established a rational description of the uncertainty inherent in both domains, the analysis of their interaction. Little research to date has investigated the duality of engineering and accounting aspects, in a statistical setting. Our approach is conceptual rather than empirical. We use an illustrative 4-component model, a) to explain the concept of SACA by means of a software demonstration tool, b) to relate financial issues of cost to engineering asset capacity to perform specified tasks, and c) to demonstrate how to produce quantified measures of return and risk, both of which are relevant in areas of life-cycle analysis, budgeting and planning decision-making.

Key Words: Cost Accounting; Maintenance; Reliability; Risk and Risk Attribution; Statistical Activity Cost Analysis (SACA); Uncertainty;

1 INTRODUCTION

The motivation for the research upon which this paper is based is to scientifically model the linkages between economic and physical processes. This is necessary to enable us to relate engineering decisions regarding the management of physical assets to financial consequences in terms of return and risk. It is also necessary to understand how financial decisions effect physical asset capacity to perform specific tasks.

Little research to date has investigated the effects of cost uncertainty and its variation in conjunction with the physical operation of fixed assets. The ability to identify sources of uncertainty which require more attention than others and the quantification of the risk in areas of planning, budgeting or life-cycle analyses facilitate better decision-making. In this paper we advocate that the cost variable in engineering models needs to be a random variable to achieve this goal. Observed costs in invoices or transaction's data give us realisations of this random variable.

In accounting, a rational framework which provides such an interpretation of costs is Statistical Activity Cost Analysis (SACA) due to Willett (1987, 1988, 1991) and extended by Gibbins & Willett (1997) and Falta & Wolff (2004). To date, applications of this framework to aspects of reliability theory, maintenance or life-cycle analysis have been limited (Falta, 2005).

From the perspective of engineering, physical aspects of assets described by concepts of reliability and maintenance are well-understood (e.g., Kumar, Crocker, Knezevic & El-Haram, 2000). However, the literature that considers the uncertainty of cost and physical asset properties *jointly* is more sparse. Most literature in engineering and operations research assumes costs are a directly observable, and in this sense, deterministic attribute of maintenance, production or usage processes. Compare, for example, an optimisation procedure for costs and safety considerations on component systems (Vaurio, 1995), statistical life-cycle cost analyses (e.g., Jiang, Zhang & Ji, 2003; Monga & Zuo, 2001), literature that targets specific assets such as water mains (e.g. Engelhardt, Skipworth, Savic, Saul & Walters, 2000), costs, efficiency and environmental implications of gas pipelines (e.g., Bergerson & Lave, 2005) or railway maintenance (e.g., Lamson, Hastings & Willis, 1983). In the operations research literature, costs of physical aspects of assets have been investigated, for example, in relation to software reliability (Pham, 2003), machine replacement decisions (e.g., Dogramaci & Fraiman, 2004), policy-making for replacement or standby decisions (e.g., Hsieh, 2005).

[2]Corresponding author: m.falta@qut.edu.au

Common to the above literature is the lack of a simple generic model that relates physical characteristics to the uncertainty and variation of corresponding costs that result from dependencies in the physical and financial dimensions of process. Using the principal *representation theorem* of SACA, which explicitly superimposes the financial structure of business processes on the input-output relationships of activities in the physical structure, costs can be modelled as *random sums of random variables*. This lays the basis for a comprehensive analysis of the financial risk involved in engineering processes.

In Section 2 of this paper we employ some fundamental concepts of the SACA framework, based on ideas given in Vaurio (1995), in a system of four components that are in a series constellation. Our focus in this section lies with the demonstration of these theoretical concepts by means of the *SACA Concept Demonstrator*. We conclude in Section 3 with some brief final remarks.

2 THE SACA CONCEPT DEMONSTRATOR

We have developed an illustrative software tool called the SACA Concept Demonstrator in order to better visualise the capabilities of the SACA approach to relate costs to engineering asset capability[3]. Let, for example, an asset have four components functioning in series with their failure characteristics described by exponential time-to-failure distributions with parameters λ_i, i=1,..,4, for each component i. After each maintenance operation on a component with expected cost C_i let the system be as-good-as-new and the MTTF (Mean Time To Failure) be $1/\lambda_i$.

For this simple hierarchical system, the SACA Concept Demonstrator is applied to two scenarios in the first of which we minimise the maintenance costs given an *a priori* minimum reliability level. In the second scenario we maximise the reliability of the system, given a budget.

2.1 Scenario 1: Cost Minimisation with Set System Reliability R_{min}

Assume that maintenance operations on a component i may be carried out at any time and at any frequency f_i. Then the total cost of maintaining the system over a single interval s is

$$C_s = \sum_i \frac{C_i}{f_i} \tag{2.1}$$

We achieve minimum costs C_s, considering for the system reliability $R_s \geq R_{min}$, by optimising f_i in expression (2.1). Using the method of Lagrange multipliers and after some calculus (cf. Appendix A) yields an explicit expression for f_i in terms of λ_i, C_i and R_{min},

$$f_i = -\left(\frac{C_i}{\lambda_i}\right)^{1/2} \cdot \frac{\ln\{R_{\min}\}}{\sum_i (\lambda_i C_i)^{1/2}} \tag{2.2}$$

In Table 1, we have displayed the results from a simulation study with R_{min}=0.97. The overall minimum cost is C_s=\$2187.28 (sum of column (6)). Using Microsoft Excel's Solver function for the same optimisation problem yields for C_s=\$3606, 39% higher than the cost calculated by the present method.

Table 1 Simulation Outputs.

(1) Component	(2) C_i	(3) λ_i	(4) f_i	(5) # Maintenance Operations	(6) Total Costs	(7) Reliability
1	\$10	0.1	0.03732	26.7974	\$267.97	0.9963
2	\$20	0.2	0.03732	26.7974	\$535.95	0.9926
3	\$10	0.4	0.01876	53.5948	\$535.95	0.9926
4	\$20	0.5	0.02360	42.3704	847.41	0.9883

Results from simulation for a four component system in series for given maintenance costs C_i, parameters λ_i and minimum system reliability R_{min}=0.95. Results from using expression (2.2) yield maintenance frequencies f_i, the number of maintenance operations per interval and respective total maintenance costs per component, and the (minimum) component reliabilities.

In the SACA Concept Demonstrator, the expected maintenance cost and its variance, assuming the Normal as the underlying distribution, for each component can be altered and so can the MTTF parameters, assuming exponential reliability

[3]Asset capability is a somewhat general expression and refers to an asset's ability to perform certain tasks. We use the reliability function to describe engineering asset capability, the physical condition of an asset.

functions. In practical applications, both cost parameters can be either estimated from observed data in form of invoices or transaction statements or fitted by theoretical distribution functions. A starting value for the MTTF parameters is usually provided by the manufacturer which, if feasible, can be later adjusted by the operator.

Table 2 SACA Concept Demonstrator Output.

Expected Maintenance Costs [$]	MTTFs [*month*]	Optimal Maintenance Frequency f_i at R_{min}=0.95
20/20/20/20	8/13/6/8	10/8/11/10
20/20/20/20	8/14/6/8	10/7/11/10
20/20/20/20	8/15/6/8	9/7/11/9
26/18/37/20	8/9/6/8	10/11/10/11
26/18/41/20	8/9/6/8	10/11/9/11
26/18/45/20	8/9/6/8	10/12/9/12

Results from variations of parameter settings of expected maintenance costs and MTTFs of single components. The results are displayed in the following form: component 1/component 2/component 3/component 4.

For each setting of expected maintenance costs and MTTFs of the system, the SACA Concept Demonstrator calculates the optimal number of maintenance operations per interval (rounded-up numbers) at minimum costs with a reliability threshold of 0.95. The calculations are performed according to expression (2.2) and the results in the SACA Concept Demonstrator are displayed according to single lines in Table 2. Note that due to the character of expression (2.2), the MTTF of one component is reciprocally correlated with the f_is of every other component but positively with its own f_i. Thus, increasing, for example, λ_2 and maintaining constant expected costs for all components might change f_1, the number of maintenance operations for component 1. Compare Table 2, rows 2 to 4 for this example. Similarly, because the expected maintenance cost C_i of one component is negatively correlated with the expected costs of all other components for constant MTTFs, increasing C_3, for example, may increase f_i, i=1,2,4, with respect to the other components while decreasing f_3, the number of maintenance operations performed on the component itself. Compare Table 2, rows 5 to 7 for this example.

2.2 Scenario 2: Reliability Maximisation with a Set Budget

In the second scenario, we use the same four component system as above, however, with a given fixed budget B. It is now of interest as to how one should allocate the maintenance frequencies in order to derive the highest possible reliability.

Expression (2.1) becomes

$$C_s = \sum_i \frac{C_i}{f_i} - B, \tag{2.3}$$

and we derive the optimal maintenance frequencies according to

$$f_i = -\left(\frac{C_i}{\lambda_i}\right)^{1/2} \cdot \frac{\sum_i (\lambda_i C_i)^{1/2}}{B}. \tag{2.4}$$

Details of the derivation of expression (2.4) are given in Appendix B.

In Table 3, some results from simulation are displayed for a budget of $1500. The maintenance frequencies that give the budget at maximum reliability are derived in the first column of the table. Note that the product of all component reliabilities has decreased to 0.9565.

2.3 The SACA Concept Demonstrator Displays

2.3.1 Reliability vs. Cost

From the above calculations, it is straightforward to plot a curve for the total cost C_s at any level of reliability. This curve is the dark, continuous line displayed in Figure 1. The impact of an increase in expected maintenance costs for single components increases with increased reliability, as would be expected (cf. left and right panel in Figure 1). In the left panel, the expected maintenance cost for components 1 to 4 are $15, $20, $12 and $39, and in the right panel, $26, $20, $19 and $39, respectively.

Table 3 Simulation Outputs.

(1) Optimal Maintenance Frequency f_i	(2) # Maintenance Operations per Interval	(3) Costs	(4) Reliability
0.054415	18.38	$183.77	0.994573
0.054415	18.38	$367.54	0.989176
0.027208	36.75	$367.54	0.989176
0.034415	29.06	$581.14	0.98294

Maintenance frequencies that yield maximum system reliability, given a fixed budget on maintenance.

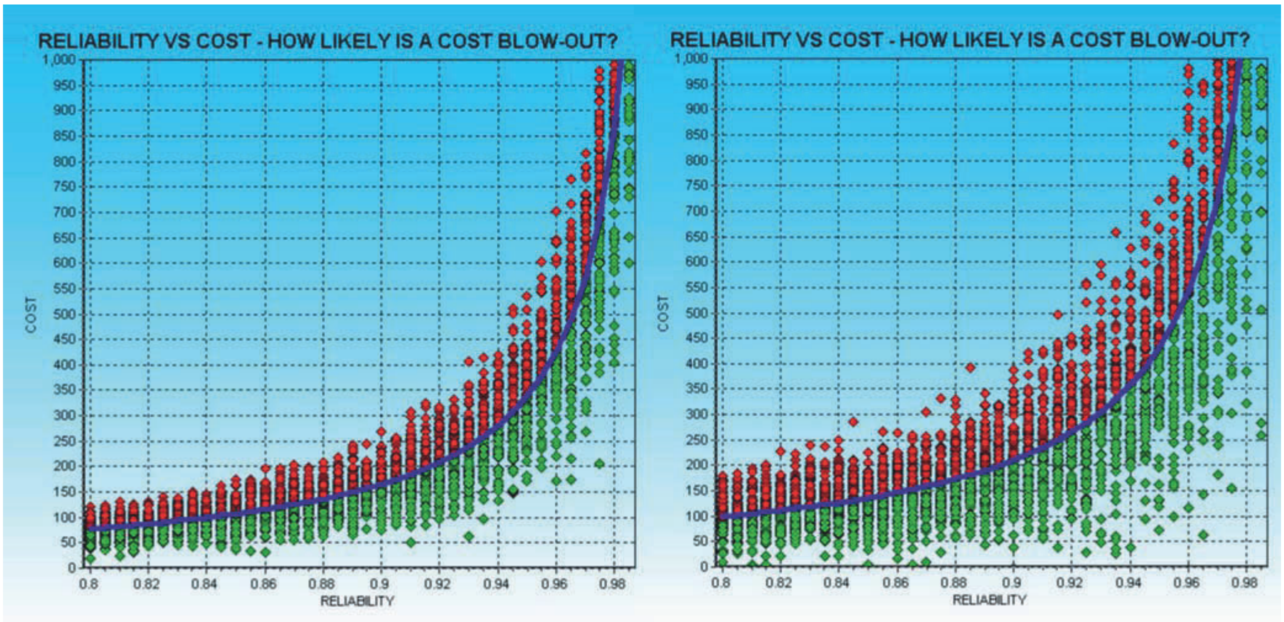

Figure 1: Printed screens from the SACA Concept Demonstrator

Curves for reliability level versus total maintenance costs (dark, continuous line). The scatter around the curve results from the variance of maintenance costs and can be used as an indicator of the risk for cost overruns (above the line) or cost savings (below the line).

The scatter around the reliability versus cost curve derives from the variation in maintenance costs, a parameter that can be varied. In Figure 1, the cost over and underruns are displayed by single dots at each reliability level for a given set of variances of maintenance costs. Notice that the increase in spread in the right plot of the figure, which is due to an increase from $6 to $12 of the variance of maintenance costs of component 1, is rather sensitive. All other parameters remained constant.

In practice, it is usual that the quality of estimates for maintenance and repair costs varies, for some are robust and others more vague. Therefore, visualisation and quantification of the likely cost overruns will be of utmost importance for the decision-maker.

2.3.2 Risk Attribution

The functionality for risk attribution is displayed on the top panel of Figure 2. The pie charts display the percentage contribution of single components to achieve the stated budget at a confidence level of 95% and given reliability.

Top panel: the calculated budget is based on the optimal number of maintenance operations for a given set of simulation parameters. The pie charts display the source of cost uncertainty from each component in order to achieve that budget at a 95% confidence level for a given level of reliability. An increase in the cost variability of component 1 from $6 to $12 increases the necessary budget to guarantee the given reliability at the 0.95 level.

Bottom panel: quarterly upper 95% limits corresponding to the pie charts in the same column above. Numbers that add up to the total number of optimal maintenance operations for each component have been assigned to each quarter according to the simple rule described in the text.

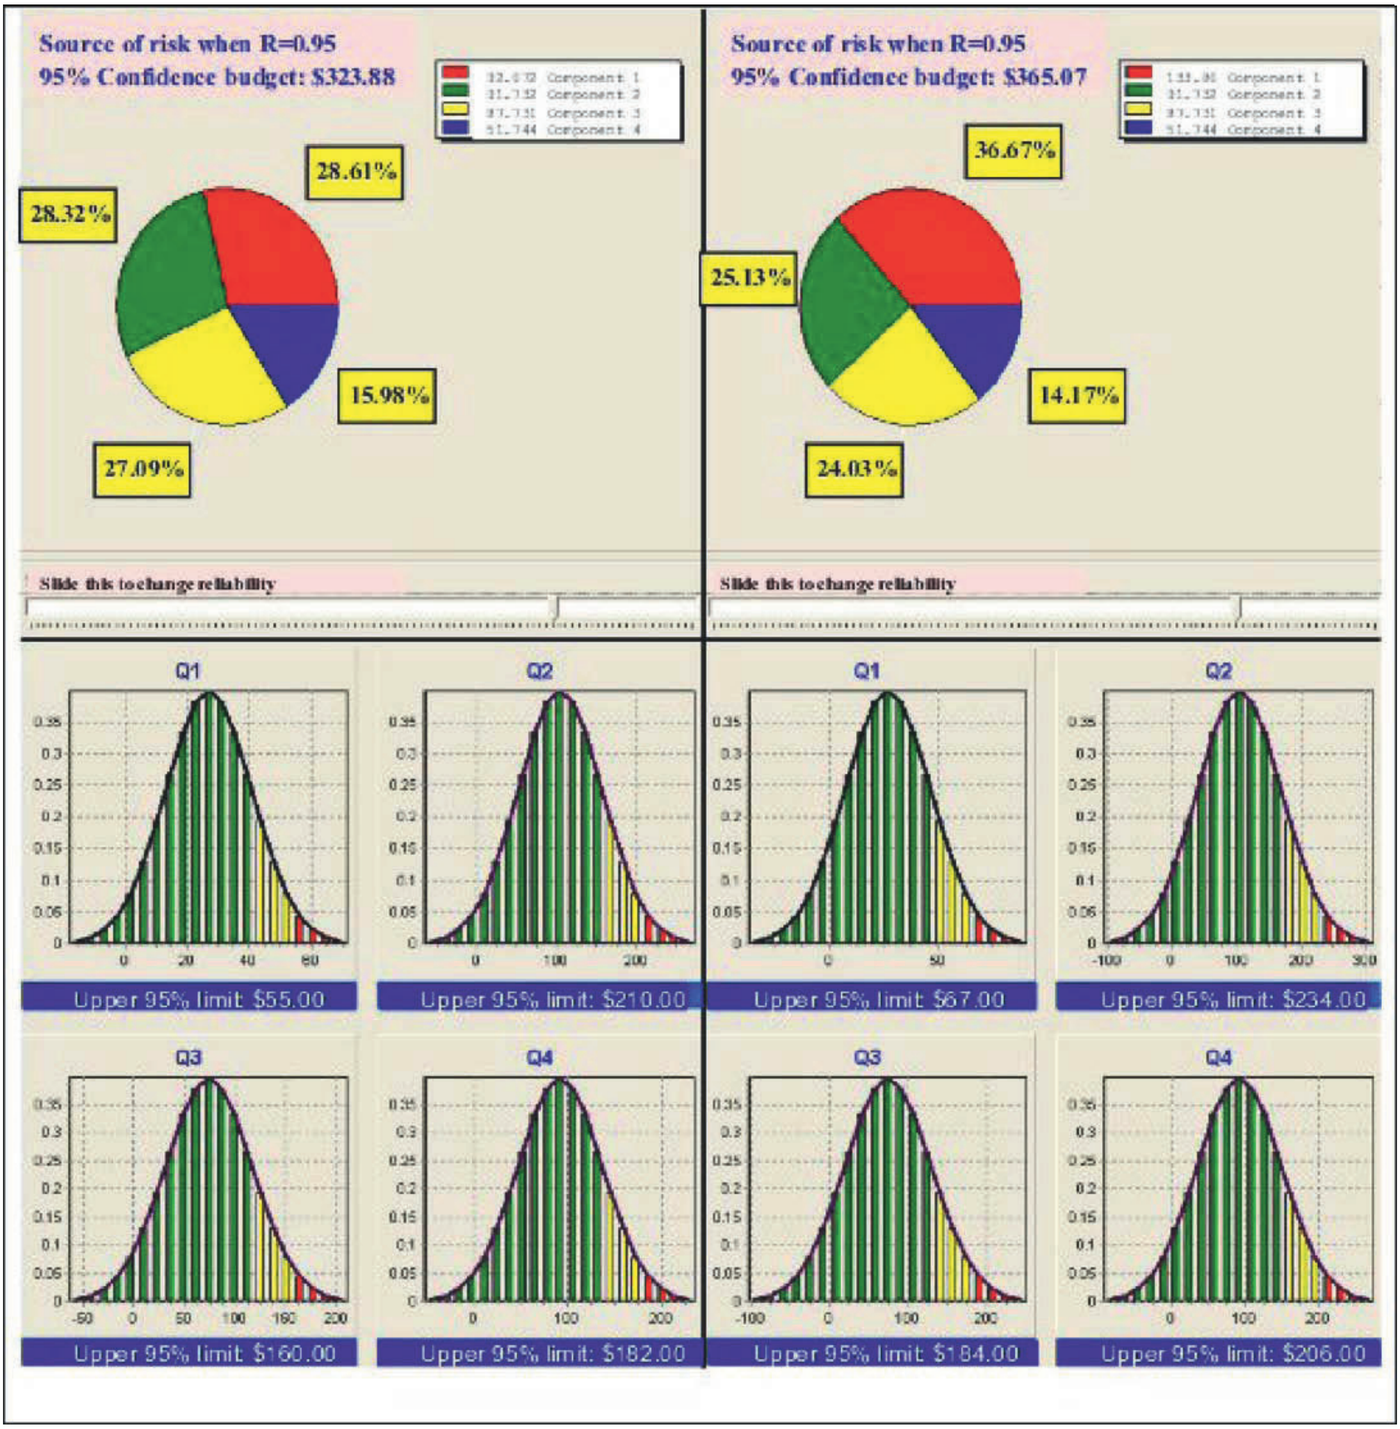

Figure 2 Printed screens from the SACA Concept Demonstrator

Thus, the decision-maker is able to assess the source of risk and quantify it. The parameter settings for the left pie chart are, for components 1 to 4, expected maintenance costs of \$15, \$20, \$12 and \$30; variances of \$6, \$15, \$8, and \$10; MTTF parameters of 8, 21, 12, and 44 months; and calculated numbers of maintenance operations of 7, 4, 7 and 2, respectively. The difference in the pie charts results from an increase (\$6 to \$12) of the variance of maintenance costs of component 1. The increase in variability of this component has not changed the optimal number of maintenance operations. However, the impact on numbers in the pie chart is significant: to guarantee, at a 95% level of confidence, that reliability remains above 0.95, a budget of \$365.07 has to be invested as opposed to \$323.88, as displayed in the left top panel. For this 12.72% increase in the budget necessary to maintain the reliability of the system, all the additional resources are consumed by component 1 (\$290.09 instead of \$200.83) and is accompanied by an increase in uncertainty from 28.61% to 36.67%. The costs of components other than component 1 remain constant with their percentage uncertainty decreasing.

2.3.3 Quarterly Budgets

In the bottom panel of Figure 2, the quarterly upper 95% confidence limits are displayed (dark bars on the right of the light bars) for identical parameter settings as shown in the pie charts. The four graphs on the left bottom panels correspond to the pie chart in the top left panel. The same pattern applies to the right side of the figure. Note the different scaling of the abscissae. The varying numbers for the quarterly risk thresholds result from assigning the given numbers of optimal maintenance operations N_i, i=1,..,4, as follows: the numbers N_i are distributed across the interval (year) at equidistant durations.

This display holds two different pieces of information for the decision-maker. Firstly, for every single period the risk of cost overruns is displayed. In organisations where budget allocations across divisions or projects are a matter of reality, the funds receiving party is able to demonstrate, on a rational basis, the adequateness of any amount allocated. Secondly, the series of amounts at the confidence limit sheds light into the time series of maintenance costs. Actual maintenance costs correct the estimates for passed time intervals and update the estimates for future time intervals. The latter point, including to account for other time intervals than quarterly periods, leads to the world of time series and financial option analysis, which we leave for future research.

2.4 Comments on the SACA Concept Demonstrator

We have demonstrated how the SACA framework can be applied to the financial assessment of a physical system and, in particular, how the cost variations can be expressed by statistical distributions. We have furthermore demonstrated how the results can be used by the decision-maker for maintenance scheduling and budget planning.

The underlying model can be extended in various directions. Below we have listed and elaborated on some of these.

1. The assumption that maintenance may be carried out at any time and at any frequency is a limitation when considering practical applications. Usually there are scheduled maintenance windows or maintenance opportunities at discrete time intervals of set durations. It is a matter of choice whether these constraints should drive the simulation, or whether the results of such simulations should be used to modify the time and frequency of operations.
2. Greater detail in the analysis of the cost-reliability relationship can be achieved by allowing for the general *k*-out-of-*n* parallel and series systems. Our choice to consider exponential time-to-failure distributions is based on the following. The illustrative 4-component model can be viewed as a reduced representation of a more complex reliability block diagram. It is usually the case that the larger the number of components and actors in an entity the larger the number of failure modes, and as a consequence the more random and unpredictable the times of failure. The exponential time-to-failure distribution models this type of situation because it implies a Poisson distribution for the number of failures during equal time intervals. For empirical evidence we refer to, for example, Davis (1952) who concluded that "the exponential theory of failure appears to describe most of the systems examined [in the article]". Any other time-to-failure distribution such as the Weibull distribution, a popular choice among engineering practitioners, may be chosen if it is appropriate to do so. A further remark on this topic is given in Point 5.
3. The lower bound used on reliability levels in the model assumes that all components are functioning at their lowest reliability, even if a maintenance operation has just been performed. A time-dependent reliability function can describe a more refined physical description of the system.
4. The resulting cost *vs.* reliability curve displayed in Figure 1 is continuous and represents the expected costs. This curve can be seen as the effective frontier, a concept used in portfolio analyses, as arbitrarily higher amounts of dollar may be spent on the maintenance of a component without improving the total system reliability, at any level. This optimisation problem is being currently investigated employing a genetic algorithm and is in preparation to accompany the current paper.
5. For other distributions that describe the component reliability, particularly those with more complex forms such as those with a bath-tub shape, numerical simulations might be the first choice for parameter estimates.

3 FINAL REMARKS

We have used a simple four component system in order to demonstrate new concepts in the field of accountancy. Invoices of maintenance operations are modelled using statistical distributions, which describe the uncertainty of varying costs incurred by businesses. For some of the components expected costs can be determined quite accurately from prior experience, others have to be estimated from observed data. The variation resulting from the former suppositions and latter estimates contributes to the overall risk of budget overruns. With the SACA Concept Demonstrator, a simple module with a graphical user interface, implements the methods described in the paper. In doing this and in further developments, we intend to bridge the fields of accountancy (finance), reliability theory (physical) and maintenance (policy) to improve fixed asset management.

Of the limitations in the model, of most immediate concern to us are the need to extend the physical model to *k*-out-of-*n* parallel redundant systems and to use observed data, which necessitates the use of reliability distributions that describe actual component behaviour.

This paper illustrates the applicability of the SACA framework to an assessment of the return and risk linkages between decisions regarding physical asset properties and financial outcomes, *and* between financial decisions and physical outcomes. The framework can be applied to any asset and typically requires information to be extracted from both accounting and physical asset management systems. At the present time this approach to modelling is being applied to assets of the Royal Australian Navy as part of the Logistics Cost of Ownership initiative of the Australian DMO (Defence Materiel Organisation). It is also being applied in the Australian food processing and utilities industry.

Appendix A

For a series system, consider constraint

$$R_{\min} \le R_s = \prod_i R_i = \prod_i \exp(-\lambda_i T_i). \tag{A1}$$

Since $T_i \ge 1/f_i$ a lower bound on each component's reliability is given by $R_i \ge \exp(-\lambda_i f_i)$ and expression (A1) is violated if

$$R_{\min} > \prod_i \exp(-\lambda_i f_i) \tag{A2}$$

implying that

$$\ln\{R_{\min}\} > -\sum_i (\lambda_i f_i). \tag{A3}$$

Note that expression (A3) is unnecessarily strong since it assumes that the lowest component reliabilities will always hold.

Expressions (2.1) and (A3) together form a constrained optimisation system which we solve using Lagrangian multipliers. Thus, combining constraint and target expressions respectively as

$$f_c(f_i) = \sum_i \lambda_i f_i + \ln\{R_{\min}\} = 0 \tag{A4}$$

$$f_t(f_i) = \sum_i \frac{C_i}{f_i}, \tag{A5}$$

so that

$$\frac{\partial f_c}{\partial f_i} = \lambda_i \quad \text{and} \quad \frac{\partial f_t}{\partial f_i} = -\frac{C_i}{f_i^2}. \tag{A6}$$

The solution to

$$\frac{\partial f_t}{\partial f_i} + \hat{L}\frac{\partial f_c}{\partial f_i} = 0 \tag{A7}$$

is an extremum of the function f_t subject to the constraint $f_c = 0$, where $\hat{L}$ is a Lagrange multiplier. We can therefore reformulate this problem by writing

$$\frac{C_i}{f_i^2} = \hat{L}\lambda_i. \tag{A8}$$

The system of equations in *n+1* unknowns represented by expressions (A4) and (A8) is solved by substituting the implied expression for f_i in (A8) back into (A4) yielding

$$\sum_i f_i \left(\frac{\lambda_i C_i}{\hat{L}}\right)^{1/2} + \ln\{R_{\min}\} = 0 \tag{A9}$$

which gives

$$\hat{L} = \left(\frac{\sum_i \lambda_i C_i}{-\ln\{R_{\min}\}}\right)^2. \tag{A10}$$

Substituting the last expression into (A8) yields expression (2.2) of Section 2.1.

Appendix B

Similar to expressions (A4) and (A5) we have functional forms for constraint and target, respectively,

$$f_c(f_i) = \sum_i \frac{C_i}{f_i} - B = 0 \quad \text{and} \quad f_t(f_i) = \sum_i \lambda_i C_i. \tag{B1}$$

Thus,
$$\frac{\partial f_t}{\partial f_i} = \lambda_i \quad \text{and} \quad \frac{\partial f_c}{\partial f_i} = -\frac{C_i}{f_i^2}. \tag{B2}$$

and we solve the expression

$$\lambda_i = \hat{L}\frac{C_i}{f_i^2} \tag{B3}$$

which, substituting for f_i back into the first equation of expression (B1) yields

$$B = \sum_i \left(\frac{\lambda_i C_i}{\hat{L}}\right)^{1/2}. \tag{B4}$$

Substituting the resulting value of $\hat{L}$ into expression (B3) yields expression 2.4 of Section 2.2.

Abstract: A Bell 206B main rotor gearbox was run at high load under test conditions in the Helicopter Transmission Test Facility operated by the Defence Science and Technology Organisation (DSTO) of Australia. The test succeeded in initiating and propagating pitting damage in one of the planet gear support bearings. Vibration acceleration signals were recorded periodically for the duration of the test. The time domain vibration signals were converted to angular domain to minimise the effects of speed variations. Auto-Regressive Moving-Average (ARMA) models were fitted to the vibration data and a change detection problem was formulated in terms of the Generalised Likelihood Ratio (GLR) algorithm. Two different forms of the GLR algorithm in window-limited online form were applied. Both methods succeeded in detecting a change in the vibration signals towards the end of the test. A companion paper submitted by the University of New South Wales outlines the corresponding diagnosis and prognosis algorithms applied to the vibration data.

Key Words: Generalized Likelihood Ratio, GLR, ARMA, Fault Detection, Bearing Fault, Epicyclic Gear Train, Vibration Analysis

1 INTRODUCTION

The vibration characteristics of epicyclic gear trains are more complex than fixed axis gears because the transmission path varies with the rotation of the planet carrier. Since epicyclic gear trains are common in helicopter transmission systems, it is important that suitable data sets be available for testing vibration based fault detection and diagnosis algorithms for helicopter transmission systems. The Helicopter Transmission Test Facility (HTTF) located at the Defence Science and Technology Organisation of Australia is a state of the art facility capable of testing a number of different helicopter transmissions systems at high loads under controlled conditions.

The HTTF was used to create vibration test data corresponding to the generation and propagation of a bearing fault in a Bell 206B-1 helicopter main rotor gearbox. In the first part of this paper, Section 2, the test procedure and outcome of the test is described in detail.

The remainder of the paper is devoted to the application of Generalised Likelihood Ratio (GLR) based fault detection algorithms to the vibration data obtained from the test. Before proceeding it is worthwhile introducing the various notations used throughout the paper. As sequences occur often, a compact subscript notation is used. The notation $y_{(j:k)}$ is used to represent the sequence $y_j, y_{j+1}, \ldots, y_k$ when $k>j$, and $y_j, y_{j-1}, \ldots, y_k$ when $k<j$. The convention of using uppercase letters for random variables and lowercase letters for the values of random variables is also adopted here. The symbol $\mathbb{R}$ is used to denote the set of Real numbers.

The general model used in statistical change detection is a (chronological) sequence of random variables or vectors, $\{Y_k\}$, $k=0,1,2,\ldots$, with known parametrised conditional density $p_\theta(y_k|y_{(k-1:1)})$. The parameter, θ, is constant (or nearly so) and equal to θ_0 before some unknown change time t_0 (i.e. for all $k<t_0$). At the change time, θ changes abruptly to a new value θ_1 where it remains for all time $k>t_0$. A typical change detection algorithm comprises a suitable test statistic, S_k, a decision function, g_k, which usually converts the test statistic into a form in which a suitable alarm threshold can be established, and an alarm time, t_a, to indicate when the decision function exceeds the chosen threshold.

As the problem formulation in statistical change detection is very general, the scope for applications is wide. Example applications include gain updating in adaptive tracking algorithms, signal segmentation for tasks such as speech recognition, and quality control (which includes fault detection). A comprehensive introduction to statistical change detection theory and applications can be found in the book [1].

The GLR is a powerful test statistic for use in change detection algorithms, however a well known problem with the online application of the GLR algorithm is that the number of operations to perform at each time step, k, grows with k to infinity. This difficulty comes about because the Likelihood ratio cannot be computed recursively. By restricting the algorithm to a data window of fixed size, the computational burden can be reduced to a manageable level, but the resulting *window-limited* algorithm becomes sub-optimal. This idea was first investigated in [2], in the context of detecting additive changes in linear state space systems.

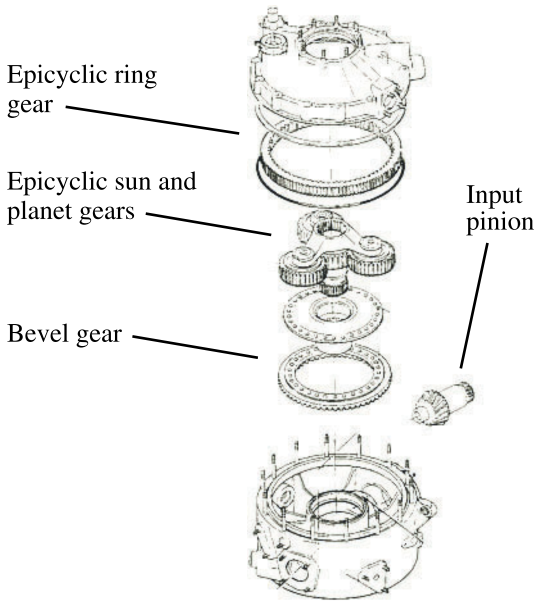

Figure 1: Major components of the Bell 206B main rotor gearbox.

It was shown in [3] that the performance of the window-limited GLR algorithm depends critically on the choice of window parameters, even in the simple case of detecting additive changes in white noise. The choice of window parameters also affects the choice of decision threshold which further complicates the issue. A number of authors [4, 5, 6] have addressed the issue of finding optimal window parameters for the case of additive changes in linear systems, however we are concerned here with the more difficult problem of detecting spectral (non-additive) changes in a signal, and in particular to spectral changes in an ARMA model.

In [3], a novel decision function for the window-limited GLR algorithm is introduced which is shown through simulations to be more robust against sub-optimal choices of window parameters. In the second part of this paper we compare the performance of the window-limited GLR algorithm with the new decision function to that of the window-limited GLR algorithm using the conventional decision function. In Section 3 the change detection problem is formulated in terms of the GLR algorithm, and in Section 4 the results are presented and discussed in detail.

2 TEST DESCRIPTION AND OUTCOME

The Bell 206B-1 main rotor gearbox, shown in Figure 1, comprises an input bevel and pinion, driven by the engine, and a single stage epicyclic reduction unit. The main rotor is driven through the planet carrier. There exist both three and four planet variants for the Bell 206 gearbox. The three planet variant was used for this test. Accelerometers were mounted on the gearbox casing in the vicinity of the pinion and bevel gear mesh and in the vicinity of the epicyclic ring gear. The input shaft also contained a tachometer producing one pulse per revolution of the input shaft. The tachometer signal was used to convert the vibration signals from time domain to angular domain.

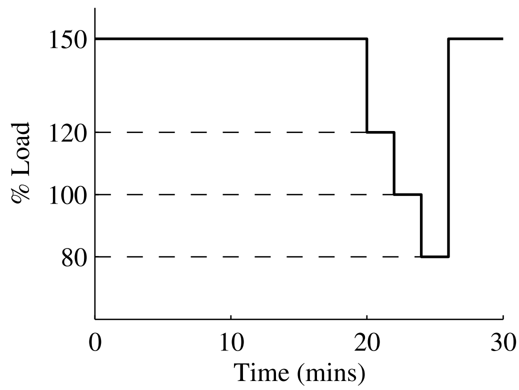

Figure 2: Gearbox load regime repeated throughout the test.

The aim of the test was to initiate and propagate a non-seeded fault in the gearbox. In order to achieve the aim in a reasonable amount of time, the gearbox was run at 150 percent of it's rated operating load, with periodic reductions in load to facilitate the recording of vibration signals. Figure 2 shows the load regime that was repeated every thirty minutes throughout the test.

The planet support bearing contains two rows of convex rollers and an outer race which is integral with the planet gear. The bearing sustained fatigue spalling and subsequent pitting damage to the inner race, outer race, and rolling elements. The majority of damage occurred to the inner race. This can be explained in part by the fact that the inner race does not rotate as the carrier rotates, therefore the load is concentrated in the same part of the inner race rather than being distributed around the whole inner race over time. Figure 3 shows the inner race of the planet bearing in which the pitting damage can be seen clearly in both the upper and lower tracks, with the majority of damage to the lower track.

3 PROBLEM FORMULATION

The vibration data from the test are modelled using Gaussian ARMA models. For positive integers p and q, the output of a scalar ARMA(p, q) process satisfies:

$$y_k = \sum_{i=1}^{p} a_i y_{k-1} - \sum_{j=1}^{q} b_j e_{k-j} + e_k \quad (1)$$

where y_k, a_i, b_j are real numbers. The *innovations*, $\{e_k\}$, are generated by a sequence of independent identically distributed (i.i.d) random variables with known density function. An important variable related to the innovations is the residual. The *residual* sequence of the ARMA process is defined by:

Figure 3: Inner race of the planet gear support bearing.

$$\varepsilon_k = y_k - \sum_{i=1}^{p} a_i y_{k-i} - \sum_{j=1}^{q} b_j \varepsilon_{k-j} \quad .(2)$$

For zero mean Gaussian distributed innovations, the conditional density for the ARMA process (1) is known to be:

$$p_\theta(y_k \mid y_{(k-1:1)}) = \frac{1}{\sigma\sqrt{2\pi}} \exp(-\varepsilon_k^2 / 2\sigma^2), \qquad \theta = (a_1, \ldots, a_p, b_1, \ldots, b_q, \sigma)^T, \qquad (3)$$

where σ^2 is the variance of the innovations, and θ is the change detection parameter.

A number of standard tests can be formulated for the ARMA process depending on the nature of the change expected. A different change detection algorithm exists for each test. To determine the correct test for this problem, an exploration of the behaviour of the parameter before and after the test is required.

Firstly, the magnitudes and phases of the frequency components of the gearbox vibration will be affected by the input and output loads applied to the gearbox, and on the operating temperature of the gearbox. In particular, changes in the gearbox casing temperature can cause changes in the casing response to excitations. The effects of load variation are minimised during the test by running the gearbox under constant load, and the effects of temperature variations are minimised by using only the vibration data recorded with the gearbox operating temperature within a fairly narrow range. Although these effects are minimal, they are not eliminated completely, therefore the parameter θ will have some variation with respect to time, caused by these variations both before and after the change time.

Before the change time, i.e. before the bearing fault is initiated, θ will be expected to remain approximately constant. But after the change time, as the test progresses, the condition of the bearing will deteriorate, therefore it is expected that θ will not be constant after the change. Furthermore the majority of the bearing damage occurs on the inner race, which does not rotate with respect to the planet carrier, therefore this damaged section remains in the load zone continuously. Thus the following reasonable assumptions are made concerning the formulation of the problem.

A1 There exists a (change) time, t_0, and a disjoint partition, Θ_0 and Θ_1, of $\mathbb{R}^{p+q+1}$ such that:

1. $\theta \in \Theta_0$ for all time $k < t_0$.
2. $\theta \in \Theta_1$ for all time $k \geq t_0$.

A2 The region Θ_0 is bounded and not too large.

Assumption A2 captures the idea that θ will remain approximately constant before the change. The notion of "not too large" shall be quantified later on in the development. Note that after the change time, the behaviour of the parameter is expected to change with time as the bearing deteriorates. This is in contrast to the assumptions used in the theoretical development of change detection algorithms, i.e. that the parameter be constant (or nearly so) before and after the change time. However, given that the behaviour of the parameter before the change is expected to be approximately constant (Assumption A2), and provided that Assumption A1 holds also, then the performance of the change detection algorithm will remain nearly optimal.

At this stage, we can say a little more about the regions Θ_0 and Θ_1. Given the nature of the bearing dynamics, it is most likely that the bearing fault will result in spectral changes in the vibration signature. Thus the change detection problem will be formulated as detecting a change in the $\{a_i\}$ and $\{b_j\}$ components of the Gaussian ARMA parameter, θ, subject to Assumptions A1 and A2.

3.1 The GLR Algorithms

The first algorithm, Algorithm 1, is the conventional window-limited GLR algorithm. For the problem statement consistent with Assumptions A1 and A2, the algorithm is given by:

$$\begin{aligned} t_a &= \min\{k : g(k) > h\} \\ g(k) &= \max\{S_j^k : k - n_1 \leq j \leq k - n_2\} \\ S_j^k &= \ln \frac{\sup_{\theta \in \Theta_1} \prod_{i=j}^{k} p_\theta(y_i | y_{(i-1:1)})}{\sup_{\theta \in \Theta_0} \prod_{i=j}^{k} p_\theta(y_i | y_{(i-1:1)})} \end{aligned} \tag{4}$$

where n_1 and n_2 are the window parameters, t_a is the alarm time indicating when the decision function, $g(k)$, exceeds the threshold parameter h, and $p_\theta(y_1|y_0) = p_\theta(y_1)$.

The second algorithm, Algorithm 2, differs from the first only in the decision function [3, (6.17)]:

$$g(k) = \max\{(g(k-1) + \bar{s}_k), 0\}, \qquad \bar{s}_k = \max\left\{\tfrac{1}{k-j+1} S_j^k : k - n_2 \leq j \leq k - n_1\right\}. \tag{5}$$

The log-Likelihood, S_j^k, requires an optimisation to be performed for each computation. It was shown in [3] that the local approach outlined in [1] could be used to obtain a local approximation to S_j^k which does not require any optimisations to be performed. The key components of the development are reproduced here.

Let $\theta_0 \in \Theta_0$ be the central, or average, value of θ before the change time. Let $\mathbf{I}(\theta_0)$ be the Fisher Information matrix, which for a Gaussian ARMA process can be written in block matrix form

$$\mathbf{I}(\theta_0) = \begin{pmatrix} \frac{1}{\sigma^2}\check{\mathbf{I}}(\theta_0) & 0 \\ 0 & \frac{2}{\sigma^2} \end{pmatrix}. \tag{6}$$

An algorithm for computing the exact Fisher Information matrix for an ARMA process is given in [7], which can be used to compute the elements of $\check{\mathbf{I}}(\theta_0)$. Introduce the variables:

$$\alpha_{k-i} = -\frac{\partial \varepsilon_k}{\partial a_i}, \quad \beta_{k-i} = -\frac{\partial \varepsilon_k}{\partial b_i}, \quad \check{\mathbf{z}}_j^k(\theta_0) = \begin{pmatrix} \sum_{i=j}^{k} \frac{1}{\sigma^2} \check{\mathcal{A}}_{i-p}^{i-1} \varepsilon_i \\ \sum_{i=j}^{k} \frac{1}{\sigma^2} \check{\mathcal{B}}_{i-q}^{i-1} \varepsilon_i \end{pmatrix} \tag{7}$$

in which $\check{\mathcal{A}}_{i-p}^{i-1}$ and $\check{\mathcal{B}}_{i-q}^{i-1}$ are, respectively, vectors of α_k and β_k ordered backwards. Note that α_k and β_k are the outputs of AR models with the same AR coefficients:

$$\alpha_k = -\sum_{j=1}^{q} b_j \alpha_{k-j} + y_k, \qquad \beta_k = -\sum_{j=1}^{q} b_j \beta_{k-j} + \varepsilon_k. \tag{8}$$

The final variable, χ_j^k, comes about through a change of basis using the Kullback divergence as a metric. For a Gaussian ARMA process it is given by [1, §8.3.3]:

$$(\chi_j^k)^2 = \frac{1}{(k-j+1)^2}\left\{\sigma^2 \check{\mathbf{z}}_j^k(\theta_0)^T \check{\mathbf{I}}^{-1}(\theta_0) \check{\mathbf{z}}_j^k(\theta_0) + \frac{1}{2}\left[\sum_{i=j}^{k}\left(\frac{\varepsilon_i^2}{\sigma^2} - 1\right)\right]^2\right\}. \tag{9}$$

The equation for the log-Likelihood obtained using the local approach is [3, (6.47)]:

$$\frac{2}{k-j+1} S_j^k = \begin{cases} -(\chi_j^k - b)^2 & \text{for } \chi_j^k \leq a \\ -(\chi_j^k - b)^2 + (\chi_j^k - a) & \text{for } a < \chi_j^k < b \\ +(\chi_j^k - a)^2 & \text{for } \chi_j^k \geq b \end{cases} \tag{10}$$

where $a, b \in \mathbb{R}$ are the Kullback divergence parameters which quantify the regions Θ_1 and Θ_2 under the change of variable to χ_j^k. Note that a region of indecision is introduced, $a < \chi_j^k < b$, due to the local approximation.

4 RESULTS AND DISCUSSION

The data used in the application were taken from recordings with the gearbox operating at 100 percent of it's rated load. The first two data sets obtained from the test were used to fit ARMA models to the data. Using standard techniques of system identification [8], a Gaussian ARMA(13,1) model was found which approximated the pinion accelerometer data well. Similarly, a Gaussian ARMA(14,2) model was found for the ring gear accelerometer data.

The window parameters, n_1, n_2, were chosen based on the geometry of the gearbox. For simplicity n_1 and n_2 were set to the same value, n_1=n_2=n, and n was set to n=9000, which corresponds to approximately one rotation of the planet carrier. The Kullback divergence parameters, a, b, for the GLR algorithms were estimated using the first four data sets from the test. Specifically, χ_{k-n}^{k} was computed for 9000 points in each of the first four data sets, i.e. by sliding the data window across 9000 points in each data set. The parameter a was set to the maximum value of χ_{k-n}^{k} computed, and the parameter b was set to $a+0.25\sigma_{\chi}$, where σ_{χ}^{2} is the variance of χ_{k-n}^{k} computed on the first four data sets. The values of a and b obtained for the two accelerometers and two GLR algorithms are shown in Table 1.

Table 1.

Estimated Kullback parameters for the GLR algorithms.

	Pinion accelerometer		Ring gear accelerometer	
	Algorithm 1	Algorithm 2	Algorithm 1	Algorithm 2
a	1.4579	1.4961	1.2144	1.3187
b	1.4760	1.5151	1.2254	1.3379

The decision functions for Algorithm 1 are shown in Figure 4. The use of a finite window of past data means that the log-Likelihood, and hence the decision function for Algorithm 1, will have an negative expected value before the change and a positive expected value after the change. As can be seen in the plot of the decision function for the ring gear accelerometer, there is a change from negative values to positive average values occurring at approximately 145 test hours. This indicates that the algorithm is detecting the fault in the gearbox. There is no change to the negative values of the decision function for the pinion gear accelerometer. This indicates that the fault is not detected in this signal, which was to be expected since the pinion accelerometer is dominated by the pinion-bevel gear mesh which is unaffected by the condition of the planet gear bearing.

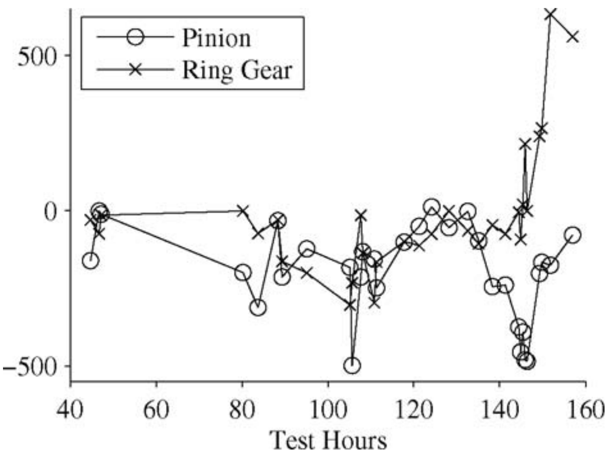

Figure 4: Algorithm 1: Window-limited GLR algorithm with conventional decision function.

The decision functions for Algorithm 2 are shown in Figure 5. The decision function in Algorithm 2 should be zero before a change and have a positive trend after a change. As can be seen in Figure 5, the decision function for the ring gear accelerometer detects a change at about 145 hours into the test, whereas no change is detected in the pinion accelerometer signal.

As mentioned in the introduction, the general formulation of the statistical change detection problem lends itself to a wide range of applications. Within a particular field of application there may be many different ways of implementing change detection algorithms. In the application given here for example, only minimal pre-processing of the raw data is done prior to implementing the change detection algorithm. The advantage of this approach is that the statistical change detection algorithm is being fully utilised to detect a wide range of changes in the signal, i.e. a wide range of faults. The disadvantage of the approach is the delay for detection. Both algorithms did not detect the change until the damage in the bearing had spread considerably. The danger here is in the possibility of a component failing before the algorithm responds.

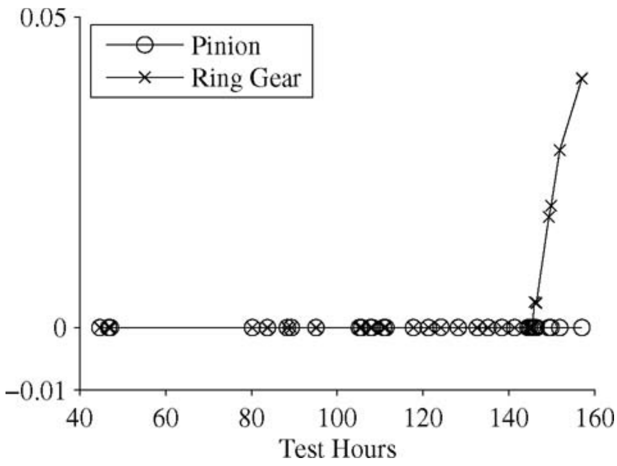

Figure 5: Algorithm 2: Window-limited GLR algorithm with modified decision function.

There are well known difficulties in detecting bearing faults. The vibration components from the (healthy) gears dominate the vibration signal masking the more subtle changes introduced by bearing faults. The level of difficulty increases further for planet gear bearings, where the motion of the bearing with respect to the transducer located on the casing introduces further modulation of the signal. Many of the current diagnostic algorithms for both gear and bearing faults rely on more complex pre-processing of the data to increase the signal to noise ratio for particular types of faults. For example, the dominant rotationally coherent gear meshing components can be filtered out using linear filters thereby increasing the signal to noise ratio of the bearing fault signature.

The general problem formulation in statistical change detection makes it easy to incorporate any amount of pre-processing prior to implementing the change detection algorithm, however there are disadvantages as well as advantages to be gained by using more complex pre-processing. For example, modelling specific fault types often leads to pre-processing algorithms which filter the data to enhance that part of the signal which the model predicts will be more sensitive to changes in the presence of that particular fault. This form of pre-processing can greatly restrict the range of detectable fault types.

IMPROVING THE INFORMATION GOVERNANCE OF PUBLIC UTILITIES THROUGH AN ORGANIZATIONAL KNOWLEDGE BASE

Stefano Gianella [a] and Willi Gujer [a]

[a] *Swiss Federal Institute for Environmental Science and Technology (EAWAG), and Swiss Federal Institute of Technology (ETH), Ueberlandstrasse 133, CH-8600 Dübendorf, Switzerland.*

Abstract: To develop and implement Information Governance (IG) in a public utility is a challenging task. While many studies focus on the "what" question of IG, less attention is paid to how IG may be realized within the utilities. However, well-organized IG is essential to guarantee effective management of information resources. We argue that IG is a complex and knowledge-intensive process. The ability to manage critical knowledge and to systematically support IG knowledge work are presented as key issues for public utilities. Most of their critical organizational knowledge is currently fragmented, not explicitly documented and difficult to share. We formulate requirements for designing IG for public utilities from a knowledge perspective. On the basis of three case studies of Swiss wastewater utilities, we present an approach for supporting IG via an Organizational Knowledge Base (OKB). We provide a framework for representing critical organizational knowledge for IG in an OKB, illustrate how an OKB supports knowledge work and explain why it guides public utilities towards more effective management of their information resources.

Key Words: Information Governance, Knowledge Management, Organizational Knowledge Base

1 INTRODUCTION

In today's increasingly competitive and cost-conscious operating environment, public utilities recognize the need to treat information as a valuable strategic asset. A large proportion of the administrative budget is typically spent on information-handling activities, e.g. for coordinating activities or for enabling data-intensive planning and design activities. Information is needed at all levels of a utility to support business functions and assist in attaining business aims and objectives. Making information available to the right worker at the right time and in the right place is vital for managing large and complex infrastructure systems.

In order to leverage the potential of information, public utilities have to configure their resources and capabilities to develop, exploit and maintain their information assets. This process is known as Information Governance (IG). IG is defined as a structure of relationships and activities designed to direct and control the information assets and the technology that supports them [1]. It establishes a framework of policies, procedures, standards and guidelines designed to ensure that the value of information assets is identified and exploited to the fullest extent.

The development and implementation of effective IG strategies and processes have been treated extensively in the literature over the past decade. Recent works have pointed out the importance not only of the "what" question of IG (e.g. improving links between information systems strategy and business strategy), but also of the "how" question, which includes the IG process and whether it yields effective outcomes [2]. Other researchers have pointed out that the process of formulating and implementing an IG strategy must be considered as a learning process for the organization that implements it [3].

This paper argues that IG is a knowledge-intensive and complex process for public utilities. The ability to manage critical knowledge for the IG process and to systematically support its knowledge work are presented as key issues for designing IG in public utilities. Although knowledge management has now gained wider acceptance, few utilities today are fully capable of developing and leveraging critical organizational knowledge to support their business functions. Many utilities are so complex that this knowledge is fragmented, difficult to locate and share, and therefore redundant, inconsistent, or not used at all. A dedicated method that explicitly considers knowledge management issues is proposed to support public utilities in designing their IG process. The paper presents design requirements for IG. It focuses on three case studies in public wastewater utilities. The findings from these studies are used to outline the proposed methodology.

2 A KNOWLEDGE PERSPECTIVE ON INFORMATION GOVERNANCE

2.1 IG as a complex and knowledge-intensive process

Complex and knowledge-intensive processes can be distinguished from other processes by a set of specific attributes and inherent problems. Several attributes for describing process complexity and knowledge intensity have been proposed by Eppler et al. [4]. The following inherent properties of the IG process can be highlighted on the basis of this proposal:

- Utilities often have no formal procedures designed to carry out the IG process, preferring to adopt ad-hoc approaches without clearly outlined activities. The outcome of IG then depends substantially on the people involved, and the internally available skills and capabilities of individuals as well as the knowledge and experience of external advisors play a major role. As a rule, it requires a lot of time to acquire such skills and capabilities. Because of today's fast-changing business environment and technological developments, knowledge soon becomes obsolete.
- IG is a process that consists of numerous activities involving many internal and external persons. Many interactions and communication schemes must be guaranteed in the context of problem-solving. Coordination mechanisms are generally complex and require time and effort. The required activities are highly interdependent and must consider the dynamic of environmental factors (such as policies for data standards).

Because of these particular characteristics, specific issues must be considered in the design of the IG process. These are intrinsically tied to the way critical knowledge for the IG process is gathered and assimilated both at individual level and at the collective level of a public utility. In the next section, we focus on two specific issues that we found to be decisive.

2.2 Key design issues for the IG process

As a complex and knowledge-intensive process, IG relies heavily on the experience and know-how of the people involved. Two critical issues thus have to be considered when designing the IG process within a public utility:

- *Which* knowledge is crucial for the success of IG and *how* can it be captured, managed and systematically exploited?
- *Which* knowledge activities are necessary for IG and *how* can they be supported?

2.2.1 Issue 1: Process knowledge of IG

Several models have been developed to describe the knowledge related to processes. Some examples can be found in Eppler et al. [4], Kwan et al. [5] and Stein et al. [6]. On the basis of these works, we define three types of knowledge that are appropriate for describing the critical knowledge relating to the IG process:

- **Knowledge about the IG process**: This first type of process knowledge encompasses all the skills necessary to design the IG process in a public utility. Specifically, this knowledge type answers the questions related to the process organization (responsibilities, stakeholder participation), the flow of activities, the necessary resources (time, expertise, money) and the process deliverables.
- **Knowledge generated within the IG process**: The second type of process knowledge includes the knowledge captured and generated in the course of the IG process. Two kinds of knowledge resources can be distinguished: knowledge that relates to the control of the process (e.g. goals and decisions) and knowledge that represents the outcomes of the process itself (e.g. business process analysis, information requirements, information inventory, information architecture).
- **Knowledge derived from the IG process**: This last type of knowledge consists of the insights gained from implementing IG activities. These include lessons learned, suggestions for improvement, experience with methods and tools and so on.

In order to capture, manage and exploit these different knowledge types, the problem of knowledge representation needs to be tackled. In particular, adequate ways of modeling the critical knowledge for the IG process as an object have to be provided. The main idea behind this "knowledge-as-object" approach is that it makes it possible to explicitly codify critical knowledge in the form of data sets [7]. Such object-like knowledge can be effectively captured, managed and exploited by means of information technologies in a similar way to data.

According to Zack [8], a meaningful representation of knowledge as an object must consider two basic aspects: *structure* and *content*. *Knowledge structures* provide the context for interpreting accumulated content. The basic structural element is the knowledge unit, a formally defined atomic packet of knowledge content that can be labeled, indexed, stored, retrieved and manipulated. Furthermore, a knowledge structure includes schemes for linking and cross-referencing knowledge units, e.g. for representing relationships. For its part, the *knowledge content* has to reflect the full range of critical knowledge that is needed. If we consider a specific process within an organization, a suitable knowledge representation should allow the embedded tacit and explicit knowledge of the process that generates and exploits it to be adequately and properly captured. In other words, the knowledge that is identified as critical for a process should be organized around the process itself [5]. In the search for an adequate representation, the fundamental question arises of determining which knowledge should be made explicit and which should be left tacit. Finally, it must also be stressed that not all the required knowledge can be explicitly codified in the form of data sets [6].

2.2.2 Issue 2: Knowledge work of IG

In order for IG to deal with its critical process knowledge, a set of embedded knowledge activities are required. These activities are intrinsically tied to each other and can be viewed as a support process within the IG process. The following activities are recognized as being suitable for describing the resulting knowledge work [6,9,10]:

- **Knowledge acquisition**: Knowledge that is not yet explicitly managed is identified and systematically captured. The source of this knowledge may be inside or outside the utility. It may already be documented or be present merely in people's heads. Knowledge that is captured has first to be verified and then integrated with existing knowledge.
- **Knowledge distribution**: Knowledge is made accessible for use. Ways of retrieving and accessing existing knowledge have to be provided to all knowledge workers inside and outside the utility.
- **Knowledge exploitation**: The exploitation of knowledge must be enabled for all knowledge workers within the context in which it is needed (e.g. within a business function). Knowledge content must be presented according to the requirements of the users.
- **Knowledge maintenance**: Knowledge has to be systematically updated, i.e. knowledge that is out of date has either to be removed or replaced.
- **Knowledge evaluation**: Knowledge has to be regularly evaluated and adapted to the changing requirements of its users.

Davenport et al. [11] demonstrated that improvement methods for knowledge work range from the classical top-down approach to a more "laissez-faire" philosophy that allows professionals to design and execute their own work. They found that an appropriate improvement method depends on several factors such as the organizational culture and the scope of the knowledge work. Lenk et al. [12] pointed out that an adequate approach to improving knowledge work in public organizations should focus on supporting knowledge workers. It has to emphasize the way people create, share and use knowledge resources and support these activities. Each knowledge worker should become aware of the knowledge work he/she carries out by doing his/her own job.

The role of information technology as an enabler for supporting and improving knowledge work has been broadly emphasized (e.g. Davenport et al. [11], Schwabe [10] and Zack [8]). Zack [8] suggests dividing knowledge management applications into two broad classes: *integrative* and *interactive* applications. Integrative applications, like IT-based knowledge bases, provide a means of integrating explicit knowledge in the organization. Interactive applications focus primarily on supporting interaction between people with tacit knowledge. Together, these approaches provide a broad set of knowledge-processing capabilities. However, a fundamental prerequisite for the effective use of information technologies to communicate and share knowledge in a utility is the existence of an interpretive context. This means that the structure and content of the knowledge have to be defined and communicated throughout the utility.

2.3 Current knowledge management practices of public utilities

Although knowledge management has gained wider acceptance both in the private and public sector, few utilities today are fully capable of developing and leveraging critical organizational knowledge to support their business functions. Nevertheless, developing effective ways of utilizing knowledge is recognized to be of increasing importance to enable utilities to offset competitive disadvantages and exploit latent corporate knowledge to its fullest potential (e.g. Blackwood et al. [13]).

Various IG projects of Swiss wastewater utilities provided us with insights into current knowledge management practices of public utilities:

- Knowledge is often fragmented, difficult to locate and share, and therefore redundant, inconsistent, or not used at all. Critical knowledge is usually unequally distributed among different knowledge carriers, and is mostly available only in tacit form.
- Utilities store knowledge in their procedures, norms, rules and forms. They accumulate such knowledge over time through learning from specific business issues. This knowledge is captured in routines and evolves in response to organizational experience. Knowledge therefore accumulates throughout the utility in the form of "knowledge silos". Individual knowledge is not systematically made accessible to others in the utility who need it. Different knowledge structures coexist in the utility and are not aligned with each other.

- Knowledge work mostly occurs implicitly at individual level. Well-defined knowledge activities, roles and responsibilities are not specified. The utilities are not fully aware of their knowledge resources.
- There is a lack of methods, techniques and tools for capturing knowledge from individuals throughout a utility. Instead, stand-alone applications are deployed independently in the utility. These applications (like GIS) can store a lot of the utility's critical knowledge. Valuable knowledge is therefore disseminated without any means of effectively integrating it.

These findings show us that current knowledge management practices in public utilities often fail to support basic knowledge processes such as capturing and securing existing knowledge, distributing knowledge and combining available knowledge. Good knowledge management involves the continuous streamlining of these knowledge processes to improve the learning capacity of the organization [14].

2.4 Design requirements for IG

By participating in IG projects of various Swiss wastewater utilities, the following requirements for an effective design of the IG process of public utilities have been identified:

- **Requirement 1: Manage critical process knowledge** – Knowledge about, within and from the IG process has to be systematically captured, exploited and updated. These knowledge resources have to be consistent, comprehensible, accessible and universally accepted in the utility.
- **Requirement 2: Make knowledge work visible** – The process of creating, distributing, exploiting, updating and evaluating knowledge about, within and from the IG process has to be clearly defined and embedded in the IG process.
- **Requirement 3: Use IT to leverage knowledge assets** – Knowledge about, within and from the IG process has to be formally structured and represented so that it can be stored in a repository. Activities such as storing, retrieving and manipulating knowledge objects must be supported by the use of IT.
- **Requirement 4: Define knowledge management roles** – Knowledge management roles and responsibilities within the IG process have to be explicitly assigned.
- **Requirement 5: Enhance knowledge awareness** – Individuals in a utility have to become fully aware of their knowledge resources and their importance for the whole utility.

In the next section, we present three case studies of Swiss wastewater utilities that show how these requirements can be implemented.

3 CASE STUDIES

3.1 Rationale

Between 2001 and 2004 we participated actively in three different IG projects of three public Swiss wastewater utilities (see Table 1). The rationale for conducting these projects was that all three utilities had recently made important investments in new information assets. The utilities became aware of the value of the collected information and recognized the importance of considering it as a key resource, together with people, finances and material assets. At the same time, the utilities realized that they faced a totally new challenge. In fact, an assessment of current IG practices revealed the following weaknesses:

- In some utilities (in particular some municipalities in case study 1) there is a complete lack of any recognizable IG process.
- Several utilities have still not considered important IG issues such as maintaining data quality, data integration, establishing data standards, metadata management and evolution of data models in response to changed requirements.
- In many utilities there is evidence that IG issues are recognized and need to be addressed. However, only ad-hoc approaches have so far been applied on a case-by-case basis.
- There is no global awareness in the utilities for the need to define appropriate standards and policies to govern the procedures and responsibilities for managing information. Responsibilities are left to individuals and are not clearly defined.
- In many utilities there is a lack of internal skills, capabilities and the experience necessary to manage information resources effectively.

Table 1

The three case studies presented

	1	2	3
Type of assets	WWTP and sewer network	Sewer network	Sewer network
Type of utility	Public joint association of 13 municipalities	Municipality	Municipality
Catchment area	76 km^2	51 km^2	48 km^2
Customers	53,000 inhabitants	38,000 inhabitants	52,000 inhabitants

WWTP: Wastewater Treatment Plant

3.2 Scope

The utilities considered here have recognized the need to improve their current IG practices. Throughout the projects, we concentrated our improvement efforts on three areas included within the scope of IG:

- **Management of information resources**. All the information resources of a utility need to be managed. IG must ensure that all these resources are known and that responsibilities for their management have been assigned.
- **Management of information processes**. All business processes give rise to operations involving one or other of the information resources of the utility. The processes of collecting, storing, accessing, modifying, deleting and archiving information must be properly controlled if the utility is to exercise satisfactory governance of its information resources.
- **Management of information standards and policies**. The utility will need to define standards and policies for its IG. Management policies will govern the procedures and responsibilities for managing information in the utility; technical policies and standards will apply to the IT infrastructure that supports the utility's information systems.

3.3 Methodological approach

Although agreement was reached on the need to improve current IG practices, an important issue remained open, namely: *how* do we proceed to bring about such improvement? For the three projects, we decided to adopt an approach based on seven steps (see Table 2).

Table 2

The seven steps of the approach used in the case studies

Step	Task	Goal
1.	Establish a participatory structure	Decision makers and key staff members participate actively in the project
2.	Achieve awareness for the *as-is* state	Understand how the utility currently manages its information assets
3.	Find agreement on what has to be improved	The major problems that need a solution are identified
4.	Define the *to-be* state	Define how the utility should manage its information assets
5.	Deduce and agree upon actions for improvement	An action plan is defined
6.	Implement the agreed actions	The agreed actions are implemented
7.	Evaluate the achieved results	Assessment of the impact of the implemented actions

In order to support each task, we developed a methodology that explicitly considers the design requirements of *Section 2.4*. The proposed methodology consists of three components that are explained below. In *section 3.4* we then show how the methodology was applied in the case studies and how the design requirements for IG were implemented.

3.3.1 Knowledge framework for IG

The first component of our methodology is a knowledge framework that we developed together with the public wastewater utilities considered here. This framework is used to properly structure and represent the embedded tacit and explicit knowledge of the IG process. Its structural design is based on six different perspectives (see Table 3). Each perspective emphasizes specific issues that have to be addressed within the IG process. Specific knowledge concepts are provided to represent the critical knowledge for each perspective.

3.3.2 Organizational knowledge base

We proceeded to construct a model containing these six perspectives on the basis of the identified knowledge concepts. In a first step, we used elements of existing enterprise models (e.g. Scheer [15]) to model each perspective. In a second step, we identified the relationships between the knowledge concepts used and integrated the models. We then refined the resulting integrated model by applying it to real-life utilities. The model was developed by using an object-oriented approach. Finally, we implemented the model in a relational database management system. We call the result of this implementation an *Organizational Knowledge Base* (OKB). It is the second component of the proposed methodology. This OKB can be used to carefully codify the critical knowledge for the IG process in the form of data sets and store it electronically in a database.

Table 3

The knowledge framework developed for this application

Perspective	Description	Related key issues	Knowledge concepts
Business processes	This perspective includes a description of business processes, business goals and business performance indicators. It describes the logical and chronological sequence of business and information-handling activities within the business processes. It also depicts the information requirements of these processes and the information produced or modified during the execution of business activities.	Which business processes within the utility have outcomes that are intrinsically dependent on information availability and quality? How will information be collected, stored, accessed, modified, deleted and archived within business processes?	• Goals • Performance indicators • Business processes • Business activities • Information handling activities • Information requirements
Information resources	This perspective includes a description of the necessary business data, their interrelationships, their ownership and the data models to use. It also describes the information objects that have to be provided for the business functions.	What information has to be developed, maintained and exploited to successfully achieve business objectives?	• Information objects • Business data • Data models • Data ownership
Organiza-tional structure	This perspective describes internal business units, external service providers and organizational structures. It specifies business roles and responsibilities of the business units. It also describes the operations of each business unit on business data within the execution of business processes.	Who in the utility will be responsible for collecting, storing, accessing, modifying, deleting and archiving information?	• Business units • Organizational structure • Business roles and responsibility • Data operations

Communi-cation	This perspective describes the information flows that take place with the execution of business processes, the business units and external service providers involved and the business data that is exchanged.	How will information be shared and distributed inside and outside the utility?	• Information flows
Information quality	This perspective describes the business rules, data quality rules and quality properties (such as accuracy, consistency, timeliness, integrity) required for the business data.	Which information quality level is necessary?	• Business rules • Data quality rules • Quality properties
Business events and triggered actions	This perspective describes the actions that are necessary to direct and control the information assets and specify the business events that will trigger them. Three types of actions are distinguished: data maintenance, data quality controls and data synchronization with external stakeholders.	How will the necessary information quality be maintained over time?	• Data maintenance • Data quality control • Data synchronization • Business events

3.3.3 Organizing and supporting the knowledge work of IG

We consider the OKB developed here as an enabling tool for organizing and supporting the knowledge work of IG. We have developed an architectural framework on its basis for designing the knowledge work of IG. This framework is illustrated in Figure 1. It is the third and last component of our methodological approach.

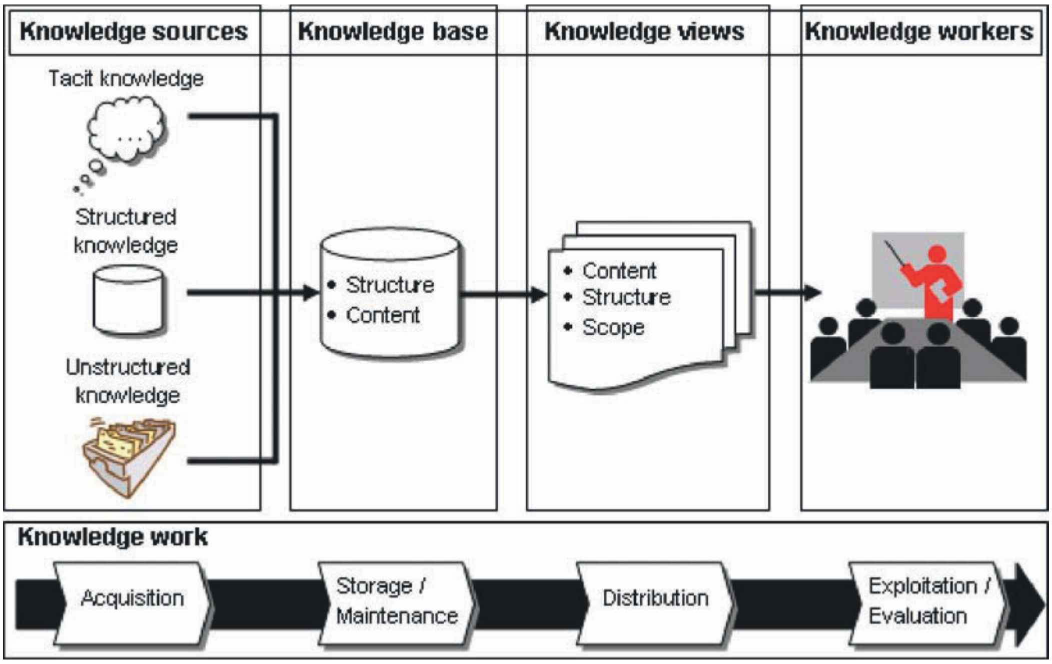

Figure 1. Architectural framework for supporting knowledge work.

The purpose of this architectural framework is to provide guidance for the utilities deploying the OKB. The knowledge base is the central component of the framework. Knowledge that is crucial for the IG process is captured from different knowledge sources and stored within the OKB. The OKB supports the maintenance of this knowledge. Retrieval of and access to existing knowledge in the OKB is provided to the participants of the IG process by means of knowledge views. Knowledge views can be seen as structured packets of knowledge derived from the OKB and supplied to address specific concerns within the IG process. The participants of the IG process are considered as knowledge workers who have specific knowledge requirements according to their roles and responsibilities within the process. They thus determine which knowledge views have to be configured for supporting their tasks within the process.

By implementing this framework in the utilities considered, we proceeded to develop a meaningful graphical user interface for accessing the OKB. We investigated the main concerns of the information managers and specified the key questions that had to be addressed. Basically, we found that the required knowledge views can be organized according to the different perspectives defined by the knowledge framework developed here (e.g. the business process perspective). A knowledge view can focus on one or more knowledge concepts (e.g. business data, business activities or information flows) and provide more or less details according to the descriptive attributes of the model. Several views can be obtained by combining different knowledge concepts using the specified relationships between them (e.g. business rules - business data). As a result of our implementation, we developed a set of functionalities to support the basic knowledge activities of the IG process such as storing, editing, deleting, searching and rendering knowledge. These functionalities are necessary to support the interaction of knowledge workers with the OKB.

In the next section, we illustrate how we applied our methodological approach in the three case studies.

3.4 Results

3.4.1 Step 1: Establish a participatory structure

A project team was set up in each case study. The resulting teams were composed of the information managers as well as the information administrators of the utilities. We insisted on including not only decision-makers or anyone else directly involved in the IG process, but also the key knowledge carriers of the utilities. In each case, we intervened directly in a coaching capacity, providing the team members with methodological know-how and data from other utilities.

The activities of the teams were organized as a series of workshops. We dedicated the first workshop exclusively to explaining the methodology we intended to adopt, to illustrate the activities we considered necessary and to explain the results we wanted to achieve. The first workshop aimed to define an agreement among the participants on the purpose of the project, project deliverables and the time frame for conducting the project. As a means of communication, we used the OKB filled with data from other utilities. By using specific knowledge views, we were able to provide the IG participants with real-life examples of the concerns we had to address. This allowed us to provide the participants with knowledge about the IG process very quickly. We observed that people initially tended to feel diffident and had different ideas on what had to be done. The discussions we had during the first workshop were mostly unstructured. We found that different participants normally considered and described the same problems, but from totally different perspectives (e.g. from a business perspective or from an information perspective). The knowledge framework we developed proved to be a suitable tool for disseminating a consistent description of important issues among all participants.

3.4.2 Step 2: Achieve awareness for the *as-is* state

After the first workshop, we proceeded to investigate the current information management practices of the utilities. This task normally required three to five workshops. These allowed us to collect the necessary knowledge from the available documentation and from the team members. Other staff members in the utility were involved to provide us with the missing knowledge as required. In these workshops, we worked interactively within the teams with the support of the OKB. We addressed the different perspectives of the knowledge framework in sequence and investigated each knowledge concept. We stored the captured knowledge directly in the OKB using the specifically designed graphical user interface.

The result of these workshops was a complete description of the *as-is* situation of each utility. Throughout the projects, the participants found it very helpful for developing a clear understanding of the way the utility operates. In fact, most participants only had access to that part of the knowledge that directly concerned their roles and responsibilities in the utility. None of them had direct access to the whole knowledge available. The workshops therefore represented a fruitful learning process for the participants and enabled considerable individual knowledge to be shared.

3.4.3 Step 3: Find agreement on what has to be improved

The documentation of the *as-is* situation of the utilities allowed us to identify several common areas where the current practices of managing information needed to be improved:

- Responsibilities are not defined clearly for all the information assets of the utilities
- Information-handling activities (e.g. collecting, storing, modifying, deleting or archiving data) are not explicitly defined within the business processes of the utilities
- There is no control of business events that produce or modify business data
- Data quality rules are not specified

- Information requirements are not clearly specified (often it is not clear if some business data still has to be managed)

While the utilities have adopted technical policies to develop information systems (e.g. for modeling data) or to exploit the IT infrastructure (e.g. IT security) in the past, management policies were still lacking. Therefore, in all three cases we agreed to develop suitable management policies for addressing the issues listed above.

3.4.4 Step 4: Define the *to-be* state

The first step towards defining management policies was to clearly specify a target state that had to be achieved. On the basis of a description of the *as-is* state we proceeded in sequence to define the *to-be* state for the utilities. Specifically, we organized two to three more workshops to interactively address the following issues:

- Specify information requirements and recognize the value of the available business data
- Specify the information objects and the business data that have to be managed
- Define responsibilities for the business data
- Explicitly define information-handling activities within the business processes
- Define roles and responsibilities of the organizational units involved in data operations within the business processes
- Define information flows
- Define a control mechanism for capturing business events that produce or modify business data and trigger the necessary actions
- Specify data quality rules

We used our OKB to support this step. For each issue, we first presented the *as-is* state by means of the knowledge views designed and then reviewed this briefly in the teams. This allowed us to discuss systematically how the *to-be* state had to look. The results of these discussions were directly recorded in the OKB. We found that the OKB was very useful in helping the project participants to specify the way things should have been done.

The knowledge framework proved to be an essential tool to design the *to-be* state consistently. It provided us with specific concepts and design rules to use for each issue that was addressed. This enabled us to effectively guide the project teams in the design process. Throughout the utilities, information managers found it to be an essential foundation for their management policies. In fact, it provided them with a straightforward way of dealing with a complex matter. Furthermore, the knowledge framework provided proved to be a suitable tool for communicating IG issues. They therefore decided to adopt this knowledge framework as a management policy for handling information.

3.4.5 Step 5: Deduce and agree upon actions for improvement

By comparing the *as-is* state with the *to-be* state of the utilities, we were able to deduce a set of actions necessary to realize the targeted state in each case. Examples of such actions are:

- Reengineering of business processes with a particular focus on information handling activities
- Making organizational units or external service providers accountable for the quality of the information produced
- Defining service-level agreements for information administrators (e.g. concerning data maintenance)

In each case we proposed an action plan and presented it to the project team. Emphasis was placed on the consequences for the utilities of implementing the planned actions. We also illustrated what costs could be expected and which benefits could be realized. The subsequent discussion with the project teams enabled us to improve the proposals. In a next step, priorities for each action could be defined. The project teams agreed upon the resulting actions plans.

3.4.6 Step 6: Implement the agreed actions

After having agreed upon the action plans, the utilities began to implement them. We observed that changing the way a utility operates and changing established structures is not a trivial process. We found that two critical success factors were especially important. Firstly, the commitment by the decision-makers who had to actively support the changes. Secondly, we found that communicating the changes throughout the utilities and making people aware of the need for change was essential. We observed that different levels of concern produced different rates of successful implementation. The system of participation that we built up during the workshops was very important to achieve the awareness and acceptance that current practices had to be improved. Making people at this early stage aware of change issues proved to be very important in making the changes succeed.

3.4.7 Step 7: Evaluate the achieved results

A successful change process must include steps for ongoing evaluation and reflection. We proposed to use the knowledge framework we designed as a checklist to investigate whether changes had really taken place and were of benefit to the utility. For example, in several utilities we observed a significant improvement in the data maintenance process. This can be explained as an effect of the better understanding of all the operations on business data that occur within a utility. In fact, by developing the knowledge framework, we precisely defined the activities in which business data was used, produced and modified. On this basis, we also defined the actions that had to be taken within the business processes in order to systematically update the data. As a consequence, it proved much easier to track data changes and to check whether they were effectively documented.

At the end of the projects, we conducted a review of the work done by the project teams in each utility. The project participants evaluated the way in which information management issues were structured as positive. The knowledge framework we developed was very helpful in focusing on specific issues and thus providing a clear understanding of the existing dependencies between the problems discussed. Our OKB and the knowledge views we provided were found to be suitable tools for communicating a complex matter. The workshops we conducted were also seen as a fruitful platform for sharing knowledge among different knowledge carriers in the utilities. The participants were able to learn from each other about the way things are done in the utility. This process was also important for becoming aware of the way things should be done. Finally, we investigated which problems resulted from using the knowledge framework for tackling IG issues. We found that the business process perspective presented the greatest difficulties to the project participants. This is because thinking in business process terms is still a challenge for many utilities.

4 DISCUSSION

On the basis of the findings from the three case studies, in this section we will review the design requirements for IG formulated in *Section 2.4*. We will describe how each requirement was implemented and discuss what effects we observed in the utilities considered.

Requirement 1: Manage critical process knowledge – We showed that knowledge about, within and from the IG process can be systematically managed through an OKB. We demonstrated that an OKB is a suitable tool for consistently integrating knowledge from different sources and making it accessible where it is needed throughout a utility. The OKB provides a utility with a consistent context for sharing and interpreting critical knowledge. We showed that the OKB is an appropriate tool for communicating issues of information management. It is very helpful to provide an IG team with knowledge about the IG process. We illustrated that the OKB supports different perspectives for addressing IG issues. This proved to be essential in view of the fact that the members of an IG team normally have different points of view and different concerns. We found that systematically capturing knowledge in the OKB helps an IG team to develop a clear understanding of the way the utility operates. This is extremely important for becoming aware of the concerns that IG has to address. We also demonstrated that the OKB can effectively guide an IG team through the process of designing the way things should be done. It therefore supports the specification of suitable management policies for the utilities. Finally, we emphasized that the OKB can also be used to capture insights from the IG process and can therefore stimulate the learning process of an IG team.

Requirement 2: Make knowledge work visible – We showed that an OKB enables knowledge activities within the IG process and make them explicit for the participants. The OKB is a suitable tool for building up a knowledge platform to support the acquisition, maintenance, distribution, exploitation and evaluation of critical knowledge. We organized these activities within the IG process in the form of workshops. This proved to be a suitable system for directly involving key knowledge carriers of a utility. We believe that making knowledge work visible enables the IG participants to reflect on the way the IG process is carried out and on the issues that have to be addressed. This shifts the attention of an IG team from the deliverables to the process that produces them. The process becomes more important than the results. We believe that this shift is essential for improving the effectiveness of the IG process over time. The IG process should not be regarded as static, but as a dynamic process that evolves over time as a learning system that continuously improves its effectiveness. We found that making knowledge work visible improves the learning of the participants and can catalyze the evolution of the IG process toward maturity.

Requirement 3: Use IT to leverage knowledge assets – We showed that knowledge about, within and from the IG process can be systematically represented by means of a knowledge framework. We illustrated how a knowledge framework can be used to implement an OKB, which can codify knowledge in the form of data sets. We showed that the basic knowledge activities can be supported by a set of IT functionalities. We found that IT can improve knowledge-processing capabilities for the IG process. This opens up new possibilities for analyzing complex issues of information management. The available knowledge can be fruitfully combined and provides new insights for solving complex issues. Codifying knowledge in a database opens up new ways of exploiting that knowledge and preserves it from losses. IT enables fragmented knowledge to be captured and integrated in a way that can provide information managers with the whole picture. This is necessary in order to achieve a clear understanding of critical issues and how they relate to each other. IT enables knowledge to be shared effectively in an IG team. It is essential to provide the decision-makers with the right knowledge.

Requirement 4: Define knowledge management roles – We showed that the OKB enables a new knowledge organization to be created for the IG process. Individuals are made responsible for documenting, sharing and maintaining critical knowledge for the whole utility. We found that this enabled a collective learning process within the IG process. IG participants could learn a lot from each other. We believe that this approach can improve the effectiveness of IG over time.

Requirement 5: Enhance knowledge awareness – We showed that an OKB improves the knowledge awareness of individuals in an IG team. Individuals became aware of their knowledge requirements and understood the importance of the knowledge they embodied for the whole utility. We believe that knowledge awareness is a fundamental condition for evolving the IG process over time.

5 CONCLUSIONS

On the basis of three case studies with Swiss wastewater utilities, we have proposed a methodological approach to supporting and improving current Information Governance (IG) practices through an Organizational Knowledge Base (OKB). We have developed a knowledge framework to systematically structure and represent the embedded tacit and explicit knowledge of the IG process. This framework was implemented in a relational database management system, thus providing us with an OKB for the IG process. On this basis we illustrated an architectural framework for supporting the knowledge work of IG. Finally, we outlined the benefits of the proposed methodological approach to the utilities considered.

In view of an increasingly competitive and cost-conscious operating environment, it is becoming more and more important to treat information as a strategic asset. Thus, public utilities should pay considerable attention to the design of their IG process and whether it yields effective outcomes. Because of the growing complexity of public utilities, managing information assets across business units and processes has become a challenging task. We argued that current knowledge-management practices fail to capture, manage and systematically exploit the critical organizational knowledge for an effective IG. We therefore emphasized that the IG process should not only be considered merely as a planning process for delivering an IS plan. Rather, IG is a learning process that requires continuous reflection on the way things are done. We believe that the approach presented here can stimulate the realization of IG as a learning process for the utility. It considers the participants of the IG process as knowledge workers and focuses primarily on the mechanisms allowing them to become fully aware of the utilities' needs.

We believe that the ability to manage critical knowledge and systematically support knowledge work is not only of crucial importance for IG, but also for other knowledge-intensive processes within a public utility (e.g. planning or auditing processes). We believe that our research may serve as an example for tackling this issue. The design requirements for IG presented here could be successfully applied to other processes. We have argued that knowledge about, within and from a process can be systematically represented in an OKB. In this regard, we illustrated how a comprehensible framework for representing knowledge as an object can be developed and implemented. Finally, we believe that the proposed architectural framework for supporting knowledge work could be fruitfully applied to other knowledge-intensive processes. A particular strength of this approach is that it focuses primarily on knowledge workers and their knowledge requirements for achieving their tasks. It emphasizes the way people create, share and use knowledge and improves the knowledge awareness of each individual.

AN ASSET MANAGEMENT FRAMEWORK TO IMPROVE LONGER TERM RETURNS ON INVESTMENTS IN THE CAPITAL INTENSIVE INDUSTRIES

Kari Komonen, Helena Kortelainen and Minna Räikkonen

VTT (Technical Research Centre of Finland) P.O. Box 1000, FIN-02044 VTT, Finland.

Abstract: The general global problems in the capital intensive industry seem to be over-capacity and low returns on investment. The means to increase returns on investment are to decrease the operating costs or to increase the turnover of capital. From the physical assets' point of view, these requirements mean a need for dynamic and continual life cycle management, optimal capacity development, higher overall equipment effectiveness, higher reliability and flexibility of physical assets, and lower maintenance costs of production equipment.

In order to develop methods, such as dynamic life cycle management, optimal capacity development, OEE development etc., to manage the above mentioned problems a general asset management framework is needed. Theframework should be based on the business objectives of the firm and on analysing and modelling various businesses and business environments from the standpoint of the physical assets taking into account technological characteristics, economic structure and uncertainty in the industrial sector in question. In this paper, a methodology to build an asset management framework and a description how it results in asset strategy has been depicted and demonstrated.

Key Words: Strategic analyses, Asset management, Capacity management, Operation and maintenance

1 INTRODUCTION

The general global problems in the capital intensive industry seem to be over-capacity and low returns on investment (e.g. Siitonen 2003)[1]. The means to increase returns on investment are to decrease the operating costs or to increase the turnover of physical capital. From the physical assets point of view, these requirements mean a need for a dynamic and continual life cycle management, optimal capacity development, higher overall equipment effectiveness, higher reliability and flexibility of the physical assets, and lower maintenance costs of the production equipment. These trends have brought also the issue of availability warranties to commercial negotiations. Availability warranties are more demanding than e.g. traditional free-replacement warranties or replacements provided at a reduced cost to a buyer.

This development lays the cornerstones for 'asset management'. The expectations of various industries concerning 'asset management' vary: besides single techniques and viewpoints, comprehensive and integrated evaluation, development and optimisation techniques are also required. Some of the companies have seen the highest benefit from 'asset management' at a plant level, and some at a corporate level. The lack of methods and tools that combine technical assessment and economical considerations has also become evident. These facts require interdisciplinary know-how and competence (Komonen et al. 2005) [2].

In the capital-intensive industry, the operating time of the production equipment after the green-field investment is typically long. During the operating time numerous rebuilds, replacements and expansion investments take place. All of these decisions, together with the chosen maintenance strategies, affect the productivity of the physical capital. In order to meet the challenge of low returns on investment enterprises need to create an asset management strategy, which is based on constructed and systematic decision making at all the levels of the corporate hierarchy.

2 CONCEPT AND SCOPE OF ASSET MANAGEMENT

According to Mitchell (2002) [3] 'asset management' is ”a comprehensive, fully integrated, strategy, process, and culture directed at gaining greatest lifetime effectiveness, value, profitability, and return from production and manufacturing equipment assets”. In this approach, which was also adopted by VTT, two different aspects may be emphasized:

(1) Maintaining and improving the profit-making capability of production assets, and

(2) Maintaining and optimising the net asset value (physical assets)

'Asset management' could also include all of the decisions concerning physical assets: e.g. green-field investments, expansion and replacement investments, modernisations, improvements in Overall Equipment Efficiency (OEE), maintenance strategies and disinvestments. However, we made a decision not to include novel green-field investments e.g. for new products or for new markets. Today, when in many countries and companies the level of investments has decreased at the lower level than depreciations, the importance of 'asset management' of existing plants has become an issue in focus.

Greenfield investments have been based on assumptions concerning a longer term demand, competition, interest rate, technology development, cost level etc. Sometimes LCP-calculations have been exploited. A LCC/LCP analysis can be applied to the evaluation and optimization of the life cycle costs and profits of the investments taking into account specified performance, safety, reliability, maintainability and environmental requirements. Other reasons for performing an LCP-analysis can be, for example, to identify cost effective improvements and cost drivers (i.e. cost factors that have large-scale impacts on the investment profitability), or to choose between different suppliers and products. Various investment alternatives and their life cycle costs and profits can be evaluated and compared (Peltonen & al. 2002) [4]. However, as soon as the installation of the equipment has been carried out the business environment begins to change (Figure 1). Changes may occur in all the exogenous or internal factors which the investment calculations have been based on (Komonen & al 2005) [5]. The essential question present is how to sustain or improve the life cycle profits of the original investment. This is the core issue of 'asset management' of the existing physical assets. Some of the changes in the external and internal business environment call for operative and some of them strategic implications. Many strategic changes require a longer term perspective in decision making.

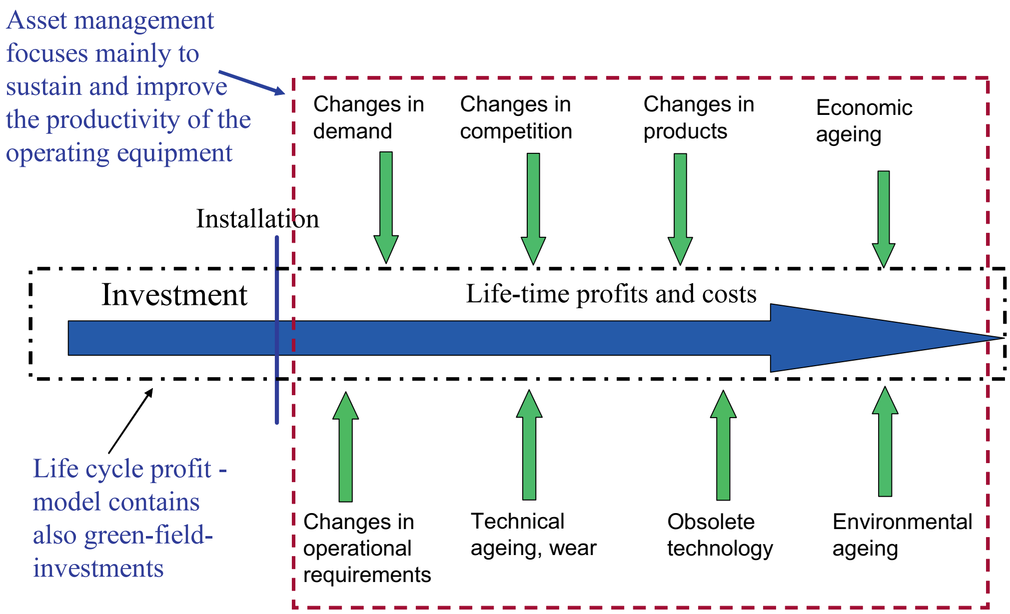

Figure 1. The focus of 'asset management

Discussions with the representatives of the capital intensive industry several issues concerning physical assets were brought on the stage. According to these discussions asset management may contain, ex ante, all the following issues:

- business requirements for physical assets and their use
- asset based capacity planning (analysis of real options)
- flexibility and agility management of production equipment

- dynamic continual life cycle optimisation (technical-economic view)
- maximisation of asset returns with respect to time horizon, risk carrying capacity and risk appetite
- physical asset centred risk management
- investment planning during the life time of the plant
- assessment of physical assets and of asset care systems
- determination of maintenance strategies
- capabilities, systems, plans and actions in order to sustain or develop the value, overall effectiveness and efficiency of physical assets and lower asset care costs.

However, although the above mentioned issues are obviously important part of 'asset management' as such they don't form an integrated and logical system to cover the whole field of asset management.

3 ASSET MAGAGEMENT FRAMEWORK

In order to develop methods to manage the above mentioned issues such as dynamic life cycle management, optimal capacity development, OEE development etc. the general asset management framework is needed. The framework is based on the business objectives of the firm and on analysing and modelling various businesses and business environments from the standpoint of the physical assets taking into account technological characteristics, economic structure and uncertainty in the industrial sector in question.

Corporate asset management requires systematic decision making at all the levels of the organisation. The proposed asset management decision making framework is schematically presented in Figure 2. The corporate asset strategy reflects corporate visions, values and mission, and the business objectives defined by the stakeholders and incorporates the information from the strategic analyses and scenarios. If the firm has several production facilities or plants the local asset related decision making needs to be in line with the corporate asset strategy and take into account the plant level objectives and constraints. At this stage, the technical and economic analyses and risk analyses create important input for the decision making. The plant or production asset strategy is allocated to the production systems and equipment and form a basis for the decision making at the shop-floor level.

The system and equipment level decision making is often regarded as 'asset management', but this standpoint is too limited to cover the identified needs of the industry. Using the definition introduced in Chapter 1 and the proposed asset management framework, the concept should cover the strategic and economic decision making and guide to the optimal use of the corporate assets to meet the business objectives.

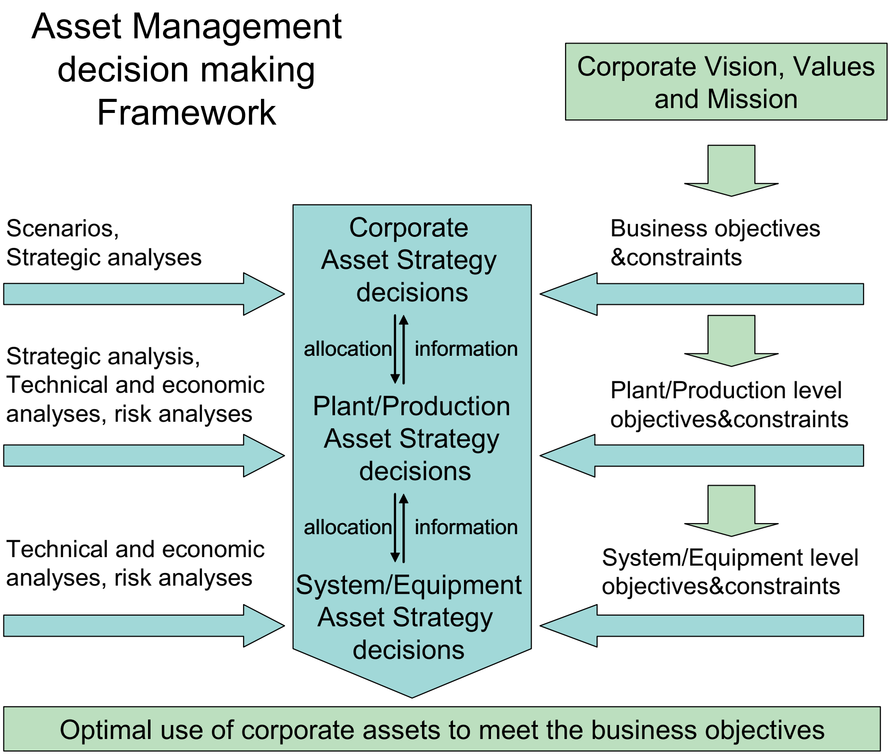

Figure 2. Schematic presentation of the Asset management decision making framework

4 DETERMINATION OF ASSET STRATEGY

Based on the above factors, analysing and decision making methods to determine the asset strategy have been developed for the various levels of the organisation as depicted in Figure 2. The scope and content of 'strategic asset management' instruments vary from level to level. The use various asset options, vertical integration, organisation of production system, mergers and choice of using asset services follow as a self-evident result of 'asset strategy'. The general development tendency of the business environment boosts strategically more flexible enterprises and production structures.

4.1 Corporate level

The corporate level is clearly strategic in nature and focus on the longer term perspective. The tools developed are close relatives to methods used in the area of 'strategic management'. The corporate asset strategy is based on the corporate business objectives and on the results of three main analyses: company, market and technology (Figure 3).

4.1.1 Markets

Market analyses determine the phase of the industrial development, asset related barriers to entries, uncertainty and volatility of industry structure and demand as well as sources of differentiation and regulatory acts by authorities. Market analyses comprise the basis for internal company analyses. The life cycle phase of the industry and the products in question have a remarkable impact on the flexibility requirements of the production system. The uncertainty and volatility of demand have the parallel effect on the flexibility requirements. An example of market analyses have been presented in Figure 4. The same type of classification, but concerning vertical integration, has been carried out by Harrigan (2003) [6].

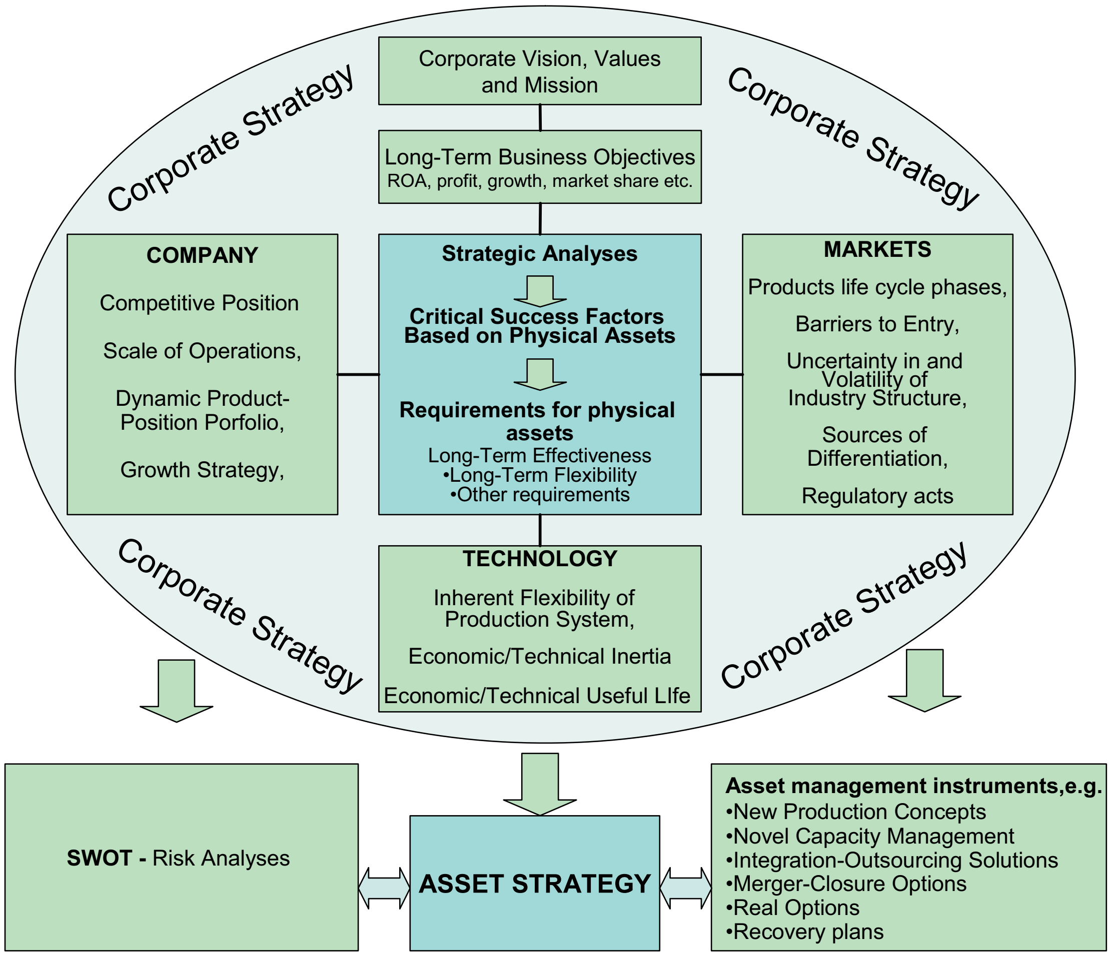

Figure 3. Schematic presentation of the Corporate Level Asset management decision making framework

4.1.2 Company

The analyses of the competitive position determine the portfolio of the competitive advantages in relation to physical assets. The scale of the operations influences possible longer run options to organise the production system in the optimal way in an effectiveness-flexibility co-ordinate. An example of the dynamic product-position portfolio is the map of company's product transitions in the life cycle- volatility co-ordinates. An example of the dynamic product-position portfolio is illustrated in Figure 4. The growth strategy describes company's actions to meet the growth objectives in the terms of the physical assets, outsourcing and mergers.

4.1.3 Technology

Technological factors have an essential impact on effective asset strategies. Specially, the flexibility of the production system (original investment), economic and technical inertia as well as the relative length of the economic and technical useful life of the equipment determine technological capabilities to meet requirements arising from the market-company interaction. The technological characteristics of the corporate production system determine significantly the possibilities of the company to meet flexibility or effectiveness requirements due to the market requirements.

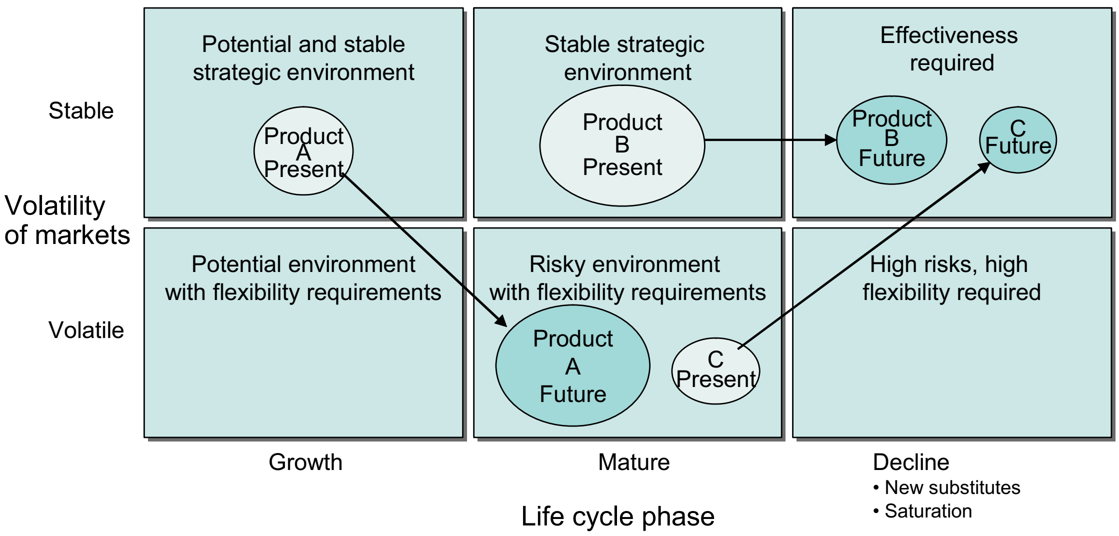

Figure 4. Example of product-position portfolio transition map in the selected time perspective

4.1.4 Strategic analyses

Company's internal strategic traits and development of the markets determine critical success factors from the physical assets point of view. The used technology gives limits and potential to the company's ability to meet the requirements of the markets and company traits. Based on the strategic analysis and critical success factors requirements for the physical assets can be identified. The asset strategy results from the requirements set by the markets and company's internal traits within the limits of technology in use and asset management options available.

4.1.5 Dynamic SWOT

In order to guarantee the long term quality of the asset strategy, risk analysis should be carried out. Dynamic SWOT analysis of the present and future circumstances could be used to improve the quality of the asset strategy and to decrease the uncertainty tied with the decisions made. The factors and analyses used in the determination of the asset strategy can also be used in dynamic SWOT-analysis.

4.1.6 Asset management instruments

Asset management instruments define a selection of strategic options in order to meet market requirements. At the same time they give the methods to find the optimal solutions to meet the corporate objectives. Examples of the asset management instruments are

- New Production Concepts
- Novel Capacity Management
- Integration-Outsourcing Solutions
- Merger-Closure Options
- Real Options
- Means to avoid risks and recovery plans

4.2 Plant level

The plant level is the mixture strategic and operative decision making in nature and focus on the middle and longer term perspective. The developed instruments are partly close relatives to methods used in the area of 'strategic management'. The plant level asset strategy is based on the plant business objectives and three main analytic dimensions: plant, plant business environment and technology of original investment (Figure 5). Strategic analyses based on the three above mentioned dimensions lead to the plant asset strategy and strategic choices. The strategic choices spring from the interaction of the possible options (asset management instruments) and asset strategy. The plant asset strategy and strategic choices give a framework to determine the optimal level of four performance factors: optimal capacity, operating rate, OEE (overall equipment effectiveness) and optimal maintenance costs.

Economic analyses are increasingly important in 'asset management'. The life cycle cost and profit objectives and life cycle cost structure have a significant influence on the plant asset strategy and strategic choices. LCP-analysis is a systematic approach aimed at assessing the total costs and profits of acquisitions, ownership, operating and maintenance, and disposal of an investment over its entire life-span. Within the asset management framework a challenge to meet is how to sustain or improve the life cycle profits of the original investment.

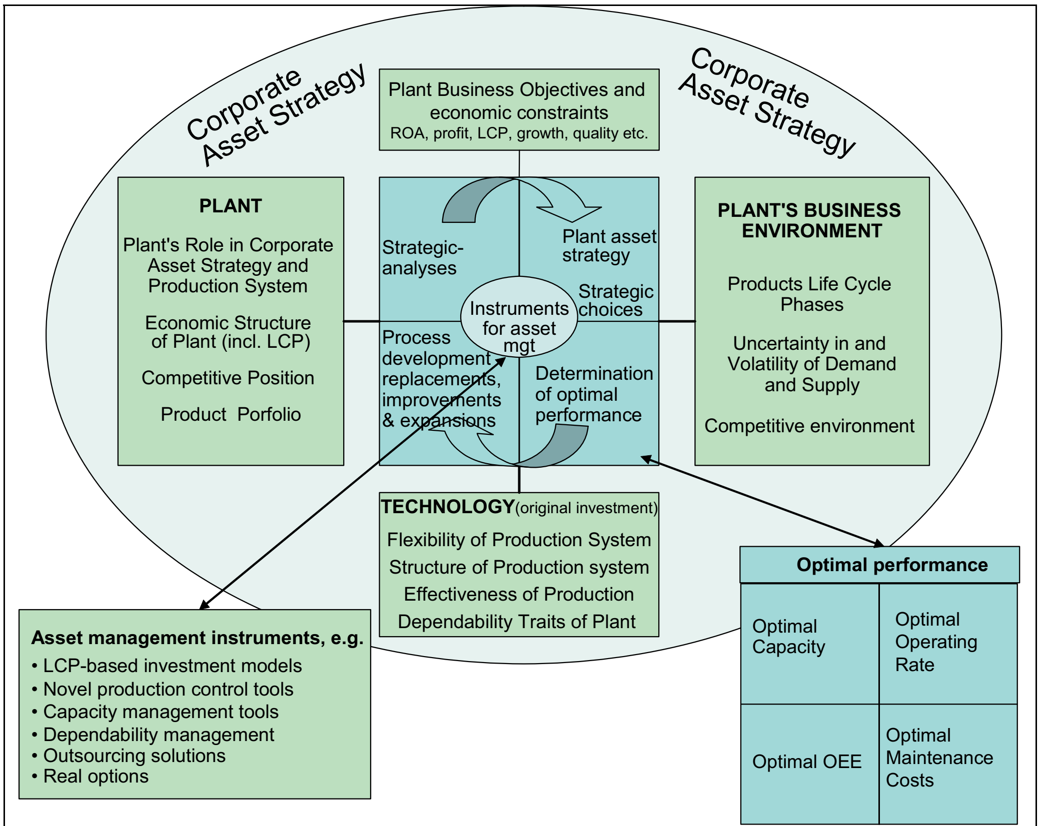

Figure 5. Schematic presentation of the plant level asset management decision making framework

4.2.1 Plant Business Environment

The analyses of the business environment reveal the phases of products life cycles, uncertainty and volatility of industry structure and nature of competition, for example, in terms of the sources of differentiation. The market analyses comprise the basis for the internal plant analyses. The life cycle phase of the industry and the products in question may have a significance impact on the flexibility requirements of the production system. The uncertainty and volatility of demand have a parallel effect on the flexibility requirements.

4.2.2 Plant

The corporate asset strategy determines the role of the plant in the corporate production system. The task of the plant could be the production of basic components, large scale production of one end product or small scale production of several products on the basis of customer order. The economic structure of the plant defines the significance of the physical assets in relation to the other variables. The life cycle cost structure determines profit potential related to various cost factors. The analyses of the competitive position determine the portfolio of competitive advantages in relation to physical assets. An example of the plant's dynamic product-position portfolio was shown earlier in Figure 4.

4.2.3 Technology of original investment

The flexibility of the production system affects capability to meet the volatility of the markets. The structure of the production system has a strong impact on the optimal activity level. The inherent effectiveness of the production system may give competitive advantage and with other traits influence the plant asset strategy. At the same time markets needs or plant's role in the overall production system determine the optimal position in the effectiveness-flexibility co-ordinate, and how well the used technologies match with requirements. The dependability characteristics of the plant differ from one technology to the other and have an impact on the optimal performance values. As depicted earlier, technological characteristics have an essential impact on the effective asset strategies. Specially, the inherent flexibility of production system, economic and technical inertia as well as the relative length of the economic and technical useful life of the equipment affects significantly the competitiveness of the plant.

4.2.4 Strategic analyses, strategic choices and performance

Plants' internal strategic traits and development in the markets determine critical success factors from the physical assets point of view. The used technology gives limits and potential to the plant's ability to meet the requirements of the markets. Based on the strategic analyses and critical success factors requirements for the physical assets can be identified. The determination of the asset strategy' and strategic choices result from the requirements set by the plant's business environment, company's internal traits, used technology and asset management options (instruments) available. The asset management options may include e.g. outsourcing, investments or better capacity management. As soon as the plant asset strategy and strategic choices have been decided, optimal performance objectives for capacity, operating rate, OEE and maintenance activities can be determined. The structure of the production system and other technological factors influence greatly the aspired performance level. Later in this paper some empirical evidence of this influence will be introduced.

The increase of capacity, operating rate or OEE requires e.g. investments, improvements, developing of maintenance processes and therefore costs money. The high values of performance figures are not necessarily optimal. The asset strategy, strategic choices and set optimal performance objectives give a basis for investment and improvement decisions.

4.2.5 Asset management instruments

Asset management instruments define the selection of various options in order to meet the requirements of the plant's business environment. At the same time they give methods to find the optimal solutions to meet the plant's objectives. Examples of the asset management instruments are following

- LCP-based investment models
- Novel production control tools
- Capacity management tools
- Dependability management and means to avoid risks
- Outsourcing solutions
- Real options

4.2.6 Empirical evidence

There exists empirical evidence of the impact of the business environment, plants internal traits and technological determinants e.g. on operating rate, OEE (overall equipment effectiveness) and maintenance costs (e.g. Komonen 2006) [7]. The structure of the production system has an impact on availability requirements as stated above. If a machine is the bottleneck of the production system, it is obvious that availability objectives are higher than in the case of a machine, which is not in the main production line and which has a low operating rate (Komonen 2002) [8]. "An indicator to model almost any production system is the degree of integration (plant replacement value divided by the number of front line production operatives in day shift), which is a multipurpose meter to measure mechanisation rate, continuity of processes and scale economies. Generally speaking, we can state that e.g. in the chemical industry and in the pulp and paper industry the integration level is high and in the manufacture of metal products it is lower. The impact of degree of integration on the above mentioned performance indicators has been demonstrated in Table 1: the higher the degree of integration of the production systems the higher availability performance they show. The same applies to the planning rate of the maintenance activities" (Komonen 2006) [7].

Table 1

The overall equipment efficiency (OEE), availability, proportion of planned and scheduled maintenance and proportion of preventive maintenance of production system as a function of integration level in Finland in 2000-2003

(N =261; N= 85-89 in each category)

Integration level	<0,65	0,65-4,5	<4,5
OEE %	69,5	72,7	80,3
Availability %	88,3	87,3	93,4
Proportion of planned and scheduled maintenance %	55,0	68,6	72,2
Proportion of preventive maintenance %	31,8	36,3	41,3

In order to make a more specific examination, multivariate regression analyses were carried out branch-wise using such exogenous independent variables as integration level, operating rate, plant size and technical capital intensity. Exogenous independent variables are factors which are often in the short run beyond the scope of production and maintenance managers to determine, but which have considerable impact on the objectives, e.g. availability or maintenance costs. The results of statistical investigations for three industrial sectors are presented below. The examples presented here are the chemical industry, processing of food and the combined data of processing of food, chemical industry and manufacture of metals. The number of plants in each sample varies, since some plants were not able to answer all the questions in the data collection form.

In the three above mentioned industrial sectors (Table 2), the degree of integration only had a statistically very significant influence on OEE. The impact of operating rate was nearly statistically significant. The third exogenous variable having some impact on OEE level was "Plant turnover / plant replacement value" (technical capital intensity). The determining power of the model was high (adjusted R^2=0,602. The statistical significance of the result was also very high ($p<0,0000$). In the chemical industry, the degree of integration only had a meaningful influence on OEE. However, its determining power was very high (adjusted R^2=0,774). The statistical significance of the results was also very high ($p<0,0001$).

Table 2

The variables having an impact on OEE in the processing of food, chemical industry and manufacture of metals

Dependent variable: OEE (Overall equipment effectiveness)

Adjusted R^2= ,602	F(3,29)=17,137	p<,0000
	t(29)	p-level
Intercept	6,566	0,000
Degree of integration	3,263	0,003
Operating rate	1,818	0,079
Plant turnover / plant replacement value	1,259	0,218

The relationship between OEE and integration level in the chemical industry is demonstrated in Scatter diagram 6 and the results for the combined data of three industrial sectors (processing of food, chemical industry and manufacture of metals) has been illustrated in Figure 7. In the scatter diagrams, predicted and observed values equal on the diagonal. The cases above the diagonal represent better performance than expected. In many other industries the degree of integration had also the most significant effect on OEE or availability of production equipment.

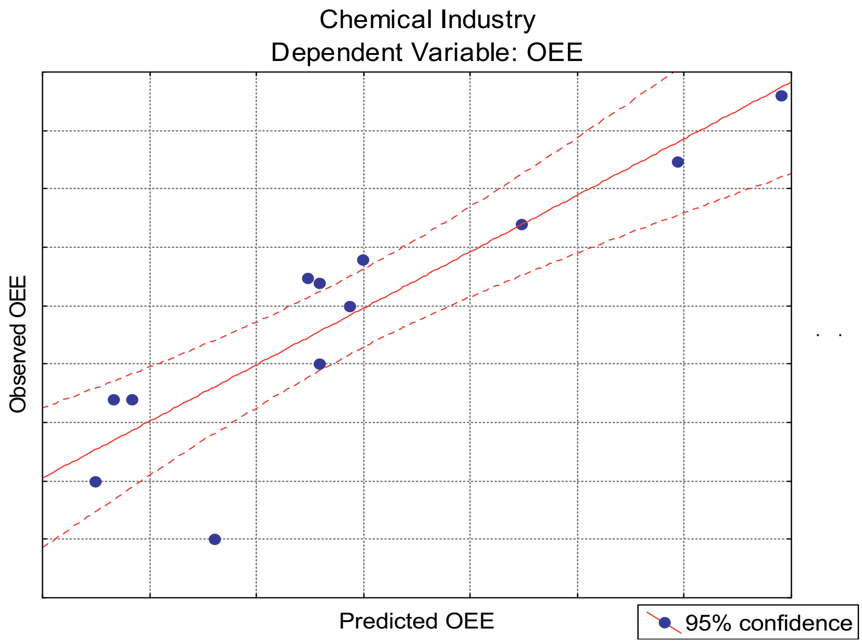

Figure 6. The predicting power of integration level on OEE in the chemical industry (Komonen 2006) [7]

As another example, it was interesting to notice that e.g. in the processing of food and liquid, the variables explaining maintenance costs were partly parallel with the variables explaining variation in OEE, although the direction of the influence was not always the same. However, in this case the replacement value was the most significant indicator. The degree of integration was the second statistically significant independent variable. The relationship between 'maintenance costs in relation to plant replacement value' and exogenous variables is presented in Table 3 and graphically demonstrated in Scatter diagram 8. In the scatter diagram, predicted and observed values equal on the diagonal (Komonen 2006) [7].

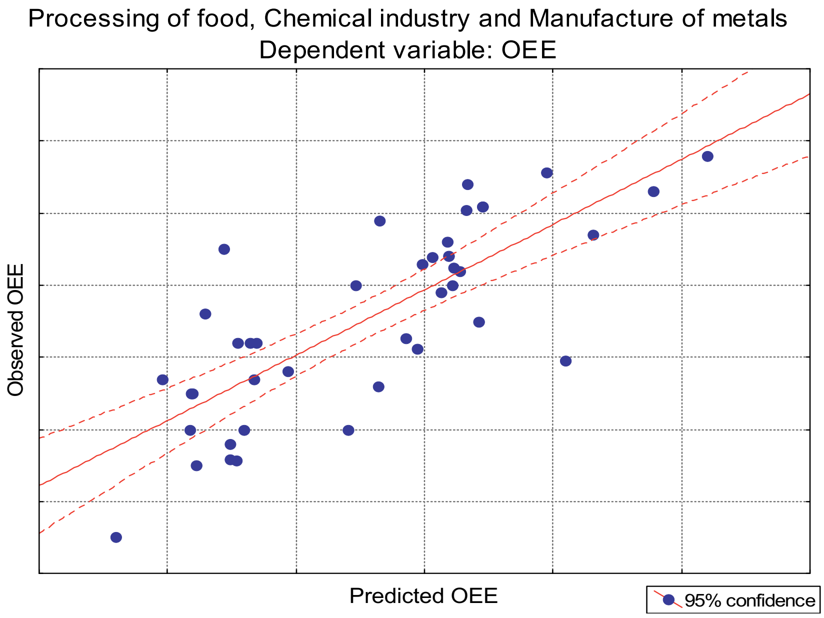

Figure 7. The predicting power of exogenous variables in the compound data of three industries

Table3

The variables having an impact on relative maintenance costs in the processing of food and liquid

Processing of food and liquid (N=34)

Dependent variable: Production equipment, Maintenance costs / Replacement value

4.3 System, equipment and item level

The focus of the equipment level asset management is on the maintenance function. Surely, the effect of the operation of the production processes has a great role in achieving high performance level. However, in this presentation the latter perspective has a minor role. The life cycle management of machines and their components are, of course, important from the machine performance point of view. Still, the justification of the machine level investments springs up from the plant level requirements. Thus, as a summary, in this presentation the machine level maintenance is a synonym for 'machine level asset management'.

The basis for the machine level examination in presented in Figure 9. The description of the maintenance system starts with the business requirements of the plant in question. These requirements have been summarized in the list located in the upper left box of the diagram. The plant asset strategy, customer satisfaction and safety considerations guide also maintenance operations. Requirements for the maintenance function and maintenance objectives spring from the above mentioned business requirements.

The system of the maintenance function consists of four separate sub-processes

- maintenance planning
- resources management and development
- management of maintenance processes
- execution
- follow-up and continuous improvement

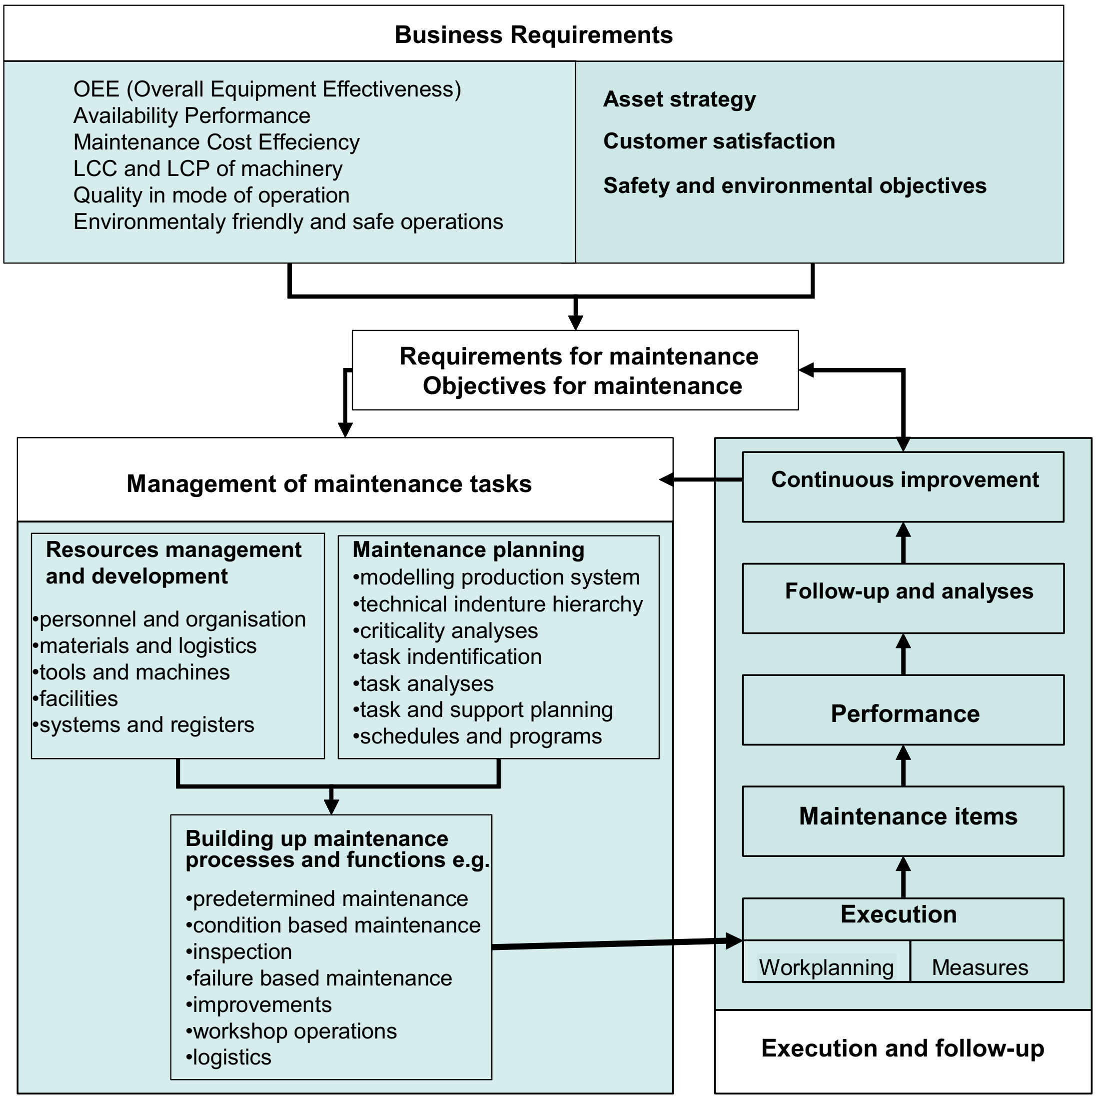

Figure 9. The system of the maintenance function

Maintenance planning includes e.g. modelling of production system in order to build up machine hierarchy for criticality analysis and maintenance policy. Maintenance planning continues with task identification, task analyses and task and support planning. The following step is to determine schedules e.g. for preventive maintenance and work lists for planned shutdowns. 'Resources management' is composed of planning, design, procurement, hiring, maintenance and development of maintenance resources. Organisation, IT-systems and condition monitoring equipment are essential parts of the maintenance systems. The third theme, maintenance processes depict the way, how the maintenance planning and execution are planned to be carried out and how the resources are planned to be used. The execution phase consists of work-planning and actions taken by the maintenance crew. The execution of maintenance actions leads to the performance of the machinery. The result of the maintenance system can be analysed and as a conclusion the improvements of the maintenance function can be carried out. The essential steering tool of the maintenance function is the system of performance indicators, which may cover business-oriented economic dimensions as well as organisational and technical factors.

There exist a lot of well known tools to carry out maintenance planning such as RCM, instead, the methods to develop maintenance processes are less frequent. Some writers, such as Kelly (1998) [9], are exceptions and have contributed also this research area.

There are various kinds of views, approaches and tools to develop and manage the maintenance function. In the field of the maintenance management and research eg. following categories can be identified:

1. overall approaches and models for maintenance management
2. asset centred planning tools and models, and statistical tools of reliability engineering
3. people and process centred methods, quality and organisational tools
4. process centred, work-planning approaches
5. mathematical economic and technical optimisation models
6. empirical research concerning causal relationships between various factors
7. continuous improvement

Some of these approaches have been discussed below.

(1) Overall maintenance management models include LCP-models, 'asset management', terotechnology and other holistic approaches on the maintenance function. LCP-models (life cycle profit) are quite a popular topic in research and consulting, but in reality they have been applied less than it could have been expected. Too many of the papers on LCP-models are listing the cost elements of LCC. However, the principle problems in LCC –calculations are the empirical responses of the changes in parameter values. 'Asset management' approaches extend the maintenance management view e.g. into choosing what equipment should be bought and when. Terotechnology emphasises the use of feedback from the field in the product development and design. Thus, there are connections between terotechnology and “life cycle profit” approaches. The basis for the good management is the system of performance indicators, which gives an instrument to identify the result , success and development needs of the maintenance function (Komonen 2004) [10].

(2) Asset centred planning tools include a wide range of methods and techniques, which are well known in the field of maintenance but too seldom used in the practical life. Examples of these methods are e.g. Quick Analyses of Production System (QAPS, developed in VTT), RCM, Experience Based RCM (EBRCM developed in VTT), RBI (Risk Based Inspection), FMECA, Fault Tree (FTA) and many other applications. RCM (Reliability Centred Maintenance) is a typical example of asset centred planning models. RCM is actually *a combination of good practices and methods*. Surely, many plants and maintenance managers have used some of the methods in RCM-toolkit. Mathematical models and statistical tools of reliability engineering can be used to support equipment and item level asset management.

(3) The third major approach contains people, organisation and process centred management tools. Perhaps, the best known concept in this field is 'total productive maintenance', TPM (Nakajima 1989) [11]. However, there are many other tools such as the use of maintenance process descriptions or process development implemented by group-work methods, simulation game based approaches or analyses of good working practices. 'Total productive maintenance emphasises the overall equipment effectiveness, operator centred maintenance, co-operation between various functions such as operators and maintenance technicians, adoption of proper working methods and attitudes, predictive and preventive maintenance methods. In this review, TPM has been interpreted to be a people, organisational and process centred management instrument, although it owes some features, which could be addressed partly to the asset centred category.

Maintenance processes to be determined, designed and developed may be grouped in several ways. Below, some examples of maintenance processes and functions have been presented:

- predetermined maintenance
- condition based maintenance
- inspections
- failure based maintenance
- improvements

- major shutdowns
- workshop operations
- materials function
- operator maintenance
- etc.

(4) Work-planning converts maintenance analyses, resources and designed maintenance processes into actions. CMMS tools and individual modes of operations guide and support the execution of "daily maintenance". E.g. Kelly (1998) [9] has approached maintenance planning from the standpoint of daily management, work planning and control.

(5) Economic and technical optimisation models have been of great interest to the practitioners of operational research. They treat such topics as the determination of optimal reliability investments (e.g. condition monitoring devices and programmes), optimal warranty policies, optimal maintenance policies, optimal timing of maintenance actions and optimal size of repair crew, optimal selection and number of spare parts. The search for optimal maintenance policies has generated e.g. a large literature of replacement models. These models could be easily used in practice. However, this is obviously not done to a great extent (Scarf 1997) [12]. In the field of warranty cost analysis W,R Blischke and D, N, P Murthy (1994, 1996) [13,14] have produced comprehensive and versatile handbooks, which present various aspects of warranties including optimisation models. Although the issues of a product warranty include several more important aspects than maintenance related issues, the maintenance function is an important tool to control the risks attached to product warranty and especially availability guarantees.

(6) An important neglected subject matter is the empirical research of the maintenance function and 'asset management'. It is very difficult to proceed in the theory formation and in the development of practical but scientifically grounded tools, if our knowledge on the “natural laws” of maintenance is not increasing. Benchmarking has been seen among maintenance managers and specialists as one of the major tools for development. However, benchmarking is not a possible option without comprehensive empirical research. There exists very little empirical work on the causalities in the maintenance field. Refreshing exception are the papers of Laura Swanson (1997 and 2001) [15, 16] and V.N. Bhat (2000) [17]. In Finland, Komonen has published papers and books concerning empirical relations between various performance indicators (e.g. 1998, 2002, 2006) [18, 8, 7].

(7) Continuous improvement is nowadays one of the critical success factors of any production plant. Several good principles of improvements could be listed. For example, active use of the versatile system of performance indicators, active and careful use of CMMS, participative leadership culture, resources for to carry out development activities, well-working cooperation between operations and maintenance function, optimal use condition based maintenance and inspections, viable quality system and systematic use of internal and external benchmarking systems.

4.3.1 Economic focus within various approaches

LCP-models, 'asset management' and market models are by their basic nature economic models. The same applies to mathematical optimisation models. RCM and TPM approaches include economic consideration, but they are not explicit quantitative models. For example, although TPM focuses on OEE, it does not employ profit or cost considerations. Some models and tools of reliability engineering employ qualitative economic considerations, usually in the form of risk assessment. Empirical studies focusing on economic causalities are surprisingly rare.

5 CONCLUSIONS

In the VTT's approach to 'asset management' two different aspects have been emphasized:

(1) Maintaining and improving the profit-making capability of production assets, and

(2) Maintaining and optimising the net asset value (physical assets)

This concept means that 'asset management' is a broader concept than just a business driven maintenance. 'Asset management' could also include all the decisions concerning physical assets: e.g. expansion and replacement investments, modernisations, improvements concerning overall equipment effectiveness (OEE), maintenance strategies and disinvestments. Also the options which offer other solutions than the exploitation of own equipment such as outsourcing, mergers, leasing belong to the field of 'asset management'. Today, when in many countries and companies the level of investments has decreased at the lower level than depreciations, the importance of 'asset management' of existing plants has become an issue in focus.

The asset management framework was divided into three levels: corporate, plant and equipment level. We have noticed that the equipment level has been quite well covered. Instead, the plant and corporate levels have often been narrowly treated. Strategic instruments created for the determination of the business strategies could also be used when determining the corporate or plant asset strategy. Of course, some further development has been required. In addition to the above mentioned issues there is a lack of economic and technical models in order to improve decision making concerning expansion, modernisation and replacement investments.

In the capital-intensive industry, considerations dealing with investment policies and maintenance development are a part of the strategic and operational decision making. In the rapidly changing business environment and increasing profitability demands, the industry would profit from new business approaches like 'broader scope asset management'.

6 FUTURE RESEARCH

During the roadmap process carried out in 2004, we identified several important topics for the future research efforts. Some examples have been presented below.

6.1 Capacity management

There is a generic need to construct a calculation technology and software solution for the optimisation of a company’s or plant’s capacity and use of that capacity. This solution should take into account uncertainty in the middle-term planning horizon and changing business environment.

6.2 Improvement investments and maintenance

A dynamic and probabilistic model to support the original LCP-objectives is required. The options available are development investments in existing production units and maintenance actions. These models should take into account various business constraints and changes in them, such as the economic age of the equipment, environmental risks, safety, price trends, technical development etc.

6.3 Risk management for Asset management

This research theme covers an overall risk management system for the physical assets, taking into account the business objectives, changes in the business environment, viewpoints of various joint-parties, the balanced governance of potential opportunities and versatile risks. The resulting risk management instruments should make it possible to carry out qualitative and quantitative risk analyses for the production system.

6.4 Intangible assets

This research area covers ICT-systems, expert knowledge, tacit knowledge and human interaction required to take the full use of the physical assets.

E-FAMEMAIN: A BENCHMARKING WEB-TOOL FOR O&M MANAGEMENT

Kari Komonen

VTT (Technical Research Centre of Finland), P.O. Box 1000, FIN-02044 VTT, Finland.

Abstract: E-Famemain is a new kind of a tool for benchmarking, which is based on many years' research efforts. It helps to evaluate users' performance in operations and maintenance by making industrial plants comparable with the aid of statistical methods. The system is updated continually and automatically. It carries out automatically multivariate statistical analysis when data is entered into the system, in addition to many other statistical operations. The system consists of four sections: data input section, positioning section, locating differences section and best practices and planning section.

Key Words: Maintenance, Benchmarking, Overall Equipment Effectiveness, Availability, Maintenance Costs,

1 INTRODUCTION

The success of the maintenance function can be evaluated (simplifying) with the aid three factors: the product of maintenance efforts, cost-effectiveness of maintenance function and the quality of maintenance processes. The product of the maintenance activities can be measured e.g. with the aid of overall equipment effectiveness (OEE), availability or reliability of the machinery. Typical measures for the cost-effectiveness of the maintenance function are 'maintenance costs in relation to plant replacement value' or 'maintenance costs in relation to production volume'. The quality of the maintenance processes can be evaluated with such indicators as planning rate, customer satisfaction, employee satisfaction, accident rate or hazard rate etc. The significance of machinery's availability performance and overall cost-effectiveness has increased because of the harder competition in many industrial branches. This trend has caused a demand for a higher OEE- level and higher efficiency requirements.

According to the management of many industrial enterprises, 'benchmarking' is a powerful tool for the development of the plant operations. However, among many problems concerning benchmarking one challenge is to make companies or plants comparable. This challenge is sometimes used as an excuse to explain away the worse ranking in a comparison. In this paper, we describe the system of benchmarking, which aims to make various production units comparable with the aid of statistical methods based on many years' theoretical and empirical research. The positioning of the production systems is one of the instruments introduced in this paper, but the other tools lean also on the results of the positioning tool.

Obviously the business environment, cost structure and technology of any production system may have a remarkable impact on the content and level of availability requirements. In the capital-intensive industry usually the high utilisation (operating) rate of the production equipment is needed for profitable operations. Also, low profit margins put pressure on increasing the production volume, which again increases the need for the higher utilisation rate and availability. The strategy of the company may also have a significant impact on availability requirements (Komonen 2006) [1].

Costs to maintain a required availability level vary also depending on the industrial sector and specific features of the plants in question. It is often beyond the scope of the production and maintenance management's determining power to influence in the short run, for example, the lack of scale economies. The same applies to the operating rate of the production equipment (e.g. Komonen 1998, 2002a, 2002b, 2006) [2,3,4,1]. Similar empirical studies are not too rich. However, there are some interesting papers concerning the business and technological determinants of maintenance expenditures e.g. Swanson 1997 and 2001 [5,6] and Bhat 2000 [7].

When determining the required input and output, there is always a trade off situation with maintenance efforts and OEE or availability. Therefore it would be very important to know the total costs of availability performance or to have the tool to make compound analyses. In certain circumstances it may be more profitable to decrease maintenance costs than to improve OEE level.

2 SOME VIEWS ON THE USE OF PERFORMANCE INDICATORS

One of the important tools for asset management is the system of the performance indicators. It is needed at all the levels of asset management. Often the systems of the key indicators are lists, which are grouped according to subject matters but not in any way linked to each other. Surely, there are classifications which aim to organise the performance indicators into various classes such as economic, organisational and technical. The aim of this chapter is to introduce the system of maintenance key indicators, which supports the building of a benchmarking system. This system helps a user to grasp the purpose and significance of various key figures.

The simplified system of the performance indicators can be classified in a hierarchical manner. The following structure is the modified version of those presented earlier by Komonen (e.g. 2002b) [4].

- business-oriented objectives
    1. first level objectives of production
    2. second level objectives of production
    3. objectives for maintenance
    4. exogenous factors for production and maintenance (external factors)
    5. intermediate internal objectives for maintenance (follow-up variables)
    6. action variables of maintenance function (means for improvement)
    7. internal descriptive (explanatory) variables

Such **fundamental business goals** as ROI, life cycle profits or profit margin belong to the top level of hierarchy. The following level of objective variables contain **the first level objectives of the production function** as 'total lost production opportunities', which stands for lost production in money terms due to external disabled time and downtime due to production and maintenance down time. Other objectives at this level may be 'turnover of capital' or 'availability performance costs' (unavailability costs plus maintenance costs). The following level of the performance indicator system is **the second level objectives of the production system**. This category has been split into three objective areas: overall equipment efficiency (OEE), the costs of the production system and the quality of the production processes. **The maintenance objectives** are metrics for the performance of maintenance operations: e.g. availability of machinery due to maintenance, sum of unavailability costs and maintenance costs ("dependability costs") or maintenance costs as a % of the estimated plant replacement value (PRV). **Exogenous independent factors** are indicators, which help management to evaluate the state of technology or business environment and at the same time are beyond the scope of production or maintenance managers to determine, but which have a considerable impact on the other objectives. Examples of this kind of factors are the utilisation rate of the production machinery, production volume, the size of the production equipment, the integration level of the production process etc. **Intermediate internal objectives** are performance indicators which should be measured and followed up since they may give more information about the development needs and may act as intermediate objective variables in order to reach the main objective.

Table 1. The O&M focused system of the plant level asset management indicators

Fundamental business objectives	*First level objectives of production*	*Second level objectives of production*	*Maintenance objectives*	*Exogenous Factors*	*Intermediate objectives*	*Means, action variables*	*Descriptive variables (internal explanatory)*
	Total lost production opportunities (€)	*OEE*	e.g. * availability * performance rate * quality rate	e.g. *operating rate * technology * integration level * capital intensity	e.g. * MTTF * MWT * MTTR * MTTM	e.g. * preventive maint. * planned maint. * spare parts * contracting rate	e.g. * inventory turnover * proportion of mehanical maintenance
**ROI, BSC,* **Growth,* * *Market share etc.*	*Production dependability costs (unavailability costs+upkeep costs)*	*Production costs*	e.g. * maintenance costs / PRV * maintenance costs / output	e.g. * operating rate * technology * scale * integration rate * capital intensity	e.g. * MRT * MTTR * MTTM * flexibility * spares / PRV	e.g. * preventive maint. * planned maint. * contracting rate	* material costs * allocated hours * unit labor costs * maintenance costs/ plant turnover
	Turnover of capital	*Quality of production processes*	e.g. * internal customer satisfaction * planning rate * job satisfaction	e.g. * technology * structure of production system	e.g. * MWT * MTTM * Accidents * Absenteeism * Claims	e.g. * feedback to clients * multi-skilled workers * keeping promises * improvement maintenance	e.g. * age structure of personnel

For example, the mean time to restoration (MTTR) is an intermediate objective when the main objective is to minimise downtime costs. These variables are objectives, because a production or maintenance manager cannot influence them directly. **The action variables of the maintenance function** are tools of the production or maintenance managers, with the aid of which objectives are achieved. Preventive and improvement maintenance, outsourcing, operator maintenance etc. are good examples of these tools. **Internal descriptive (explanatory) variables** give additional information, for example, about the cost and organisation structure, cost level and capital intensity of the maintenance function.

Although the above mentioned performance indicators cover partly both the production and maintenance functions, the main focus is on maintenance activities. The system of the key figures could be illustrated by several centric zones (Komonen 2002a) [3], but here a matrix presentation is applied. The results presented in Table 1 are examples. The table does not include all the possible indicators. Owing to lack of space some variables are in the form of a ratio and some in the form of a concept. However, for all the variables presented it is possible to construct an indicator in the form of a ratio or a value.

2.1 Exogenous factors a priori

The top management of the companies should be interested in the structural causes (exogenous factors) of the maintenance product and cost level in order to develop the operations of the company. The maintenance management should be interested in the impact of the exogenous factors in order to draw correct conclusions concerning the maintenance function when using benchmarking.

In the studies mentioned before, multiple regression analyses were used to estimate the causalities between the exogenous factors and the key performance indicators (objectives). Logarithmic forms of the variables were often needed in the analyses, because the model to be estimated was non-linear. Logarithmic transformations have also other statistical and mathematical advantages (e.g. estimated parameters measure the elasticity of the variables). The explanatory power of the models (adjusted R^2) was high (mainly between 40% and 90 %) and the estimated parameters were statistically highly significant (e.g Komonen 1998, 2002a, 2006) [2,3,1].

As mentioned above, different kinds of production units or plants can be made comparable with the aid of exogenous factors. Thus, for example, objectives such as 'overall equipment effectiveness' (OEE) or availability are dependent on the external factors, which cannot be influenced in a short time span. Examples of the exogenous factors can be a priori the following variables (the signs + and – indicate the direction of the impact):

- integration level of the production system (+)
- operating rate and /or shift work rate (+)
- technical capital intensity (plant turnover / plant replacement value) (+)
- redundancy (+)
- severity of the production environment (+)

In the case of maintenance costs in relation to the equipment replacement value, exogenous factors may be the following:

- integration level of the production system (which has, in practice, often parallel impacts to maintenance costs as replacement value) (-)
- scale (replacement value of the production equipment) (-)
- production volume / production equipment (replacement value) (+)
- shift work rate, operating rate (+)
- industry –dummy variables (industry specific factors) (-, +)

In the case of 'maintenance costs / production volume' the results were similar, but the direction of impact was partly different:

- integration level of the production system (-)
- scale (replacement value of the production equipment) (-)
- production volume / production equipment (replacement value) (-)
- production volume (-)
- industry –dummy variables (industry specific factors) (-, +)

The ratio 'maintenance costs / plant replacement value' tells us how much it costs to maintain a certain type and size of equipment or facility. When using this ratio we should make a difference between the total costs of maintenance and the maintenance costs of the machinery. In certain branches the proportion of real estate of the total fixed capital may vary a lot, and therefore this index may give misleading results, at least, as far as the maintenance costs of the machinery are concerned. Altogether, the problem with the above ratio is the determination of the replacement value. Very often the fire insurance value is a good estimate of replacement value. The advantage of this ratio is that it makes it possible to compare various kinds of plants within or between industrial branches. The disadvantage of this ratio is that it does not take into account the availability of the production equipment

The ratio 'maintenance costs / production volume' takes implicitly into account production losses and both the factors can be defined quite exactly. The disadvantage of this ratio, however, is that very often the output of the production is very difficult to determine physically. Thus, in many branches benchmarking with the aid of this index is difficult. In some branches it may be possible to use substitutes, for example the consumption of energy or raw material. Another challenge is that the production volume is often more flexible than the maintenance costs.

3 EMPIRICAL EVIDENCE CONCERNING EXOGENOUS FACTORS

There exists empirical evidence of the impact of the business environment and technological determinants e.g. on OEE (overall equipment effectiveness), availability and maintenance costs (e.g. Komonen 1998, 2002b, 2006) [2,4,1]. The structure of the production system has an impact on availability requirements as stated above. If a machine is the bottleneck of the production system, it is obvious that availability objectives are higher than in the case of a machine, which is not in the main production line and which has a low operating rate (Komonen 2002) [8]. "An indicator to model almost any production system is the degree of integration (plant replacement value divided by the number of front line production operatives in day shift), which is a multipurpose meter to measure mechanisation rate, continuity of processes and scale economies. Generally speaking, we can state that e.g. in the chemical industry and in the pulp and paper industry the integration level is high and in the manufacture of metal products it is lower. The impact of the degree of integration on the above mentioned performance indicators is demonstrated in Table 2 and is illustrated in Figure 1. The higher the degree of integration of the production systems the higher availability performance they show. The same applies to the planning rate of the maintenance activities" (Komonen 2006) [1]. In Figure 1 the predicted and observed values equal on the diagonal. Cases above the diagonal represent better performance than expected.

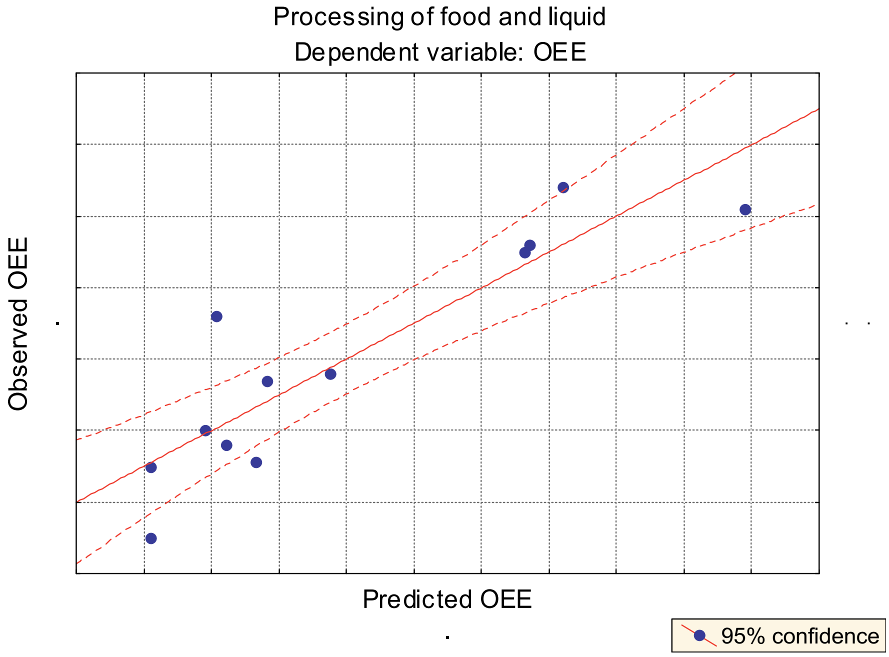

Figure 1. The predicting power of the integration level on OEE in the processing of food (Komonen 2006) [1]

Table 2

The variables having an impact on OEE in the processing of food and liquid (Komonen 2006) [1]

Processing of food and liquid (N=12)		
Dependent variable: OEE		
Adjusted R^2=0,721	$F(3,8)$=10,498	p<,0037
	t(8)	p-level
Intercept	6,608	0,0002
Degree of integration	4,265	0,0027
Production equipment replacement value	-2,183	0,061
Plant turnover / plant replacement value	-1,328	0,221

The relationship between the relative maintenance costs and some exogenous factors concerning the same industry as above is demonstrated in Figure 2. In Figure 2 predicted and observed values equal on the diagonal. Cases below the diagonal represent better performance than expected. The specific impact of various exogenous variables is shown in Table 3.

Table 3

The variables having an impact on the relative maintenance costs in the processing of food and liquid (Komonen 2006) [1].

Processing of food and liquid (N=34)		
Dependent variable: Production equipment, Maintenance costs / Replacement value		
Adjusted R^2= ,542	F(4,29)=10,773	p<,00002
	t(29)	p-level
Intercept	3,865	0,0006
Replacement value	-4,386	0,00014
Degree of integration	-2,275	0,030
Plant turnover / plant replacement value	1,859	0,073

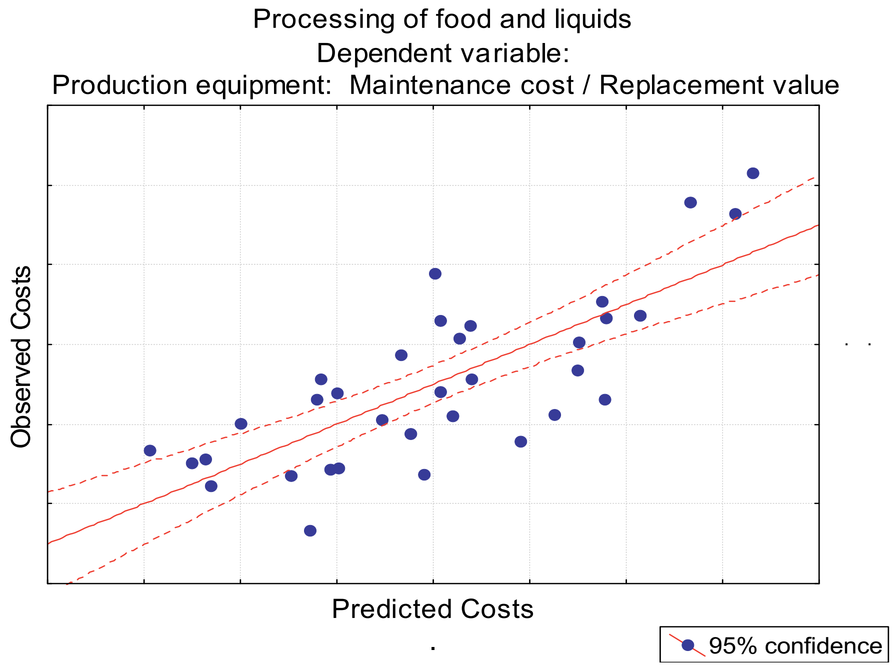

Figure 2. The predicting power of exogenous variables on the relative maintenance costs in the processing of food and liquid (Komonen 2006) [1].

It was interesting to notice that in the processing of food and liquid, the variables explaining maintenance costs were parallel to the variables explaining variation in OEE, although the direction of the influence was not always the same. However, in the first case the replacement value was the most significant indicator.

The results presented above offer an opportunity to judge whether a plant in question has been successful or less successful. This evaluation can be carried out with the aid of a two by two table illustrated in Figure 3. In Figure 3 the measure for production effectiveness is availability instead of OEE. The deviation of availability from the diagonal has been presented on the vertical axis and the deviation of maintenance costs from the diagonal on the horizontal axis. In the case of the upper right-hand corner the plant in question is obviously successful, and in the opposite corner unsuccessful. In the case of the upper left-hand corner, a good strategy may be to concentrate on maintenance costs keeping availability at the present level. The lower right-hand corner represents a situation where a good option would be to focus on the availability of the production equipment.

The ultimate goal surely is that managers would be able to calculate the dependability (availability performance) costs of plants. Therefore, at least, unavailability costs, maintenance costs and investments on availability performance should be included. However, in practice, usually maintenance costs and availability as a time concept (%) has been followed. When optimising maintenance operations there is always a trade off situation with maintenance efforts and availability. Therefore it would be very important to know the total costs of availability performance.

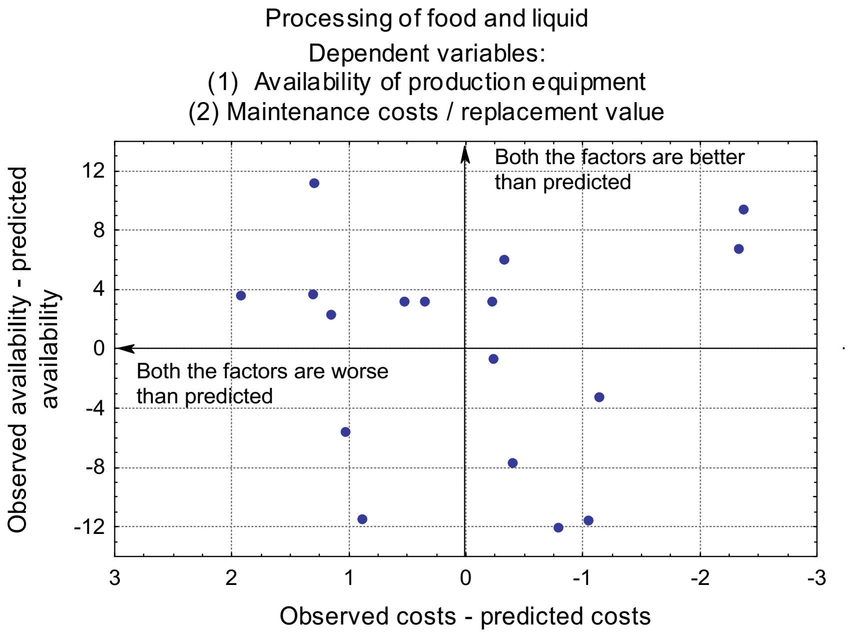

Figure 4. Positioning of availability and maintenance costs (Komonen 2006) [1]

Total costs are, however, very seldom calculated. As an example, the correlation between the total availability performance costs and utilisation rate of the production equipment has been illustrated in Figure 5 (Komonen 2002) [4]. The causality below is empirical and it has been calculated for only one industrial branch. Therefore, the mechanism behind this phenomenon is not clear. However, it can be stated that availability should be high when operating rate is high.

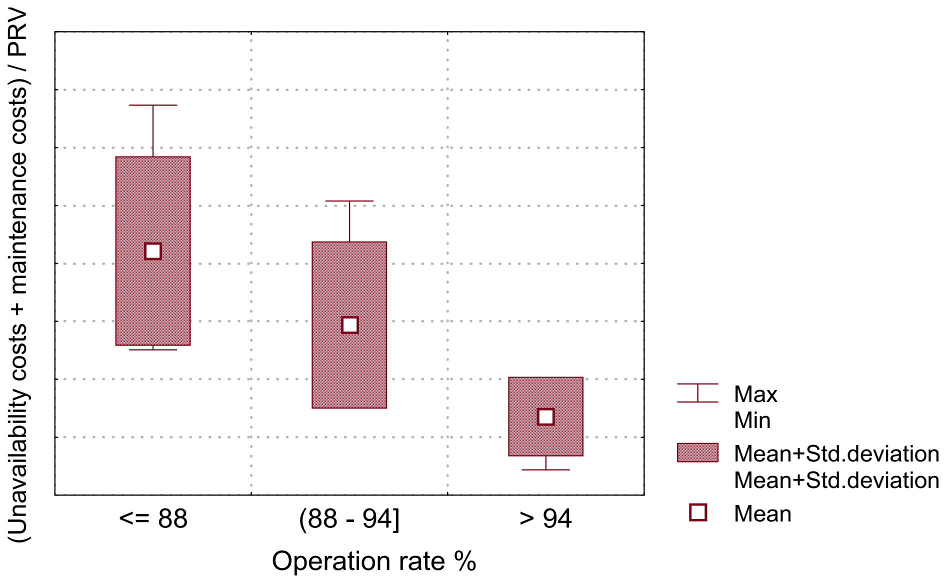

Figure 5.Relationship between the total availability performance costs and the utilisation rate of the production equipment.(PRV=Plant Replacement Value)

On the basis of the empirical examination and on the basis of estimated equations, a positioning tool can be produced for various industrial sectors. The commonly applied benchmarking procedure has been the comparison of the average values of the particular industrial sector with the company's own values. However, in the field of industrial maintenance this kind of benchmarking does not help very much. The "owners" of the best figures are too "proud" of their performance and the "owners" of the poor ones are on the brink of despair. According to the results of this research, the above-mentioned average value based methods are inappropriate. Even the misuse of benchmarking values and opportunistic behaviour are possible.

4 WEB TOOL FOR BENCHMARKING

4.1 Use of positioning results

With the aid of positioning results the sample of plants in the benchmarking data-base can be split down into two groups: successful plants and unsuccessful plants. These two groups can be used when trying to identify causes for successful or less successful performance of the individual plant.

Applying positioning to all the cases in the sample it is possible to compare industry-wise the plant's mode of operations with the average plant or with the successful plants or with the less successful plants. Comparison can be made with the aid of several economic, technical and organisational indicators. Examples of the modes of operations are the amount of operator maintenance, preventive maintenance, contracting and improvements or the use of criticality analyses. By following the techniques introduced above, it is possible to find some hints of which kind of modes of operations lead to successful results. Therefore the proper way to improvements depends on the plant's present results and present mode of operations.

As soon as the differences in the modes of operations have been identified it is possible to investigate which modes of operations are effective and which are not. The benchmarking tool introduced below is based on the above mentioned research results concerning both positioning and successful modes of operations.

4.2 General description of benchmarking system

The benchmarking system consists of four sections or tools. (1) 'Data input section' is an electronic form to insert the data of the plant in the database. An incorporated test tool will give the user a notice in the case of the most probable mistakes. (2) In the 'positioning section' there is an option to evaluate the success of the plant's maintenance function branch-wise (by industrial sector) with the aid of several indicators such as OEE, availability of machinery, production losses due to maintenance, maintenance costs as a percentage of estimated plant replacement value and many other. In the 'locating differences section' it is possible to compare the plant's mode of operations with the successful plants, with the less successful plants and with an average plant in the industrial sector in question. Comparison can be made with the aid of several economic, technical and organisational indicators. In the 'best practices and planning section' the user of the benchmarking system may find more hints of which kind of the mode of operations leads to successful results. The structure of the tool is illustrated in Figure 6.

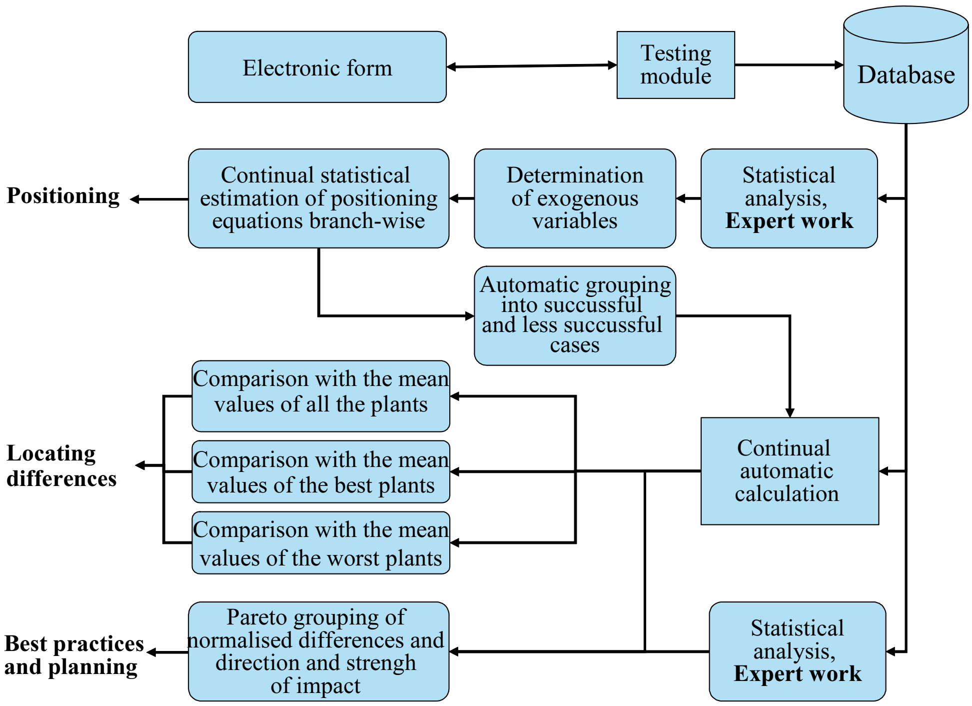

Figure 6. Schematic description of the benchmarking system

The system is automatic and runs all the automatic calculations recieving commands from the username and password entered in the system. All the needed calculations are carried out when changes occur or the user commands to execute any task. Simulations are also possible options, for example, for planning purposes. The determination of the variables, which should be taken into account when the system executes automatic multivariate analyses for the positioning, is an expert's job. The same applies to the determination of the impact (direction and strength) of the modes of operations on the selected objectives. The users of the system are able to see only their own data and statistical key figures concerning the industrial branch in question.

4.3 Detailed description of various tools of the benchmarking system

The web-tool for benchmarking consists of four sections.

"Data input section" serves the user with an electronic form to insert data concerning the plant's maintenance function. An incorporated test tool will give the user a notice in the case of the most probable mistakes. Data entered by the user is a precondition for the broader use of this benchmarking system. Data input sheet is illustrated in Figure 7.

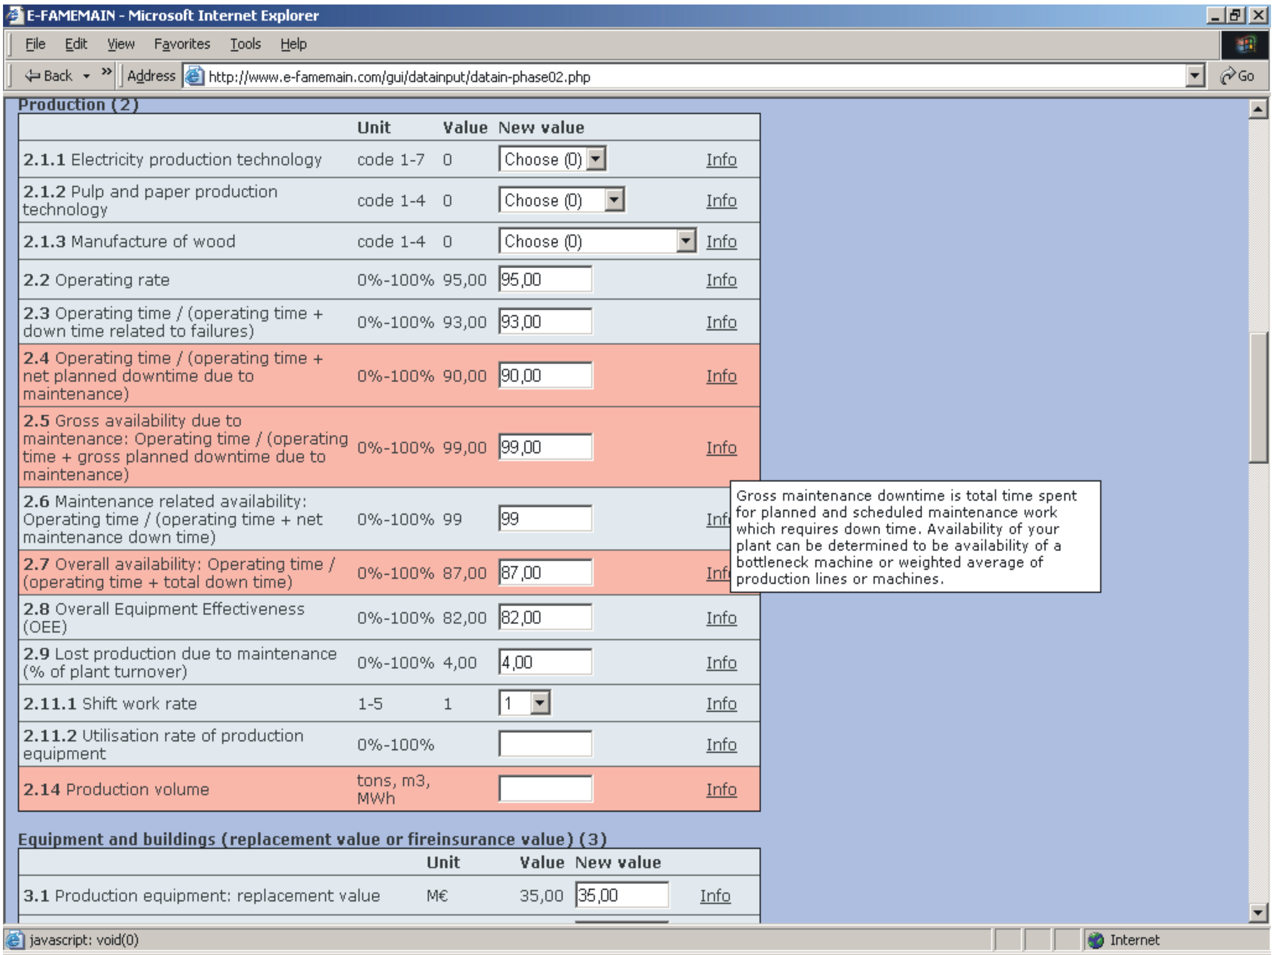

Figure 7. The illustration of the data input page

In the **"positioning section"** the users are able to evaluate the success of their maintenance function branch-wise (by industrial sector) with the aid of several indicators such as availability of machinery, production losses due to maintenance, maintenance costs as a % of the estimated plant replacement value and many other. The above mentioned indicators are affected by several exogenous factors which are beyond the scope of the plant management or maintenance managers to determine, but still they have a considerable impact on the performance indicators. Examples of exogenous factors are process severity, plant size, utilisation rate, age of the plant, technology. These factors are taken into account when evaluating one's success with the aid of multivariate statistical models. The conclusion page of the positioning section is illustrated in Figure 8.

As stated earlier in the positioning section, various plants are made comparable with the aid of exogenous factors. The benchmarking tool will take care of this analysis automatically for the user. The developed software calls plants' data from the data base, takes into account influencing factors and calculates for the users an expected, predicted value for each performance indicator the users have chosen. Users can also make simulations, how things would change if they were able to change factors which are or are not under their own control. This benchmarking software also groups all plants into successful and less successful subgroups.

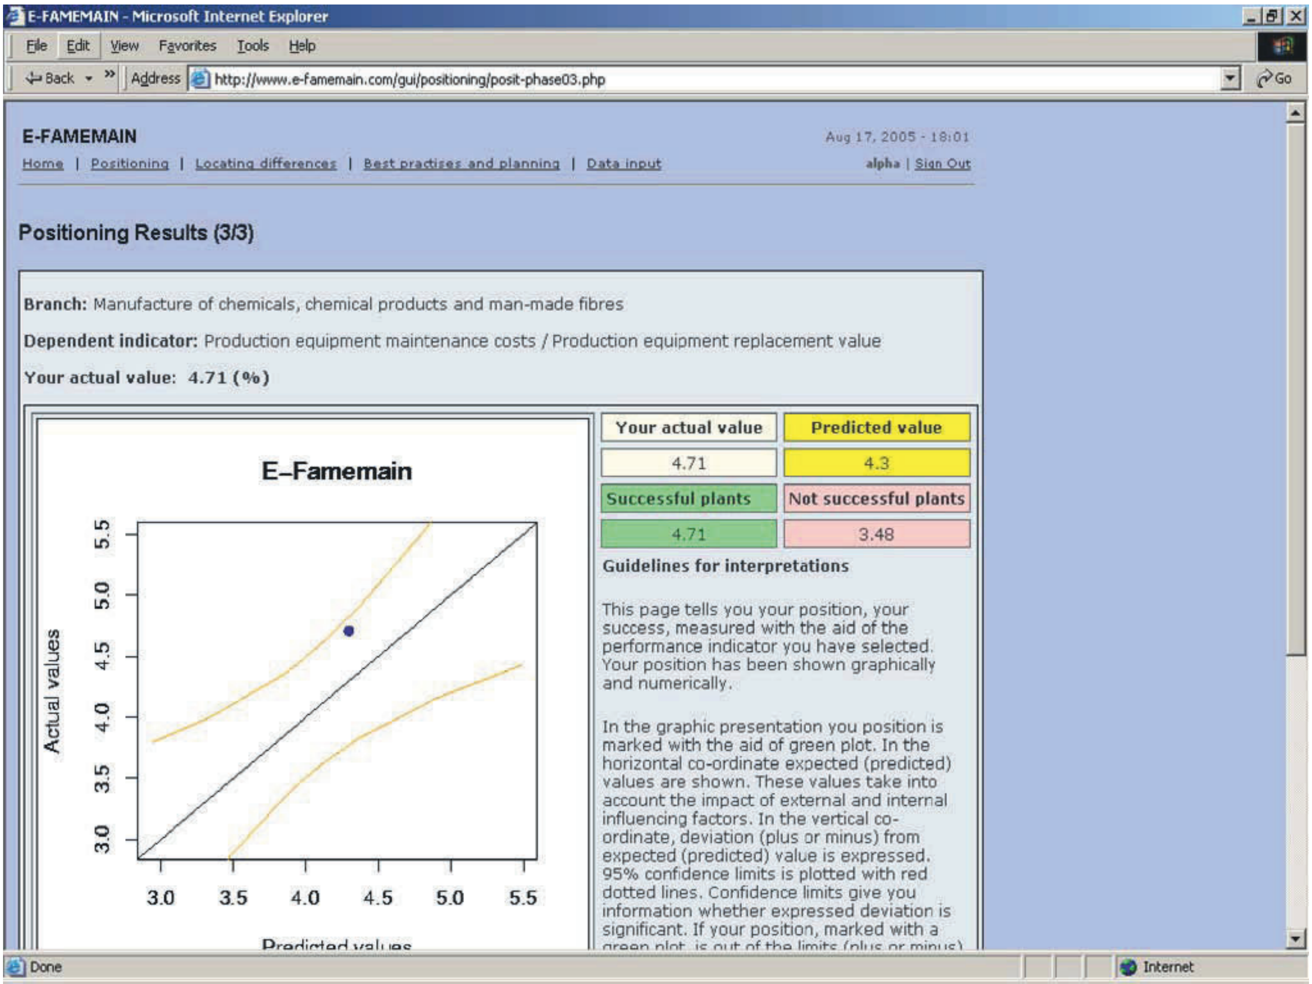

Figure 8. The conclusion page of positioning

The above page tells the users their position, their success, measured with the aid of the performance indicator they have selected. Their positions are shown graphically and numerically. In the graphic presentation their positions are shown as a green plot. The horizontal co-ordinate shows predicted values. These values take into account the impact of the external and internal influencing factors (exogenous factors). The vertical co-ordinate shows the actual values of users. 95% confidence limits are plotted as red lines. The confidence limits indicate whether the expressed deviation is significant. The position of the green plot marking plant's performance can be changed by using the simulating tool in the previous page.

In the **"locating differences section"** the user is able to compare the plant's mode of operations with the successful plants, with the less successful plants and with an average plant in the industrial sector in question. Comparison can be made with the aid of several economic, technical and organisational indicators. The conclusion page of "locating differences section" is illustrated in Figure 9.

The objective of this analysis is to find probable causes for deviations from the expected (predicted) values in the positioning section. The benchmarking tool will take care of this analysis automatically for the user. The software calls all the needed data from the data base and carries out positioning for each case and in this way groups all the cases into successful and less successful subgroups. Finally, the tool calculates means and deviations for the groups of all cases, successful plants and less successful plants and for each performance indicator the user has chosen. Plants' own actual values for the selected indicator is shown as a green plot. The user can also make simulations about how things would change if he would able to change factors which are or are not under his own control.

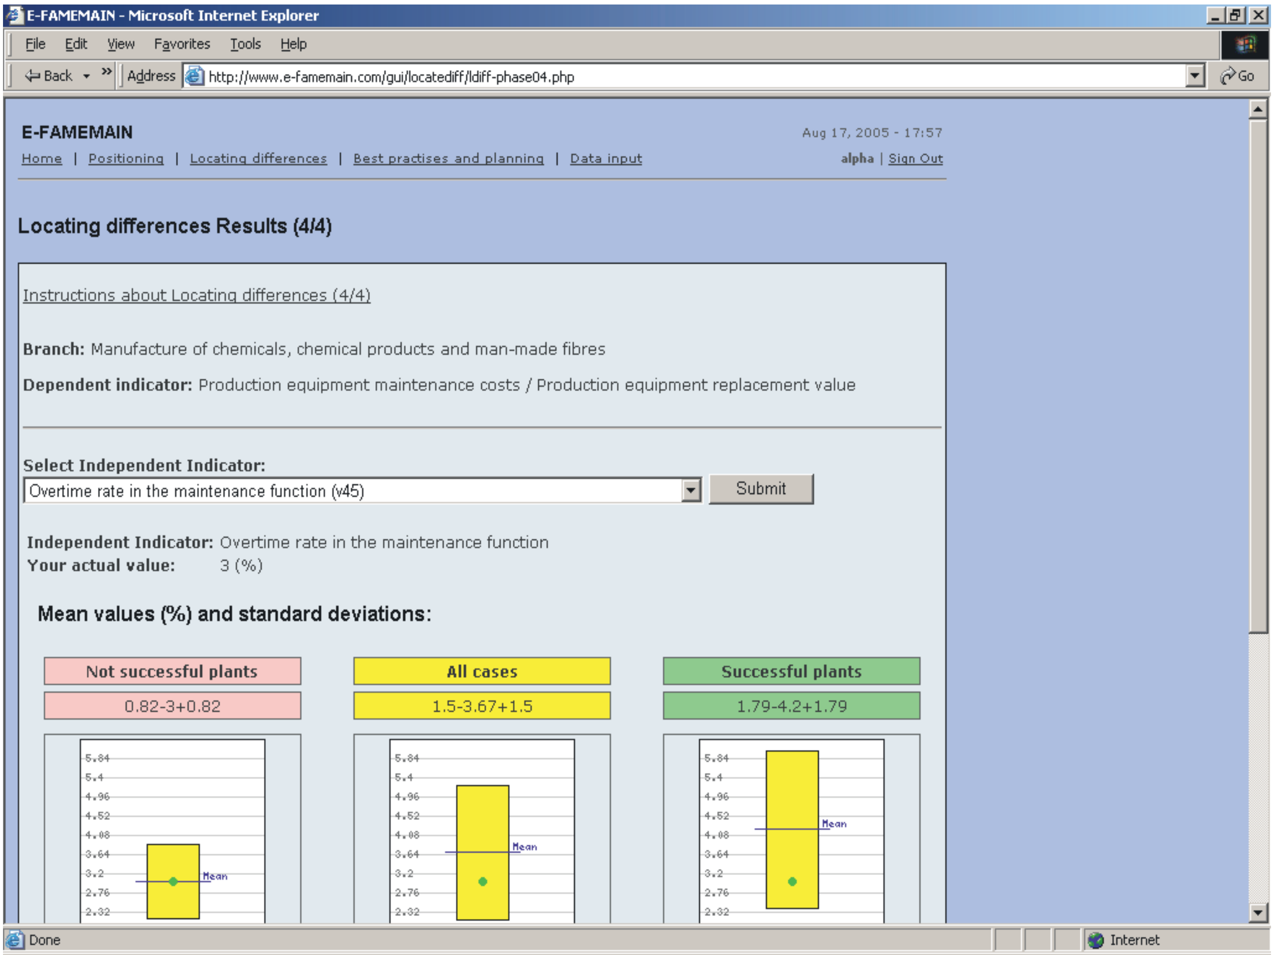

Figure 9. The conclusion page of locating differences

In 'best practices and planning section' the user can find some hints of which kind of a mode of operations leads to successful results. Since the proper way to improvement depends on the user's present results and present mode of operations, this section includes also a management tool to help in the planning process.

The user is able to compare the plant's mode of operations with the successful plants. The comparison is a summary of the 10 largest deviations in the form of Pareto-diagram and the comparison can be carried using several economic, technical and organisational indicators. The objective of this analysis is to find a course of actions which should be carried out in order to improve the performance of the objective variables (e.g. OEE, availability or cost effectiveness). Deviations can have positive or negative values.

Since the statistical performance of the successful companies is based on the results of positioning, those results are presented here once again in order to make the interpretation easier. Thus, the simulation tool is also available in this section. The differences between the mean values of the most successful plants and the users' own indicator values have been normalised. The graphical conclusions are presented in Figure 10. The effect of the indicators in question on the dependent variables (e.g. OEE, availability or cost effectiveness) is indicated in the same table (direction and strength). The causalities between independent and dependent variables are studied using the sample entered into the data base. Clear causalities can not always be identified.

The strength of impact is presented with the aid of five levels: no impact, small influence, medium influence, significant influence and very significant influence. The direction of the effect denotes what happens to an objective value (e.g. availability) if the numerical value of an independent indicator (indicator which depicts the mode of operations) increases.

In the following page the summary of the largest deviations and their influence on the performance indicators are presented in a two by two table. The greatest attention should be focused on the factors which indicate the largest deviations and strongest impact. Further, less attention should be focused on the factors having smaller deviations and smaller impact. If e.g. the availability and maintenance costs are studied simultaneously, the actions needed may be conflicting. In this case, focus should be directed to those activities which have a positive impact on both the factors.

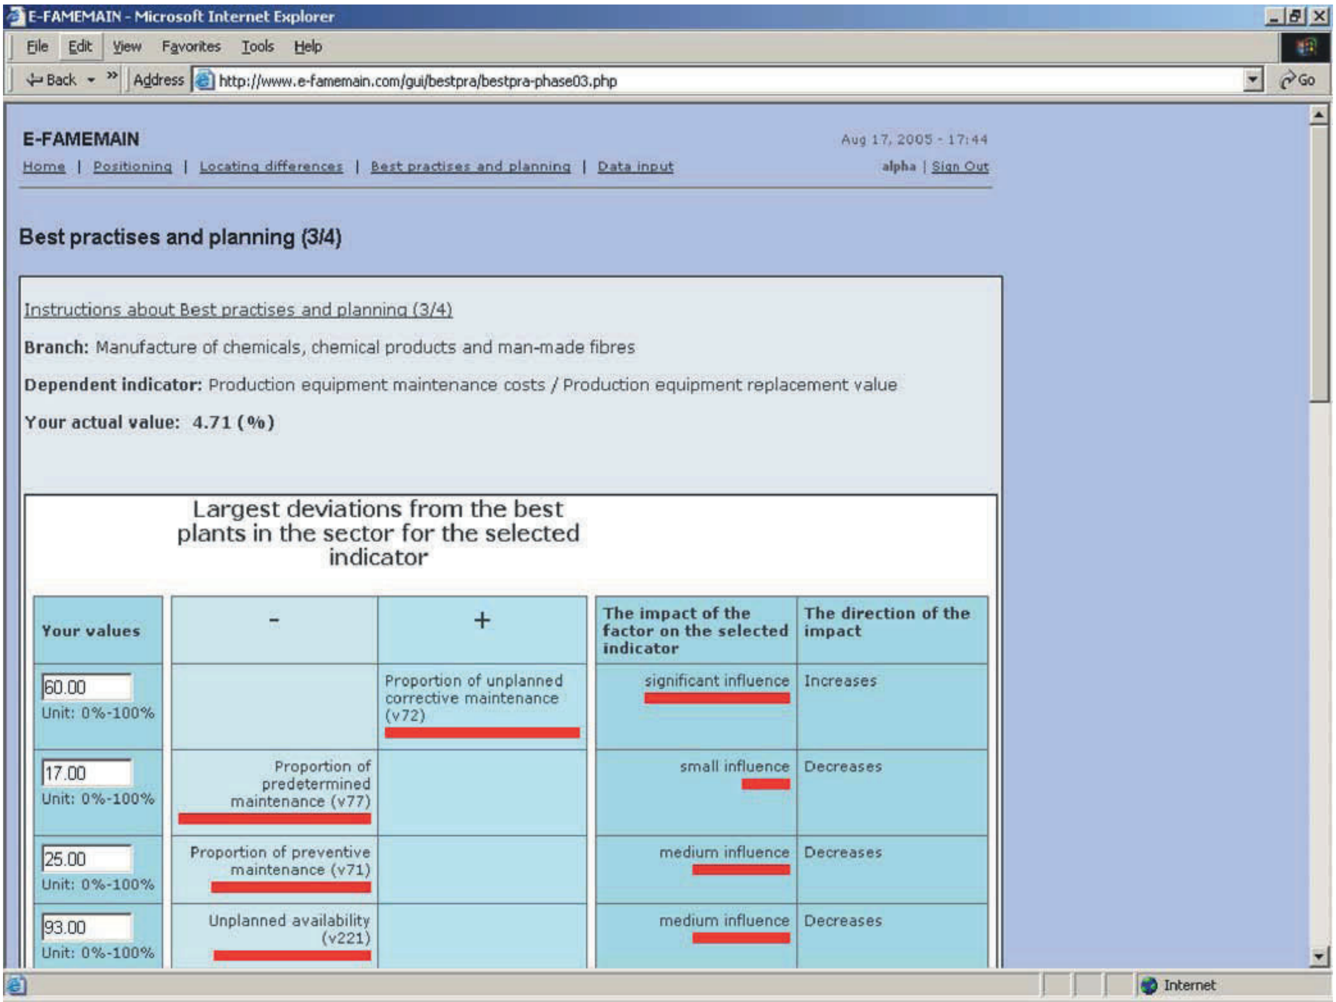

Figure 10. The first conclusion page of the best practices and planning section

5 DISCUSSION

The introduced web benchmarking tool is based on the research concerning causalities between objective variables and exogenous influencing factors, and on the research concerning causalities between the successful plants (determined with the aid of the positioning) and modes of operations determined by action variables such as preventive maintenance or training of personnel. The results of the first mentioned causalities have been clear and the samples have been sufficiently large. However, the latter causalities are not as clear. The main reason here is the strong data erosion due to diverse answering activity to various questions, that is, various indicators.

Regardless of the above mentioned problems some clear results have been achieved. In several industrial branches, the means which improve the product of maintenance activities such as OEE or availability increase the relative costs of the maintenance function and vice versa. Sometimes the results are opposite to expectations. Therefore, the optimisation of the efforts is crucial. The quality of data and sufficient data are also crucial issues when improving benchmarking tools. In empirical research there is always a trade off between the detailed data and the number of cases in a sample. The ability of the companies to deliver data for a large number of sophisticated indicators is limited. The introduced benchmarking system is quantitative in nature. There is surely a need to add qualitative features to the system. However, as soon as the scope of the tool is broadened to the qualitative field there is a need to change the research strategies, and that means challenges in the architecture of the benchmarking tool and also problems in willingness to deliver data.

For the improving the benchmarking system, the use of new performance indicators should be activated. These indicators should facilitate and intensify co-operation between maintenance and operator functions. In order to draw correct conclusions when using those indicators, more research concerning causal relationships between objectives and exogenous factors (and also action variables) should be carried out. These causalities should be used when constructing benchmarking systems and tools. There is also a development process going on to add some new technical features to the system.

6 CONCLUSIONS

The significance of machinery's availability performance and overall cost-effectiveness has increased because of the harder competition in many industrial branches. This trend has caused a demand for a higher OEE- level and higher efficiency requirements. Obviously the business environment, cost structure and technology of any production system may have a remarkable impact on the content and level of availability requirements.

According to the management of many industrial enterprises, 'benchmarking' is a powerful tool for the development of the plant operations. However, among many problems concerning benchmarking one challenge is to make companies or plants comparable. This challenge is sometimes used as an excuse to explain away the worse ranking in a comparison. In this paper, the benchmarking system to avoid this problem has been introduced. The positioning of the production unit seems to work well and the quality of the positioning system has improved during the years of research.

The identification of the best practices has been a harder task because of the strong data erosion caused by inadequate filling of the questionnaires. There is also a trade off situation with maintenance efforts and OEE or availability, which makes it more difficult to draw clear conclusions concerning the effective modes of operations. Therefore, there is still room to make better compound analyses.

The introduced benchmarking tool is the result of more than ten years' systematic research. It leans on the following phases.

(Phase 1) Several years research work on the causalities between various performance indicatos based on the annual data collection in Finland.

(Phase 2) Several years development and standardisation of performance indicators to build up the common system of indicators for benchmarking activities in Europe. The hierarchy of indicators used in the e-Famemain benchmarking system has been designed together with Finnish maintenance society (KPY) and Swedish Maintenance Society (UTEK).

(Phase 3) The development of the first generation bechmarking web tool, which was installed in the year 2000.

(Phase 4) Identification and description of the best practices: causalities between various practices and objective variables, and the development of methods to transfer the research results into the properties of the benchmarking system

(Phase 5) Specification and programming of the web-tool during the years 2004 and 2005.

A METHOD FOR MANAGING THE AVAILABILITY IMPROVEMENT EFFORTS

Barabady J [a] and Kumar U [b]

[a, b] *Division of Operation and Maintenance Engineering, Luleå University of Technology.*

Abstract: Availability is an important characteristic of a repairable system. When the availability of system is low, efforts are needed to improve it. Any improvement in the availability of a system is associated with the requirement of additional effort and cost. Therefore, it is essential to use methods or techniques for availability allocation amongst various components/subsystems of a system with the minimum effort and cost.The concept of importance measures could be used to prioritize the components or subsystems for the availability improvement process. The study shows, it is useful to obtain the availability importance measures value of each component in the system prior to deploying resources towards improving the specific components. With the assistance of importance measures one can identify the components/subsystems that merit additional research and development to improve their availabilities, so that the greatest gain is achieved in the system availability. Each component should be assigned a value and the component with a greater value will have a greater influence on the availability of the system. Generally, the importance of components should be used during the design or evaluation of systems to determine which components or subsystems have the greatest importance for the availability of the system.

Key Words: Availability, Availability importance measures, Failure rate, Repair rate, MTBF, MTTR

1 INTRODUCTION

It is clear that equipment availability continues to be a significant issue for industry. As the size and complexity of equipment continue to be increasing, the impacts of failure become even more critical. One method of mitigating the impact of failure is to improve reliability and availability of a system. Improvement of reliability and availability has been the subject of a large volume of research and a great number of articles have been published in this area [1, 2, and 3]. Availability and reliability are good evaluations of a system's performance. Their values depend on the system structure, as well as on the component availability and reliability. These values decrease as the component ages increase; i.e. their serving times are influenced by their interactions with each other, the applied maintenance policy and their environments [4]. The main requirements for the operation of complex systems are usually specified in terms of cost and availability and/or reliability, or equivalently in terms of mean operating time and/or mean down-time under a cost constraint. These requirements have then to be taken into consideration in the system design stage in order to determine the appropriate reliability and availability of each of the system's components [5].

In a simplistic sense there are some issues to be resolved during the development of an availability improvement or optimization process during design and operation, such as: i) where it is best to attempt improvements in availability, and ii) how to effect improvements in availability when the areas which merit attention have been identified. Finding appropriate answers to these questions, however, can be quite difficult and the solutions to the many problems which result in loss of availability are frequently not obvious. Reliability and availability engineers are often called upon to make decisions as to whether to improve a certain component or components in order to achieve better results. There are two ways to improve availability of repairable system: i) reduce the failure rate of component or components, and/or ii) improve the repair rate of component or components.

In this paper a methodology is defined to manage the availability improvement efforts of a repairable system, which consists of three steps. In order to manage the availability improvement efforts by applying those three steps, the concept of importance measure can be used, therefore some availability importance measures are defined which can be used as a guideline in process. The main objectives of this paper are: i) to define some availability importance measures in order to find the criticality of each components, and ii) to define a methodology for managing the availability improvement efforts.

2 SYSTEM AVAILABILITY DEFINITIONS

Availability is the probability that a system or component is performing its required function at a given point in time or over a stated period of time when operated and maintained in a prescribed manner [6]. Like reliability, availability is a probability. Consider a system (device) which can be in one of two states, namely 'up (on)' and 'down (off)'. By 'up' it is meant that the system is still functioning and by 'down' it is meant that that the system is not functioning. In the latter case the system is being repaired or replaced, depend on whether it is repairable or not. Let the state of the system be given by a binary variable:

$$X(t) = \begin{cases} 1, & \text{if the system is up at time t} \\ 0, & \text{otherwise} \end{cases}$$

An important characteristic of a repairable system is availability. Barlow & Proschan (1975a) [7] define four measures of availability performance: the availability function, limiting availability, the average availability function and limiting average availability. All of these measures are based on the function *X(t)*, which denotes the status of a repairable system at time *t*. The instant availability at time t (or point availability) is defined by:

$$A(t) = P(X(t) = 1) \tag{1}$$

This is the probability that the system is operational at time t. Because it is very difficult to obtain an explicit expression for A(t), other measures of availability have been proposed. One of these measures is the steady system availability (or steady-state availability or limiting availability) of a system, which is defined by:

$$A = Limit_{t\to\infty} A(t) = \frac{MTBF}{MTBF + MTTR} \tag{2}$$

This quantity is the probability that the system will be available after it has been run for a long time, and it is a very significant measure of the performance of a repairable system. If the failure rate and repair rate of system are constant, then the steady state availability can be calculated by equation 3.

$$A = \frac{\mu}{\lambda + \mu} \tag{3}$$

Consider a system which consists of *n* s-independent subsystems connected in series and which fails when at least one of its components fails. The steady-state availability for a series-system is the product of the component availabilities [6, 8].

$$A_s = \prod_{i=1}^{n} A_i = \prod_{i=1}^{n} \frac{MTBF_i}{MTBF_i + MTTR_i} \tag{4}$$

Consider a system which consists of *n* independent subsystems connected in parallel and which works when at least one of its components works. The steady-state availability of a parallel-system is given by equation 5 [6].

$$A_s = \coprod_{i=1}^{n} A_i = \coprod_{i=1}^{n} \frac{MTBF_i}{MTBF_i + MTTF_i} = \coprod_{i=1}^{n} \frac{\mu_i}{\mu_i + \lambda_i} = 1 - \prod_{i=1}^{n}\left(1 - \frac{MTBF_i}{MTBF_i + MTTFR_i}\right) \tag{5}$$

Consider a system which consists of *n* independent subsystems connected in series and each subsystem consists of m component, the steady-state availability for a series-parallel system is given by

$$A_s = \prod_{K=1}^{n}\left(1 - \prod_{l=1}^{m} 1 - A_{km}\right) \tag{6}$$

3 AVAILABILITY IMPORTANCE MEASURES

The concept of importance measures came from the perception that in any orderly arrangement of components in a system, some of the components are more important than others in providing certain system characteristics. In order to evaluate the importance of different aspects of a system, a set of importance measurements, including Structure Importance, Birnbaum Component Importance, Reliability Criticality Importance, Upgrading Function, Operational Criticality Importance, and Restore Critically Index [9, 10, 11] have been well defined and widely used in engineering practice. Birnbaum first introduced the concept of importance in 1969 and one of the most widely used reliability importance indices is Birnbaum's component importance [10]. The component reliability importance measure is defined as: probability that component i is critical to system failure [12]. The reliability importance of a component can be determined based on the failure characteristics of the component and its corresponding positioning in the system. The reliability importance measure of component i in a system of n components is given by

$$I_A^i = \frac{\partial R_s(t)}{\partial R_i(t)} \tag{7}$$

$R_S(t)$ is the system reliability, and Ri (t) is the component reliability.

It was found that the reliability importance of a component is a function of time and it is useful to obtain the reliability importance value of each component in the system prior to investing resources toward improving specific components. This is done to determine where to focus resources in order to achieve the most benefit from the improvement effort. If the reliability of the system needs to be improved, then efforts should first be concentrated on improving the reliability of the component that has the largest effect on reliability.

By using the same concept in the case of system availability performance, some importance measures can be defined and used as a guideline for developing an improvement strategy. One motive for applying this concept of importance measures in the availability improvement process is the fact that the concept is easy to understand and the applications of these measures are very simple. In this study the availability importance of a component is defined as a partial derivative of the system availability with respect to this component availability. Analyses of these measures for a numerical example are performed and the results are presented. Availability Importance Measures are function of operating time, the failure rate, the repair rate, and the system structure and it is useful to obtain the availability importance measure value of each component in the system prior to deploying resources toward improving the specific components. This is done to determine which component needs to be improved in order to achieve the maximum effect from the improvement effort. The availability importance of component i in a system of n components is given by

$$I_A^i = \frac{\partial A_s}{\partial A_i} \tag{8}$$

Availability importance measure shows that the effect of availability of component i on the availability of the whole system. The subsystem with the largest value has a greatest effect on the availability of the whole system. If the availability of the system needs to be improved, then efforts should first be concentrated on improving the subsystem that has the largest effect on the availability of system. The availability of a system is a function of Mean Time between Failures (MTBF)and Mean Time to Repair (MTTR). Therefore two other set of importance measures can be define in order to find to manage the availability improvement process for each component based on the MTBF or MTTR.

Availability importance measure based on the MTBF shows the effect of the MTBF of subsystem i on the availability of the whole system, and the subsystem with the largest value has the greatest effect on the availability of the whole system. It can be calculated by

$$I_{A,MTBF_i}^i = \frac{\partial A_s}{\partial A_i} \times \frac{\partial A}{\partial MTBF_i} \tag{9}$$

Availability importance measure based on the MTTR shows the effect of the repair rate of component i on the availability of the whole system, and the subsystem with the largest value has the greatest effect on the availability of the whole system. It can be calculated by

$$I_{A,MTTR_i}^i = -\frac{\partial A_s}{\partial A_i} \times \frac{\partial A}{\partial MTTR_i} \tag{10}$$

If the failure rate and repair rate are constant, then availability importance measure based on repair rate and availability importance measure based on repair rate can be used instead availability importance measure based on MTBR and availability importance measure based on MTTR.

$$I_{A,\lambda_i}^i = -\frac{\partial A_s}{\partial A_i} \times \frac{\partial A}{\partial \lambda_i} \tag{11}$$

$$I_{A,\mu_i}^i = \frac{\partial A_s}{\partial A_i} \times \frac{\partial A}{\partial \mu_i} \tag{12}$$

Comparing these two importance measures shows which of the two importance measures, the MTBF of The MTTR, has more influence on the availability of the whole system. In other words, this comparison will show whether the availability improvement should be based on reducing the MTTR or increasing the MTBF of critical components or subsystems.

3.1 Availability importance measures for a series system

The availability importance measures consider a series system in section 2 can be calculated by equation 13, 14 and 15.

$$I_A^i = \frac{\partial A_s}{\partial A_i} = \prod_{\substack{k=1 \\ k \neq i}}^{n} A_k \tag{13}$$

$$I_{A,MTBF_i}^i = \frac{\partial A_s}{\partial A_i}\frac{\partial A_i}{\partial MTBF_i} = \prod_{\substack{k=1 \\ k \neq i}}^{n} A_k \times \frac{MTTR_i}{MTBF_i(MTBF_i + MTTR_i)} \times A_i = A_s \times \frac{MTTR_i}{MTBF_i(MTTR_i + MTBF_i)} \tag{14}$$

$$I^i_{A,MTBF_i} = -\frac{\partial A_s}{\partial A_i}\frac{\partial A_i}{\partial MTTR_i} = \prod_{\substack{k=1 \\ k\neq i}}^{n} A_k \times \frac{1}{(MTBF_i + MTTR_i)} \times A_i = A_s \times \frac{1}{(MTTR_i + MTBF_i)} \tag{15}$$

3.2 Availability importance measures for a parallel system

The availability importance measures consider a parallel system in section 2 can be calculated by equation 16, 17 and 18. Equation 15 shows that the availability of a component doesn't affect on the availability importance measure of its component in a parallel system.

$$I^i_A = \frac{\partial A_s}{\partial A_i} = 1 - \prod_{\substack{k=1 \\ k\neq i}}^{n} A_k \tag{16}$$

$$I^i_{A,MTBF_i} = \frac{\partial A_s}{\partial A_i}\frac{\partial A_i}{\partial MTBF_i} = 1 - \prod_{\substack{k=1 \\ k\neq i}}^{n} A_k \times \frac{MTTR_i}{MTBF_i(MTBF_i + MTTR_i)} \times A_i \tag{17}$$

$$I^i_{A,MTTR_i} = -\frac{\partial A_s}{\partial A_i}\frac{\partial A_i}{\partial MTTR_i} = 1 - \prod_{\substack{k=1 \\ k\neq i}}^{n} A_k \times \frac{1}{(MTBF_i + MTTR_i)} \times A_i \tag{18}$$

3.3 Availability importance measures for a series-parallel system

The availability importance measures consider a parallel system in section 2 can be calculated by equation 17, 18, and 19.

$$I^{ij}_A = \frac{\partial A_s}{\partial A_{i,j}} = \prod_{\substack{k=1 \\ k\neq i}}^{n} \left(1 - \prod_{l=1}^{m}(1 - A_{kl})\right) \times \left(1 - \prod_{\substack{l=1 \\ l\neq j}}^{m} A_{il}\right) \tag{19}$$

$$I^{ij}_{A,MTBF_{ij}} = I^{ij}_A \times \frac{MTTR_{ij}}{MTBF_{ij}(MTBF_{ij} + MTTR_{ij})} \times A_{ij} \tag{20}$$

$$I^{ij}_{A,MTTR_{ij}} = I^{ij}_A \times \frac{1}{(MTBF_{ij} + MTTR_{ij})} \times A_{ij} \tag{21}$$

Equations 13, 16, and 19 are shown that the availability of a component doesn't affect on the availability importance measure of that component. In other words the availability importance measure of component depends on the availability of other component in the system and also the position of that component in system configuration.

4 AVAILABILITY IMPROVEMENT PROCESS

Availability is an important characteristic of a repairable system. When the availability of a system is low, efforts are needed to improve it. The question of how to meet an availability goal for a system arises when the estimated availability is inadequate. This then becomes a reliability and availability allocation problem at the component level. There are two ways to improve the availability of a repairable system, i) reduce the failure rate of the component in question or, in other words, increase the mean time between failures, and/or ii) improve the repair rate of the system, structure or component (SSC), or, in other words, reduce the mean down-time.

In the present research it is found that the availability improvement process could be implemented by following three steps:

Step 1: Identification of an ordered list of candidates for the availability improvement process.

Step 2: Identification of effective changes or remedial actions for each candidate, which will either reduce its failure frequency or reduce the time required to restore a component.

Step 3: Justification and prioritization of the actions for each candidate on the basis of cost-benefit comparisons.

In order to find the availability improvement strategy by applying these three steps, the concept of importance measures is used in this paper. One motive for applying this concept of importance measures in the availability improvement process is the fact that the concept is easy to understand and the applications of these measures are very simple. In step one an ordered list of candidates for availability improvement can be identified by using of the availability importance measure, but this measure does not provide more information about a component. Therefore, in step two the availability importance measure based on MTBF and the availability importance measures based of MTTR for each component must be used. Comparing the two importance measures shows which of the two factors, MTBF or the MTTR, has more influence on the availability of the whole system. In other words, this comparison will show whether the availability improvement should be based on reducing the failure rate or increasing the repair rate of critical components or subsystems.

To find the final strategy for the availability improvement process (step 3) the cost trade-off is essential. When the availability of the system is less, it needs to be improved by using the special budget C. The question is how to manage improvement efforts and which component or components, if improved, will give better results. This question can be answered through the following procedure. The cost needed to change the failure rate, denoted by $\Delta\lambda_i$, and the cost needed to change the repair rate, denoted by $\Delta\mu_i$, can be calculated by using equations 9 and 10.

$$\Delta C_{\lambda_i} = \frac{\partial C}{\partial \lambda_i} \times \Delta\lambda_i \tag{22}$$

$$\Delta C_{\mu_i} = \frac{\partial C}{\partial \mu_i} \times \Delta\mu_i \tag{23}$$

$\frac{\partial C}{\partial \lambda_i}$ and $\frac{\partial C}{\partial \mu_i}$ explain the variation of the availability improvement cost with respect to the failure rate and the repair rate of component i, respectively.

If budget C is spent on increasing the repair rate for the critical components, the repair rate will increase as $\Delta\mu_i$:

$$\Delta\mu_i = \frac{\Delta C_{\mu_i}}{\frac{\partial C}{\partial \mu_i}} = \frac{C}{\frac{\partial C}{\partial \mu_i}} \tag{24}$$

Therefore the availability will increase as $\Delta A_{s,\mu_i}$, which can be calculated by

$$\Delta A_{s,\mu_i} = I^i_{A,\mu_i} \times \Delta\mu_i = \frac{\partial A_s}{\partial \mu_i} \times \frac{C}{\frac{\partial C}{\partial \mu_i}} \tag{25}$$

If the budget is spent on reducing the failure rate of the critical component, the failure rate will be reduced as $\Delta\lambda_i$:

$$\Delta\lambda_i = \frac{\Delta C_{\lambda_i}}{\frac{\partial C}{\partial \lambda_i}} = \frac{C}{\frac{\partial C}{\partial \lambda_i}} \tag{26}$$

Therefore, the availability will be increased as $\Delta A_{s,\lambda_i}$, which can be calculated by:

$$\Delta A_{s,\lambda_i} = I^i_{A,\lambda_i} \times \Delta\lambda_i = \frac{\partial A_s}{\partial \lambda_i} \times \frac{C}{\frac{\partial C}{\partial \lambda_i}} \tag{27}$$

By comparing $\Delta A_{s,\lambda_i}$ and $\Delta A_{s,\mu_i}$ the strategy can be identified. If there are some restrictions, the budget can be spent on both increasing the repair rate and decreasing the failure rate. We then allocate a fraction *f* of the budget for decreasing the failure rate and the remaining fraction *1-f* for increasing the repair rate. And hence the availability improvement can be calculated by:

$$\Delta A_{s,\lambda_i,\mu_i} = \frac{\partial A_s}{\partial \lambda_i} \times \frac{fC}{\frac{\partial C}{\partial \lambda_i}} + \frac{\partial A_s}{\partial \mu_i} \times \frac{(1-f)C}{\frac{\partial C}{\partial \mu_i}} \tag{28}$$

5 CASE STUDY

To illustrate the model, we use a case study of a crushing plant in Bauxite mine of Iran. The crushing plant is divided into six subsystems and all subsystem work in series system which means the crushing plant is in working state if all subsystems work. The best fit distributions for all subsystem of the crushing plant are calculated by using Weibull ++6 based on historical data form the period of one year. Table 1 shows the best-fit distribution for Time between failures data and also for Time to Repair data for all subsystem of the crushing plants.

Table1. Best-fit distribution and thire parameters for TBF and TTR data sets

Sub-system	Time Between Failures		Time to Repair data	
	Best-Fit	Parameters	Best-Fit	Parameters
PCRCS (Primary Crusher)	Weibull 3 P	Beta=1.34, Eta=78.6,Gamma=3.873	Lognormal	Mean=0.4638, Std=0.922
SCRCS (Secondary	Weibull 3 P	Beta=1.115, Eta=78.96, Gamma=8.931	Lognormal	Mean=0.720, Std = 1.515
PSCCS (Primary Screen)	Lognormal	Mean= 3.373, Std = 1.1421	Weibull 2 P	Beta= 1.4998, Eta = 1.5843
SSCCS (Secondary Screen)	Lognormal	Mean= 3.868, Std = 1.101	Lognormal	Mean=0.10, Std = 1.021
COCS (Conveyer	Lognormal	Mean= 3.18, Std = 0.841	Lognormal	Mean=0.154, Std =1.1157
FECS (Feeder Subsystem)	Exponential 2P	Lambda=0.0057, Gamma= 24.80	Exponential 2P	Lambda=1.039, Gamma=0.159

Based on equation 13, 14, and 15, the availability importance measures for all subsystem of the crushing plant are calculated and tabulated in Table 2. The availability importance measure I_A^i shows that the SCRCS and COCS subsystems have more influence on the availability of the whole system, and, therefore, improvement in the availability of the SCRCS and COCS will cause the greatest increase in the system availability.

By comparing $I^i_{A,MTBF_i}$ and $I^i_{A,MTTR_i}$ one can determine whether the MTBF or MTTR has more influence on the availability of the crushing plant. In the case studied, if the availability of the crushing plant needs to be improved, one should first concentrate one's efforts on increasing the availability of the SCRCS and COCS. In addition, it is better to pay more attention to the MTTR of SCRCS and also MTTR of COCS subsystem, because the effect of MTTR for both of them, on the availability of the whole system is about 13 and 16 times respectively greater than the corresponding effect of the MTBF of both subsystem, which is indicated by a comparison of $I^i_{A,MTBF_i}$ and $I^i_{A,MTTR_i}$. However, the investment required to decrease the MTTR may be much grater than that required to increase the MTBF. Cost trade-off is essential for making final decision

Table 2. Availability importance measures for all Subsystem of the crushing plants

Sub-system	I_A^i	$I^i_{A,MTBF_i}$	$I^i_{A,MTTR_i}$
PCRCS	0.829	0.00033	0.01024
SCRCS	0.866	0.00068	0.00874
PSCCS	0.826	0.00040	0.01395
SSCCS	0.818	0.00016	0.00900
COCS	0.854	0.00139	0.02201
FECS	0.808	0.00002	0.00401

6 CONCLUSIONS

In this paper we propose a method for implementing the availability improvement process which consists of three steps. In the case of a system's availability performance, availability importance measures could be used as a guideline in developing a strategy for availability improvement. The availability importance of a component/subsystem is defined as a partial derivative of the system availability with respect to this component availability. It is useful to obtain the value of the availability importance measure for each component in the system prior to deploying resources toward improving the specific components.

THE NATURE OF ENGINEERING MAINTENANCE WORK: A BLANK SPACE ON THE MAP

James Trevelyan, Leonie Gouws, and Adrian Stephan[a]

[a] *School of Mechanical Engineering, The University of Western Australia.*

Abstract: Engineering maintenance work is assumed and taken for granted. It is surprising to find that there are just a handful of carefully researched accounts of engineering work, and only one of engineering maintenance work. Yet there is strong evidence that engineering maintenance work is far from satisfactory with reported losses from equipment and plant breakdowns exceeding 40% of turnover. These losses often exceed direct maintenance costs by several times. While there are many prescriptions for organizing maintenance work, there is no research to substantiate these prescriptions. This paper reviews the available literature and describes research that is mapping the nature of engineering work in a form that could lead to significant improvements.

Key Words: engineering maintenance work, qualitative research, ethnography

1 MAINTENANCE IS CHEAP?

There is little doubt that many companies are continuing to have major problems with maintenance work and we outline just a few of the issues in this paper. Recent work has highlighted continuing high costs sustained by companies due to plant and equipment failures. Computer-based maintenance management systems (CMMS) have been proposed and implemented in the hope of controlling these failures and costs without much apparent effect. Given the direct costs of maintenance and also the magnitude of costs associated with maintenance failures, it is therefore surprising to find almost no research on the actual nature of maintenance work. The research literature contains little that helps us understand how it is done, the different roles played by different people, the skills and knowledge actually used. Instead the work is assumed to be known. After all, what could be so difficult to understand about some people carrying basic hand tools following directions on computer-printed slips of paper? Yet, ultimately, maintenance failures occur because people make mistakes or forget to perform important actions. These are people who experience meaningful contact with the machines or process plant and each other. We cannot hope to understand why maintenance fails to work well if we do not attempt to understand what these people are actually doing.

Recent work by Hägerby and Johannson [1] is just one of many accounts illustrating the magnitude of maintenance failures in modern enterprises. Figure 1 illustrates their results which show losses of up to 40% of turnover due to lack of plant availability. While this is a problem in industrialized countries, poor maintenance in developing countries leads to unacceptably high end-user costs for essential services such as water supplies. Poor people in developing countries simply cannot afford to wash their hands because the real cost of water is too high, typically up to 30 times higher than in Australia in real dollar terms. [2, 3]

2 RESEARCH LITERATURE

It is not easy to find the research that lies behind contemporary industrial maintenance texts [e.g. 4, 5]. Few include reference sources. After a thorough search we have found only a small number of research reports that provide any detailed insight on engineering maintenance work. Technical processes such as inventory controls, condition measurement, reliability forecasts and remediation methods have been reported in detail and it is tempting to assume that these methods describe what maintenance work actually involves. The few reports of systematic research, however, tell us that this assumption is likely to be false.

The first aim of this paper, therefore, is to review research literature that can inform us on the nature of engineering maintenance work. Even if we enlarge the scope of our literature search to include all engineering work, there is just a handful of systematically researched accounts that has appeared over the last 30 years.

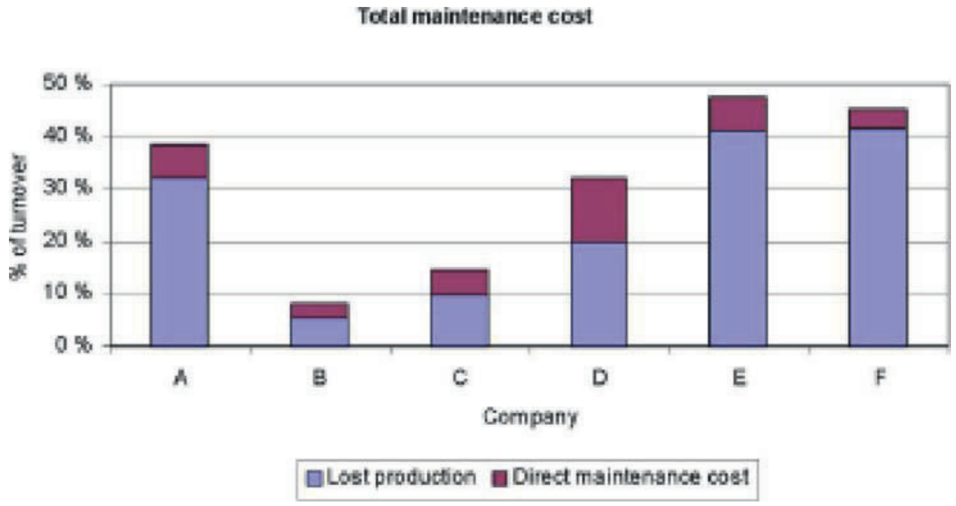

Figure 1: Results of survey of maintenance costs in six major Scandinavian firms. Note how the reported value of lost production is far higher than direct maintenance costs (reproduced from [1]).

What do we mean by ‘engineering work’? We would like to avoid distinctions between occupational groups, especially between ‘engineers’ as professionals and other workers such as technologists. Instead we will focus on all the work, including the planning and organization that leads up to the ultimate ‘production’ work whether executed by production workers, technicians, tradespeople or machines. It is essential to recognise that most engineering involves highly coordinated work by many people with different roles and success relies on the ultimate production work being done correctly. Engineers seldom do this themselves yet they are often held responsible for the production and service delivery work performed by other people, the ‘production’ or ‘service delivery’ workers. We can distinguish aspects of ‘engineering work’. Planning, analysis, design, organization, and administration precede the final ‘hands-on’ production or maintenance work that results in useful products, solutions and services, yet all are part of engineering work. In practice there is no clear dividing line between the different aspects. Engineers often engage in hands-on work and technicians are often involved in planning and coordination, as we see in Orr’s detailed account [6]. At the same time we also need to be interested in diverse roles of engineers. Engineering workers may refer to some of their roles as “not real engineering” work, sometimes “all that admin stuff”. They even organize social activities. Yet these roles are still part of the picture if we are to understand what engineering is all about.

In some discourse, engineering work is considered to be purely technical. For example, Hoag [7] presents a comprehensive work on continuing education and on-the-job learning for engineers without mentioning any non-technical skills training at all. On the other hand, Connelly [8] surveyed “personal and professional” skills, i.e. non-technical skills and knowledge, even though in the introduction they acknowledge that enhanced oil and gas recovery methods, decommissioning and abandonment will have an impact on the skills engineers need to acquire and develop.” Barley & Orr [9, Ch 2] provide evidence of a prevailing image that separates management from engineering. A person is either a manager or an engineer: the former has little or no technical content in his work and the latter has little or no social dimension to his work. However, our own work informs us that engineers and technologists perform roles that involve management of people.

There is a small group of richly detailed ethnographic style studies of working engineers, not all with the explicit intent of understanding engineering work. Several provide useful field data and observations which could be useful in testing different models of engineering work. However none seem to include a detailed classification of engineering work or a broad enough coverage to attempt to build one. The few studies informed with detailed technical understanding are mainly on design, only one of many roles undertaken by working engineers. However design carries considerable glamour and status, particularly in high technology and aerospace, and this area of engineering work has been studied extensively by many researchers. However, for most of them their interest lies in the *design process* rather than all the other less glamorous work that designers also have to accomplish (For example, see Eckert [10] for a description of recent work).

A recent survey of about 100 research publications [11] reveals two major groups of reports. Investigations on engineering education have stimulated about half of all the reports on engineering work. The other half has emerged from researchers who have been interested in engineering management. However, the vast majority of these results were obtained using methods based on questionable assumptions. Only a small number can be relied on, mostly using anthropological approaches based on qualitative research. Most of these were written by social scientists or students with little engineering experience.

Schön [12] is one of the earliest accounts of this type. His interests lie in the reflective aspects of professional work and he describes engineers inventing a new process. He uses the term "technical rationality" to describe science-based professionals as technical problem solvers. According to this model "problem-solving is a manipulation of available techniques to achieve chosen ends in the face of manageable constraints."

Solomon and Holt [13] use an ethnographic approach to study mechanical engineering work with the stated aim of revisions to engineering education. The paper appears to foreshadow a more extensive analysis though none seems to have subsequently appeared.

The work of Bucciarelli [14, 15] is significant because he is one of the few engineers who has made extensive contributions to the literature on engineering work. He introduces the useful notion of “object worlds” – domains in which engineers conceive their designs and explain how they work, analogous to the “planes of objects” described by Foucault [16].

In their collection of studies, Barley & Orr [9] attempted to define technical work. They suggested that such work "requires understanding and utilisation of abstract knowledge", presumably mathematics or science acquired through formal education. They acknowledged that many technical workers, particularly technicians and trades workers, acquire their knowledge and skills through experience and working with more experienced workers (e.g. apprenticeships), rather than through formal education. They also suggested that “technical acumen is the result of contextual and tacit knowledge”. "Technicians are usually charged with ensuring that machines, organisms and other physical systems remain in good working order. Caretaking often requires technicians to employ theories, diagnoses, documentation, and other representations drawn from the symbolic realm they support.” [17, p89]

Barley and his co-workers have made several other significant contributions. Barley and Bechkey [17] point out that technicians mediate between professionals and the phenomena over which the professionals are reputed to have mastery. To do this technicians translate "aspects of physical phenomena into science, symbols, or information that physicians, scientists, engineers and other professionals subsequently use in their own work". "Technicians in nuclear power plants... create and monitor flows of data on production systems that engineers and managers used to make decisions." They also report

"informants claimed that accomplished technicians were obsessively organized.... lab workers spoke of maintaining records, scheduling activities, and keeping supplies in their proper place.... lab staff viewed 'being organized' as the primary weapon in their war against uncertainty. To say that a technician was highly organized was to say he or she was adept at a work style that lab workers viewed as independent of procedure or discipline."

Orr [6] also reports this in his highly detailed ethnography of photocopier technicians working in a West Coast USA commercial environment. His contribution is soundly based on extensive first-hand technical knowledge through his previous career as a maintenance technician. He concludes that chaotic work is associated with finding and solving problems by luck rather than by competence and is frowned upon in the community of maintenance technicians. This is the only report we are aware of that presents a comprehensive account of engineering maintenance work. Orr describes relationships between service technicians, customers and individual machines. While the work is very accessible in its writing style, there is no attempt to derive a systematic description of the work. Instead, the focus is on the technicians as a group and a description of their social networks with an anthropological audience in mind.

Several other social scientists have studied engineering work though they have been mainly interested in the place this occupies in society and firms rather than the detail of the work itself [See for example 18, 19-23]. Social scientists have acknowledged difficulties in understanding technical work. "Engineers continue to play havoc with conventional models of work even though they are the prototypical technical workers of high industrialisation." In this one sentence the authors admit that they really do not understand the work of engineers. [20, p34]. One of the obvious barriers for social scientists is technical knowledge, presenting an intellectual dimension that requires years of practice to fully comprehend. “... much of engineering is desk work based on thought processes whose character is manifest only partially in the various pieces of paper that are intermediate product. ... Some aspects of engineering work, especially its technical content, resist observation…” [21, p28-29, also p35].

One of the more recent contributions has been a collection of work by Vinck [24] and his colleagues. In the first chapter we find a detailed account of the work of a young engineering intern as a way of gaining a better understanding of engineering design work. Once again the focus is on design work, but there are some highly detailed accounts of various engineering roles which can provide useful evidence for testing models.

Ergonomics and human factors engineering researchers have studied specific work practices, of course, but the focus has predominantly been on specific machine and process operators, for example, pilots and air traffic controllers. [25] provides a useful example: a detailed analysis of errors in aircraft maintenance work, yet a detailed description of the work seems to be assumed: it is not described.

Vinck has also pointed out how weak our real understanding of engineering and technological work really is.

“We live in an era of paradoxes. On the one hand, we are faced with an ever-growing array of technological developments that affect communication, work, travel, domestic and leisure activities, and political and ethical debates. … On the other hand, in many ways we do not understand these technologies. The surprising thing is that this is true for technological professionals as well as for lay people. Our situation is characterised both by our ignorance of new technologies and by our faith in them." [24]

It seems that our knowledge of the nature of most engineering work, including maintenance work, remains largely at the state that our knowledge of management work was in the mid 1960s when Mintzberg [26] started his research on the nature of managerial work. The questions he posed then in relation to managers could just as well be asked about engineers and technicians today.

3 MAP MAKING

In this section of the paper we will describe our ongoing research that aims to fill this blank space on the map. It is part of a larger project on the nature of engineering work using contemporary social sciences investigation methods. This project has already yielded some valuable insights from preliminary results coming from analysis of 55 interviews with practising engineers, drafting staff, technicians, tradespeople, planners and schedulers with similar fieldwork in several countries. Most of the interviews, so far, have been with engineers.

We have used an ethnographic research technique. We analyze transcripts taken from 90 minute semi-structured interviews that explore the daily work of an individual involved in engineering work. The analysis extracts quotations that provide evidence for different kinds of engineering work roles. We use three 'triangulation' methods to check the validity of this analysis. First, the interviews and analysis are performed by experienced engineers. This has proved to be essential because lack of significant engineering experience makes it difficult to understand what can lie behind a cryptic comment by an engineer or technician. Second, we shadow a limited number of interview subjects, recording their activities over a limited period ranging from 1 day to a week. By doing this we can check for the relative significance of the interview comments and check for roles missed in the interview. Through this process we have gradually built up a relatively complex framework of engineering roles and technical knowledge categories, defined in terms that are not specific to any one engineering discipline (see Appendices for examples). The third triangulation method is to check the limited available research literature to see whether we have missed roles and knowledge categories, and also to see whether our results can explain observations made by other researchers.

One result is a systematic framework for interpreting the nature of engineering work [27]. The framework consists of approximately 80 different roles performed by engineers and other people involved in engineering work (for a small selection see Appendix 1). Certain roles have dominated interview responses, particularly roles that involve the coordination of work by other people over whom engineers have little or no authority. This can only happen with cooperation and our interviews show that an important feature of engineering work is gaining the *willing* cooperation of other people. While similarly non-technical generic roles are more prominent in interview responses than purely technical roles, it is clear that technical knowledge still plays a vital part. However, the kinds of technical knowledge and the ways in which it is used appear to be only distantly related to the technical content of university engineering training. This helps to explain why social scientists find it difficult to make progress in understanding the nature of engineering work: understanding the technical dimension is crucial.

An examination of the technical knowledge used in engineering work reveals another factor that helps to explain difficulties in maintenance work. We identified about 35 categories of technical knowledge ranging from knowledge of components and suppliers to process applications. Some of these categories appear in appendix 2. Our research shows that much of the knowledge used in engineering work is unwritten knowledge and people are often not consciously aware of the knowledge that they use on a daily basis. This is often referred to as tacit or implicit knowledge [28].

Another result concerns the ways in which people interact and communicate in the course of engineering work. These results might help to explain many of the difficulties encountered with maintenance management information systems. Oral or spoken interactions seem to be more important in many ways than written forms of communication, particularly in the effective coordination of technical work.

From our interviews there are several dimensions to technical work and different people appear to have different strengths in each.

- Familiarity with contextual and tacit technical knowledge usually acquired in a framework provided by formal education typically covering mathematics and science subjects.
- reative thinking, ability to conceive new approaches to technical problems that resist logical and analytical solutions.
- Manual skills acquired through a combination of childhood play, curiosity with respect to mechanisms and machines, possibly classes and formal education and finally on the job or extracurricular practice.
- Social skills that involve interactions with other people to obtain information and cooperation in technical work.
- Ability to manipulate abstract concepts, with a particular affinity for mathematics and philosophy that would be almost certainly strongly reinforced by formal education.
- Ability to pay meticulous attention to details that enables the person to work systematically through complex processes with few if any errors.

All five of these dimensions seem to be present in engineering workers to varying extents. Many prefer analytical and technical work, almost seeking refuge from personal interactions by burying themselves in this kind of occupation. Others have strong social skills and in some cases show signs of atrophy in their technical and analytical skills. Many kinds of engineering work require meticulous attention to detail without necessarily a strong abstract theoretical and analytical component. Many engineers have negligible manual skills: mechanical engineers are often notorious for the poor mechanical state of their cars. However a minority have highly developed manual skills and can outperform highly skilled technicians. Some engineers adapt to management very easily because they have highly developed social skills. Others with less advanced social skills manage but with much greater difficulty and less performance. There is an intriguing contrast in the apparent characteristics of some of the people involved in engineering asset management and maintenance. Asset management analysis, and particularly the use of computer-based asset management systems requires someone who feels comfortable with extensive and detailed written documentation. Meticulous attention to detail is essential for success. Yet maintenance management requires the successful coordination of in-house technical staff, operations staff, logistics, and often a host of outside contractors. 'Firefighting' is often used by these people to describe their role and they have little time for patient analytical work. The maintenance work itself is performed by technicians who need to have well developed manual skills and the research reports we have suggest they exchange much of their technical information verbally. Finally operations personnel also interact with the machinery and they seem to have a strongly developed verbal culture. Written information, even if available, is typically incomplete and seldom referred to directly. This explains communication difficulties that we have observed between these different people, especially if a CMMS forms a significant component of the communication process.

In a companion paper [29] we have noted the relatively low status of engineering maintenance work. One significant result from our interviews with engineers across a wide spectrum of disciplines is that maintenance was only mentioned by a tiny minority. From this we have confirmed that maintenance work is not a significant part of work for many engineers.

Social science methods, particularly ethnographic and qualitative research methods, provide some powerful research tools to investigate maintenance work practices. However they are expensive. We have learned that experience in engineering work is a pre-requisite to understand the technical factors that underlie the work. It takes time for people with an engineering background to learn the required investigation techniques, develop interviewing and field observation skills, read the required literature, and understand precautions that have to be taken to avoid personal bias affecting the results. The results come only through writing and distilling huge amounts of written text in the form of interview transcripts and field observation notes into readable 'quotes' and 'vignettes' that illustrate the essential aspects of working roles. Once a robust theoretical framework can be established with these methods, we can develop quantitative survey questionnaires that will help collect data from a wider range of workplaces.

All this takes time. It will take several years to collect sufficient data to provide a comprehensive analysis of engineering maintenance work. However, there are many potential benefits, some of which could be obtained without waiting so long. With a clearer understanding of how knowledge is transferred in engineering work we can already be confident that direct human contact is necessary to retain the value of unwritten knowledge that cannot be represented in a CMMS. Similarly, supervision and control of maintenance work is likely to be more effective with regular first-hand exposure to the technical work. History data is likely to be more accurate if it is checked when first entered by engineers who are likely to use the data rather than relying on maintenance technicians. By clearly understanding maintenance work we can define more effective training and development programmes. While this approach to maintenance requires more costly oversight, it may provide large savings in indirect maintenance costs.

4 CONCLUSIONS

Engineers often complain that their work is poorly understood by outsiders. In contrast to architects, lawyers, accountants, doctors and preachers, engineers have little face-to-face contact with the general public. Even if senior non-technical staff in major companies were curious enough to learn more about what their engineers do, there are almost no easily accessible accounts that they could read. The work of technicians is mainly invisible and taken for granted, even by engineers: it only becomes obvious in its absence or failure. A comprehensive description of engineering work, particularly engineering maintenance work, could be of enormous help.

The analysis and research necessary to compile such a description could also lead eventually to significant improvements in work practices. While management work has been researched systematically for more than a century, it is only in the last 40 years that our understanding has been sufficient to provide new insights, working methods and training programmes. Research on the nature of engineering work has hardly begun.

6 APPENDIX 1

This selection describes 17 of the 80 roles we have defined in our model of engineering work. Not all people perform all roles: engineering teams bring people together to provide expertise needed for all the roles required in a given project.

Personal research	Research technology developments, organisational and planning methods, business approaches, components and alternatives: when one type of material or component is not available which ones can be used instead, all to build personal knowledge and expertise.
Apply for job	Apply for positions outside organization, register with employment agencies, maintain current resumé and portfolio of achievements.
Documentation	Document existing systems, components, processes, conduct tests where necessary to determine performance, material properties etc.
Respond to query	Respond to technical, business or financial questions from peers, subordinates, sub-contractors and clients on construction, installation, maintenance and operating procedures. Suggest repair and maintenance procedures when unexpected operating conditions result in failure to achieve required results.
Acceptance test	Perform (or supervise) acceptance or commissioning tests on purchased (or in-house produced and/or installed) equipment, software, systems and materials, to ensure compliance with specifications.
Diagnose problem	Diagnose performance issues (may be partial or total failure, or sub-optimal or sub-specification performance), check with databases, consult experts, gather appropriate evidence, perform measurements, locate the root cause, and possibly devise alternative technical solutions.
Predict failure modes	Predict component and system failure modes and probabilities, determine consequences and costs of failure
Work package instructions	Design and write instructions, construction, installation, maintenance and operating procedures and instructions, preparing work packages.
Assign tech staff	Allocate responsibility for technical work: balance technical expertise and experience against cost and availability, decide whether to employ additional staff or contractors etc. Select appropriate working methods and tools.
Plan maintenance	Plan maintenance, condition monitoring, maintenance and asset management plan for components and systems with high failure costs and/or consequences
Coordinate insiders	Supervise or coordinate work of peers, subordinates and superiors. Perform technical checks on work, watch for roadblocks, may provide advice and feedback, may review technical competence, may assess training needs, provide informal training when appropriate.
Recruit staff	Assess qualifications, knowledge, skills and experience of engineers and technical staff from resumé, curriculum vitae, referees and employment reports for a given job description. Interview engineering and technical/administrative job applicants for given job description, assess suitability.
Hands-on tech work	Hands-On technical work; production or maintenance
Follow org'n procedures	Learn and practise standard organizational procedures (eg purchasing, tender preparation, design review, configuration management, safety risk assessment, quality measurement, quality control and quality management, etc.)
Manage production	Manage production capacity and resources for product delivery (product is the output of resources being managed: can be people, plant or machines or combination).
Invoicing & debt collection	Manage invoicing and debt collection, payments to contractors, maintain background knowledge on contractor financial status.
Networking	Networking; develop and maintain network of contacts to help with performance of job

7 APPENDIX 2

Our framework of technical knowledge is built on the notion that engineering creates products and services by combining and transforming components and materials with predictable value, performance, cost and timescale so that the people involved can be adequately remunerated and investors rewarded with appropriate return on capital. Most of the materials and components are usually the results of other engineering activities.

The following list is a selection of technical knowledge categories applicable in typical engineering disciplines. Each discipline (or even organization) will involve different items under these categories. Some categories may involve thousands of separate items, for example, knowledge of components and materials. Much of the working knowledge is unwritten knowledge, sometimes known as 'know-how'.

Applications of the product: knowledge of how product is applied and used by client's personnel. The client is more likely to have detailed knowledge than the engineers developing and making the product.

Customer needs (technical, social, business): understanding of individual client needs, including technical requirements for performance, life, maintainability, compatibility, industry standards etc., understanding client social needs, both within local community and as individual people, understanding client business needs such as price, financing method, delivery timing, client organisation logistics, business rules, installation, maintenance, service and support, repairs etc.

Definition of Product: knowledge of product details and components, function and location of each component, how each component contributes to the function of the whole assembly.

Diagnosis methods for product: technical methods for collecting data and analysing data to determine the cause of performance loss or failure. This also relies on having a model of how the product functions (T01) and relevant physical principles (T29).

Properties of completed product: models of product behaviour (technical and commercial) in given applications. Software, mathematical models of technical or commercial performance. Methods for predicting product performance, both commercial and technical.

Prediction, forecasting: knowledge to predict future events based on present conditions, anticipation of future events, knowledge of models and methods to calculate future conditions.

Industry standards and codes applicable to product and components, government regulations, including national standards (e.g. BS, DIN, AS), industry standards (IEC, API), and international standards (ISO), codes for design and operations (ASME, ASCE, ASTM etc.), government regulations for technical work. Companies can also have their own internal standards.

Measurement, test, inspection methods for product and components

Normal standards for technical work, production faults and defects in product and components, symptoms of "trouble"

Manufacturing methods, assembly of product, construction methods, time/cost and resources needed

Control of production or working environment, elimination of errors, quality control, safety.

Failure symptoms, signs of "trouble" with the product: problem indicators, clues, queues and symptoms can include unusual noise, smell, heat, and visible fragments (chips, smoke, rubbings, flakes, fragments, dust, particles -- particles may be attracted or retained by secondary effects such as wet or oily surfaces). Evidence of heating can include discolouration, burn marks, heat haze, shimmering as well as direct tactile contact or temperature indications. Visible damage can include cracks, dents, scratches, marks, rubbing, bends, crazing, discoloration, wrinkling, distortion in light reflections, and burn marks. With electronic equipment signs of trouble can include intermittent failures, heating, even audible noises. Problems can also be evident from operator comments, even the contents of trash bins, for example discarded copies from a photocopier [6].

Knowledge of components, materials

Information retrieval: locating required technical information in large amounts of mostly irrelevant written documentation.

Defining complete list of parts and materials required for given assembly and tools and other equipment required for construction, production and assembly.

Human behaviour, in design, production work, maintenance and operation of the product.

THE FUTURE OF ASSET MANAGEMENT

Author: S. Bradley Peterson

Presenter: Ralph Hedding

Strategic Asset Management Inc.

Abstract: Deming was famous for asking people, "By What Method?" an objective would be accomplished. Any useful concept has embedded in it the answer to that question.

Asset Management, to be a valuable concept, must demonstrate a method that leads to success. The method should be inclusive of all the necessary elements, yet be simple to understand.

We present a broader view of Asset Management here, built upon three core operating functions: Lead, Execute and Enable. The Execute function is always performed in the plant environment. Manufacturing success is relative to the competition however. Whoever can make the best products at the lowest cost will win. Lead and Enable are the great determinants of that relative success.

In addition, Physical Asset Management has an identity crisis. Most practitioners use the term synonymously with the maintenance function. Asset Management's opportunity, however, goes beyond maintenance to be a guiding principal for all of manufacturing. This paper explores the four integrated facets of the Execute function in the plant:

Capacity acquisition and disposition

Production

Asset Healthcare

Logistics

Our model, then, represents the Future of Asset Management, suggesting "The Method", necessary elements for successful manufacturing.

Key Words: Asset Management, Maintenance, Function, Manufacturing, Execute ,Healthcare, Logistics.

1 INTRODUCTION

Any useful model to guide action will have several characteristics.

- Simplicity. All of the greatest ideas are simple in concept. If not kept simple, they are not yet fully understood or remembered, and fail as guiding principles.
- Intuitive. Readers should be able to understand the underlying principles without guidance.
- Utility. The model should work consistently in application.
- Completeness. All necessary elements of success should be contained.

Our experience with the ***Strategic Asset Management*** (SAM) model (Figure 1) indicates these criteria are met. However, you as the reader will make your own judgments.

Our description of *Strategic Asset Management (SAM)* begins with the key elements of success, namely ***Lead, Execute and Enable.***

2 RECOMMENDATIONS

2.1 LEAD.

There are hundreds of books written about leadership, and each one has some valuable point to make. Frequently, though, the description is of individual leadership, and often charismatic leadership. Leadership in the plant setting, in our opinion, is creating consistency of purpose and action. Manufacturing is a large set of complex and interrelated systems of marketing, technology, finance, human resources, execution functions and equipment. Physical Asset Management then must take all of these into account.

Putting things as simply as we can into the SAM model, the LEAD element consists of the Managing System (Figure 2), Strategic Planning and Information Management.

Managing System. Disciplined, aligned action is the underpinning of any human endeavor. Examine any consistently great achievement and you will find alignment and discipline. That is the purpose of the managing system. Among the elements found here are:

- Top down and cascaded goals. Goals of profitability at the company level become volume and product mix goals for the plant. At the unit level these become volume goals, equating to equipment availability and product quality goals. For the operator these become daily production and equipment surveillance goals. For the craftsman they become equipment condition goals.
- Plan-Do-Review. Everything we do is a process. Take emergency maintenance for instance. The process is: 1. get a request, 2. go do it, repeated all day long. Even a planned and scheduled job doesn't improve the system without a review process to examine the effectiveness of the plan, the execution of results, and a critical understanding of what is happening with the equipment.
- Measurement systems. Assuring that in addition to outcome (lagging) indicators, each job in the plant has process (leading) indicators will enable each worker to make a more positive contribution.
- Reward systems. Each plant rewards behavior in subtle ways. It may promote the overbearing craftsman to a supervisor position because "he gets people going". We may reward equipment breakdown with money and admiration (overtime and attaboys). We may reward production achievement at any cost to people and asset condition. We reap what we sow, so we must be careful that our reward systems actually encourage proactive behavior.
- Roles, responsibilities and accountabilities are clear. If job expectations are not clear and results measurable we have muddled accountability. Fingers point in all directions, and the blame game goes on all day. Being proactive in such a system takes more courage than most people will risk. Clarifying jobs and accountabilities is a leadership function.
- Feedback. This is part of the Plan-Do-Review process, but gets special emphasis. We shape behavior by giving honest feedback without punishment. Under the right circumstances people *want to improve*. Leadership fails if it doesn't capture that spirit.

Strategic Planning. In every plant environment we encounter we hear the same (legitimate) complaints: "Improving maintenance is important, but we just don't have time. We have 4 major plant initiatives and 5 corporate initiatives, and don't know how any of them are going to get done!" Or, "Everything we do is a 'flavor of the month'. We seem to start lots of stuff, but never finish".

How do you set a plan that is timeless? One that has approvals all the way to the top of the company? How do you assure you have a single initiative instead of 20? **Through the act of *strategic planning!***

The product of functional strategic planning is *alignment around a multi-year improvement plan.* To get alignment requires more than a few words in a book. It requires that every level of the organization believes the content of the plan is the most important set of things the company can do with its resources. That means a real and compelling business case for the senior executives. For plant executives it means working on those things which are most practical, which make a difference in daily control of the work and reduction of variance. For the staff functions it means an understanding of the support they must render to enable the plan to be successful.

The elements of the Strategic Plan are these:

1. Benchmarking the function. Where are we today? What are the measures saying?
2. Developing a vision for the future of plant operations. Difficult to do, sometimes requires “Industrial tourism” to see the bigger picture, and using outside help to understand what’s possible. This part has to be done right, or the plan will fall apart. Our clients have found the Execution Triangles (Production, Logistics and Asset Healthcare) to be valuable to setting the vision.
3. Identify Gaps. Where do we fall short of the vision?
4. Identify Strategies to close gaps. It would be easy to shortcut this task. But one may find that, for instance, a distributed control system may be a strategy that helps with product quality, product mix direction, faster changeovers, and equipment condition monitoring. So one strategy cover several gaps.
5. Describe Projects to implement strategies. This can get creative, and will be an integrating force. For instance, a planning and scheduling project may be combined with a safety improvement initiative. Preventive maintenance improvement may combine with and ISO calibration standard.
6. Develop the implementation plan. It will require resources, so don’t shortcut or lowball what the implementation will require. Remember that training won’t create new behaviors. People need to be coached for new behaviors, and measures put in place to determine success.
7. Develop the Business Case. By integrating the initiatives into a single Strategic Plan we can avoid the silliness of double counting for results. Was contractor reduction due to the purchasing initiative or planning and scheduling? Who cares? As long as the goals for contractor reduction were met, and we stayed within the resource guidelines we requested and received approvals for.
8. Create the implementation governance. Plant leadership integrates the Strategic Plan into the Annual Planning Cycle, and the entire Managing System is engaged to see that the results of the Strategic Plan have accountabilities built into the entire organization.

Information Management. The good and bad news: as of the end of the last century most plants are now working with an ERP system. Initial results are typically very negative: lots of rejection of the new system as hard to use, can’t get reports out. But slowly organizations learn to live with and even like the new systems.

The deficiency, as always in IT, is there is confusion as to the difference between the *system* and the *tool.* The system is your set of internal processes and procedures. The tool may be SAP PM module. When your actual work process and methods aren’t reflected in your tool, the disconnect creates great dissatisfaction and waste. But when integrated, there is great synergy to get information to manage the business.

After the Strategic Plan, we undertake a detailed design for one or more of the Execution functions. In that design process we assure complete alignment between the tool and work processes, leading to a virtuous cycle of increasing understanding and utility of the system.

2.2 EXECUTE. Four functional areas exist in any manufacturing environment. These arenas are the typical focus of leadership. If done well, they lead to *functional excellence.*

- Capacity Development is usually considered to be the Design Engineering and Project Management functions in an organization. This function consumes $100’s of millions in what are often risky bets made on optimum market assumptions. A thoughtful and complete method to assure all excellence in the assumptions, design, construction and preparation for production can be a valuable tool. This is a future area for SAMI to define.

- Production Management. Everyone in the plant believes with good reason that production is the reason we are all here. And indeed this is the vehicle for value creation.
- Logistics include materials management, purchasing and movements of people and materials. This function can make or break the Production and Asset Healthcare Management functions.
- Asset Healthcare Management. Is this just another term for maintenance and reliability? Perhaps at some levels it is. But it is concerned with optimizing and integrating with all parts of the business based on risk and value, and so goes beyond the traditional boundaries of M&R.

We have developed improvement models for Production (Figure 3 & 4), Logistics (Figure 5 & 6) and Asset Healthcare (Figure 7 & 8). Indeed the Asset Healthcare model is the well-known *SAMI Triangle*, relabeled and integrated in the context of *Strategic Asset Management.*

2.3 ENABLE.

Many programs for change are viewed as a simple matter of documenting procedures and providing training. If these things are done, change should happen, right?

Wrong. Human nature doesn't work that way. Prescriptive formulations may work for machinery, but (fortunately) the human machine is more complex!

First, why do I say this is fortunate? Most of our corporate clients have a large number of related but disintegrated goals. Safety, reliability improvements, 6 Sigma, Lean Manufacturing, Supply Chain rationalization, etc. These are often presented to the plant as a series of corporate staff visits, all requiring the plants time and attention. If the plant acted on the sum of these "required programs" with full gusto, they would quit producing product. Their time and attention would be taken in team meetings, developing procedures, and trying to rationalize the differing demands of each program.

Fortunately, plant personnel know their jobs are tied to making budgeted quantities of quality product. So their view of change is to ignore these directives until they evaporate from lack of momentum and commitment. Their approach is well-rewarded; most programs do indeed get replaced by the next wave of "best practice" from corporate. I apologize to readers who have corporate development roles, as I may seem cynical. But in my experience the only change that lasts in the plant are those things that make sense to the guy on the plant floor. Safety, for instance, is in his best interest. It may have taken a decade or more of emphasis on safety, but everywhere we go we see good results and lasting change.

Some criteria for change of any kind to take hold in the plant are:

1. Intellectually it makes sense to the plant population. That sense means that improved productivity will *likely* result from such a program.
2. The plant population has a major say in how it will happen in their environment. They have the power, collectively, to determine *whether* it will proceed, and *how* it will proceed.
3. They see true commitment to the results. That means a number of things.
    - i. Some executive's future is tied to making this happen
    - ii. It has worked somewhere else that is similar enough to their environment
    - iii. The leadership team are all on board, no quibbling or sidebars
    - iv. Results are measured and posted visible locations in the plant
    - v. Valuable line people are assigned to the job, taken from other important tasks

2.4 Ownership.

How do we *enable* our work with our clients? What might apply to your own organization?

- **Leadership Consensus to Proceed.** SAMI won't proceed with billable work unless and until we know our client's leadership team, at the appropriate level, has consensus to proceed. Sometimes that means refusing an order for services from a plant manager, for instance, if we don't think the operations manager is fully supportive. To accept work under these conditions violates a cardinal rule, namely: *Anyone who has not been consulted does not feel he has to support the decision.* No matter how assured the person at the top of the organization is that the group will follow his decision, our experience is that lack of commitment by the *entire* leadership team is the number one cause of failure.
- **Worker Consensus to Proceed.** We usually begin our billable engagements with our clients with a baseline assessment of current processes, practices and results. Our clients typically believe this is because we need the data to know how to improve. The more important reason by far, however, is to engage the organization in a decision-making process that includes representation from all areas. Our assessments are designed to touch the greatest number of people practical, to solicit from them their issues, ideas and experience. There is an interesting pattern we almost always see. Leadership wants us to get the hourly workers to be willing to change; the hourly workers in turn challenge leadership to do its job and lead with strength of purpose, consistency and with high standards. The assessment process brings their views together, enabling them to see they want the same results: a productive, safe and competitive workplace where people are valued.
- **Develop a Workable Process and Passionate Owners.** Virtually every engagement we participate in has a work process design phase. The designers, typically a team of 8-10 part-time people, represent all types of jobs and all levels of the organization. We ask for leaders, even if those leaders can be negative at times. This team goes through the forming, storming, norming and performing stages of development, and we are careful to prepare them for the "J" curve effect (they go down emotionally before they go up). Their product is a completely thought out work management process, with all the details that will enable it to work in their environment. Our experience is that the product is 95% the same as virtually any other plant's. The 5% difference is critical, though, in practical workability. But the most important result of the design is a team of people who see the future and are passionate about making that future happen.
- **Client-Driven Implementation.** Only when workers see peers passionate about change will they pay attention. Outsiders (consultants) are seen a nuisances to be avoided. But if your respected peer is deeply committed to a new method of work, you will pay attention. And if he is willing to risk your relationship by making it not-optional, then you will believe it is a worthy change. Our consultants *support the client* in making the changes, not the other way around.

You should note that most of what we have written here is about enabling change, not about the core maintenance or production process. We assure that we have qualified experts in the process on the teams. Our clients seldom fail because they don't understand best practices, but because they can't get them implemented. We have learned to focus on change because it is the critical barrier for success!

2.5 Development.

It is possible that your people can work at much higher levels than they are today. In a reactive environment vs. a proactive environment these are frequent roles:

Job/Role	Reactive Environment	Proactive Environment
Craftsman	Component Replacer	Troubleshooter/RCF analyzer
Operator	Victim, Problem Identifier	Proactive Worker, Minor Maintenance
Supervisor	Expeditor	Work enabler, coordinator, troubleshooter
Engineer	Troubleshooter	Equipment defect elimination/optimization

Changing these roles is partially a matter of removing obstacles to being proactive and clarifying expectations, roles and responsibilities. But to a significant extent there is a requirement to assist people to be able to fill new roles. This is training, but much more than training. It involves coaching and testing the limits of the individuals in the job. Some operators are mechanically inclined, and some are not. Some will be eager to take on new roles, and some very resistant. Development takes time and energy for a supervisor to understand what is possible, and work with each of his people on a specific development program, customized to the specific task, and the native abilities of the worker. A training organization can be invaluable here, but the task cannot be delegated. The approach is rifle shots, not grandiose, one-size-fits-all programs. **Empowerment.** The "E" word has lots of bad connotations from the failures of quality programs in the 80's and early 90's. The popular method of empowerment was a week's worth of training in "soft skills", and an admonition that they should step up and be their own bosses. The result was lack of direction, anger, *disempowered* supervisors and management, and a decrease in productivity. Lee Solomon, founder of Soloman Associates who benchmark most of the world's refineries, once told me: ***"There is a high, negative correlation between implementation of self-managed work teams and performance".*** Empowerment as implemented not only didn't work, but it made things worse.

What ***is*** empowerment? It is enabling a worker to do more, and to take responsibility for his own performance. How can this best be done? First, by having a disciplined and well defined system to follow, and <u>enabling</u> the worker to be successful in the context of the system. Next, is to <u>develop</u> the worker to be successful in an expanded role. Finally, we give the worker the tools to understand whether he is mastering the job. This includes measures, feedback, coaching and encouragement. Empowerment is the **result** of a disciplined system of work, *not a prerequisite.*

3 CONCLUSION

Strategic Asset Management (SAM) is the systematic process that enables the dream of *Operations Excellence.* It emphasizes a logical approach to best practices through the developmental stages of the EXECUTE Triangles. Functional excellence will never be enough, however, to be the best. LEAD functions are the glue that brings all the pieces together in an optimized set of systems, especially through the mechanism of the *Managing System and Strategic Plan.* Finally, we can only be as successful as our workers endorsement and participation in these functional excellence practices. We must ENABLE our people to bring us the success we all desire.

We really become the best if we start our journey with the right model.

5 APPENDIX:

Figures 1 thru 8

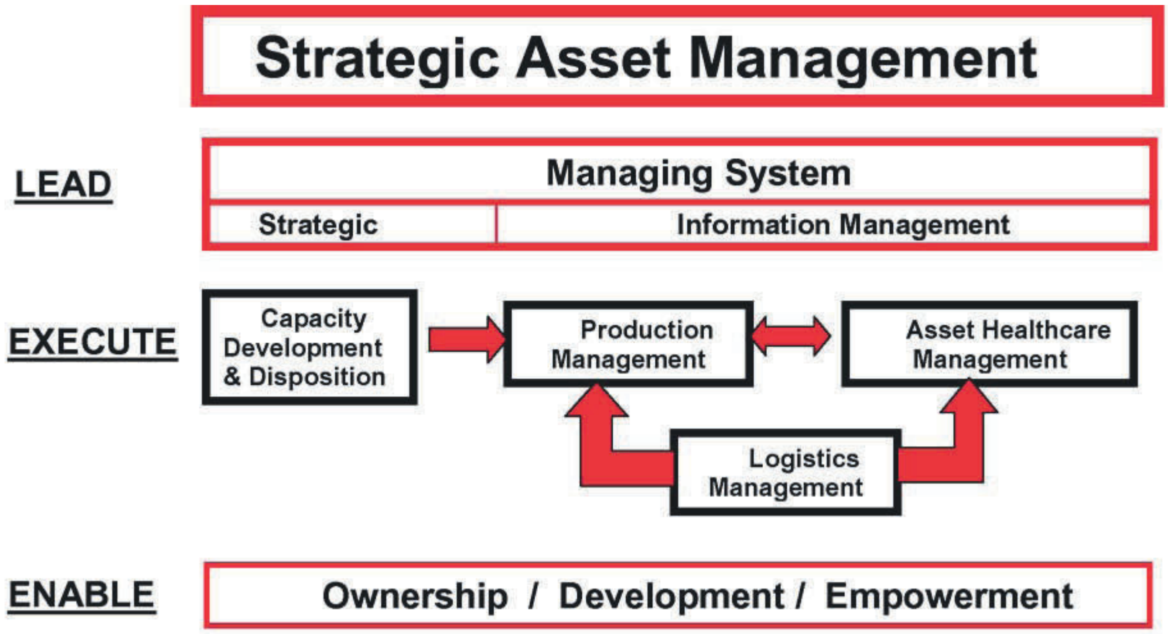

Figure 1: Strategic Asset Management Model (SAM Model)

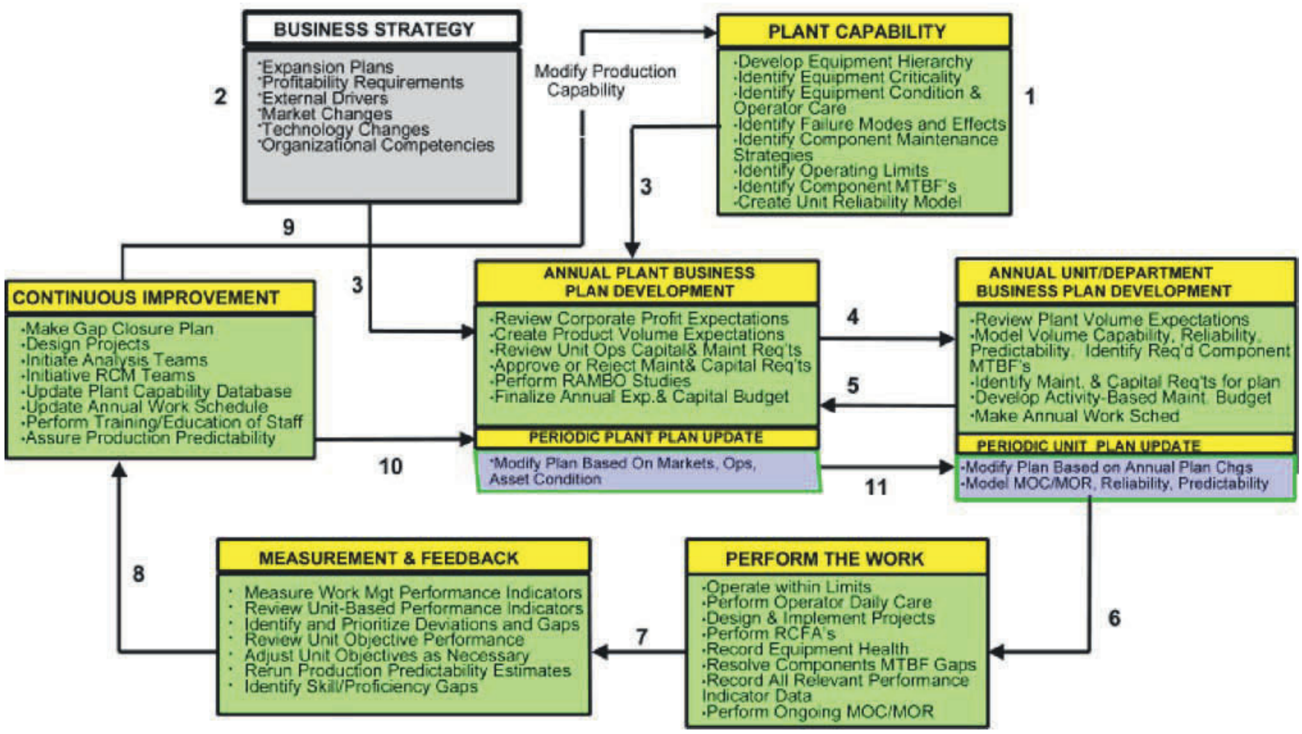

Figure 2: Managing System Model

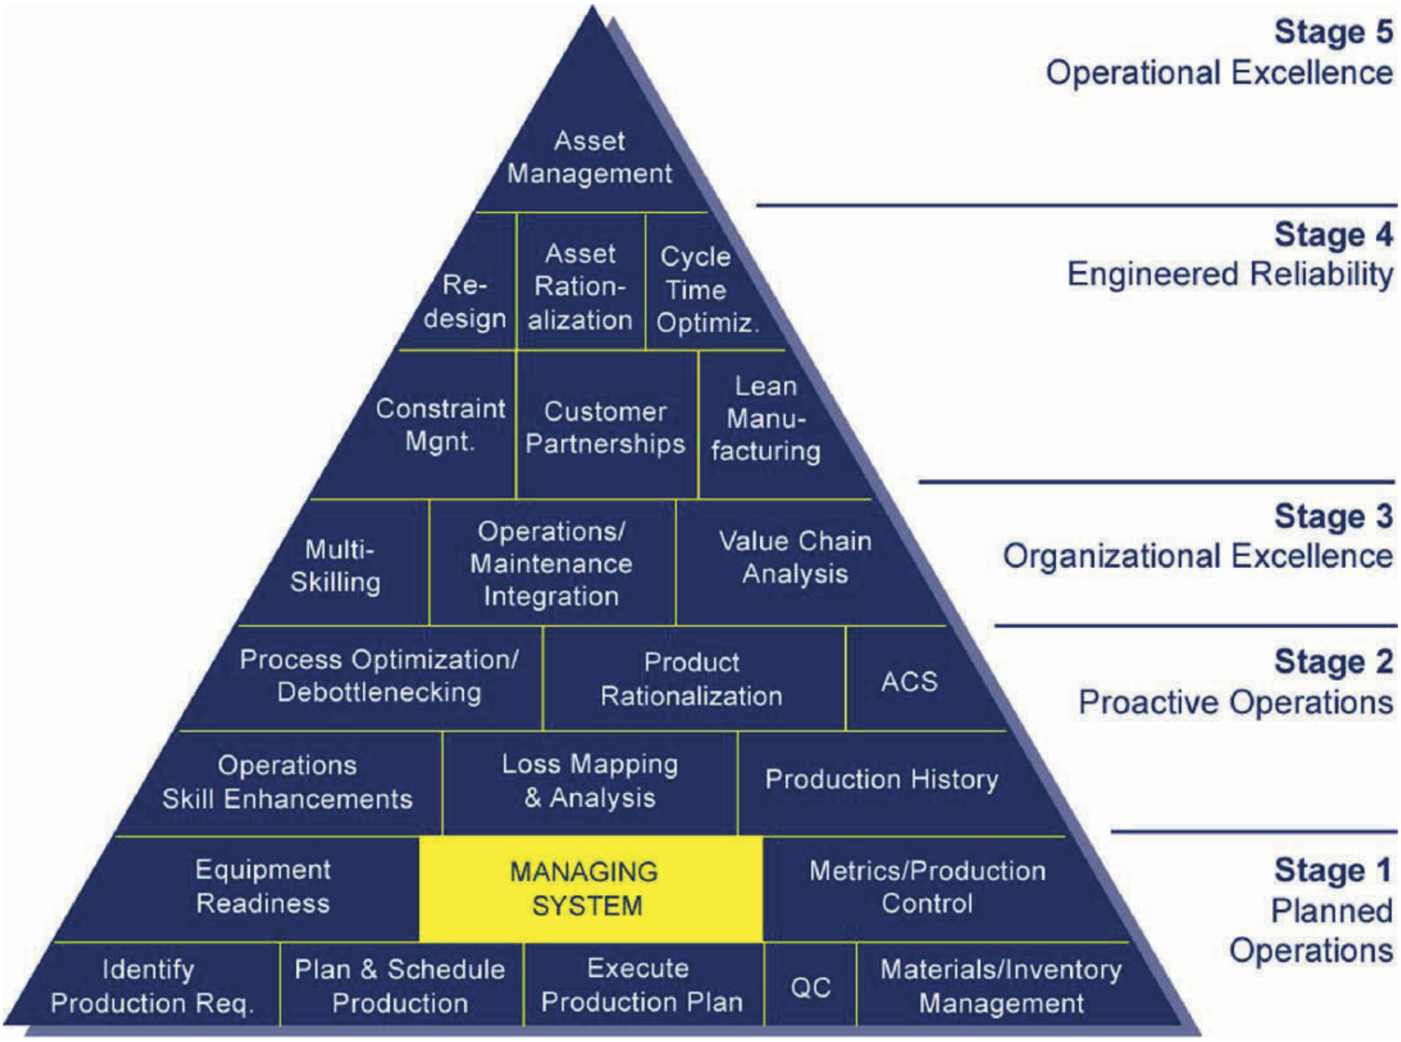

Figure 3: Production Triangle Model

Stage \ Class	Low Performing	Competent	High Performing
Stage 1 Planned Production	• Production Schedule Changes Daily • Little coordination between shifts • Frequent unplanned production interruptions • Raw materials have quality problems • Offspec product a way of life • No time for preventive maintenance • Frequent order expediting • Production targets seldom met	• Production schedule planned and executed • Raw materials available and meet spec • Equipment is made available for planned maint. • Operators capable normal production needs • Downtime and slowdown reasons logged • Equipment inspected, defect notifications done •Equipment permits is prepared for maintenance • Production targets usually met	• Minimum WIP inventory maintained • Scheduling is exact for materials, staff, time • Production meets or exceeds Q1 spec • Equipment is prepared daily by operator • Preventive maintenance is a religion • High level of cooperation among functions • Operators show equipment ownership • Production targets routinely exceeded
Stage 2 Proactive Production	• Operating spec's undocumented or ignored • Operators not trained on equipment/process • Production bottlenecks frequent • Little or improperly used automation • Operators have little process visibility • DCS antiquated, unstable, circumvented • Equipment not designed/maintained to perform required function	• Unplanned events evaluated, corrected • Operators educated in process & equipment • Production bottlenecks identified and worked • Operating specs identified & surveyed • DCS upgraded to perform additional functions • Quality built into process, not inspection • Raw material acquisition quality specified	• Asset healthcare program for all equipment • Predictive techniques minimize downtime • Failure analysis done for 80% of failures • Results of RCFA's implemented routinely • Condition monitoring based on cost & risk • Prevention is a cultural imperative • Trades work on designing out failure
Stage 3 Organizational Excellence	• Training unconnected to real work practice • "Team" implementation causes confusion • Supervisors lack authority, accountability • Unclear roles and responsibilities • Skills flexibility in contract, not implemented • Operators don't inspect or maintain equipment • No individual performance targets/goals	• Supervisors have clear roles & accountability • Operators inspect, lube, prep equipment • Task teams form, identify solutions, disband • Most work is directly by a priority system • Natural work teams effective at routine maint. • Service contract exists between maintenance & operations • Craft multi-skilling and flexibility implemented	• Work teams flexible, self-directed • Supervisors coach & advise • Continuous improvement embraced, effective • Clear priorities established for work • Reward/Recognition support best practices • Skills predominate over functions • All staff systems competent
Stage 4 Engineered Reliability	• RCM implementation creates confusion, results not implemented • Jobs changed on paper, not in reality • Stages 1&2 are ignored to "eliminate work" • Emphasis on analysis, not implementation • Vendor reduction brings lower service levels	• Reliability models run for critical systems component MTBF specifications defined • Equipment standards implemented • Critical equipment assessed via RCM • Projects get input from maintenance, ops • Equipment types, models rationalized • Purchasing buys by lifecycle cost, not price	• Concurrent engineering assures RAMBO • Reliability tied to financial results • Lifecycle costs are the basis for decisions • Vendor contracts pay for function reliability • Production targets set by reliability models • Equipment failures are a rare occurrence
Stage 5 Asset Management	• Management unclear re: goals & methods • Equipment condition not factored into goals • Equipment run parameters changed daily to respond to market pressures • Too many priorities prevent focus • Poor understanding of plant potential/liabilities	• Clear organizational alignment • Goals cascaded from plant level to individual • Production goals based on plant capability • Most work identified and planned prior year • Hourly help set unit goals & work improver's • Activity-Based Management implemented • Prod's reliability is part of product marketing	• Each employee knows & is rewarded for role • All decisions based on facts and models • 80% of work is preventive or project, & is identified prior to the start of the year • Production is 98% predictable • Lowest cost producer • Plant becomes corporate expansion site

RAMBO=Reliability, availability, maintainability, buildability, operability **WR=**Work request **RCFA=**Root Cause Failure Analysis **KPI=**Key Performance Indicator **OUE=**Overall Unit Effectives (OEE)

Figure 4: Production Maturity Matrix

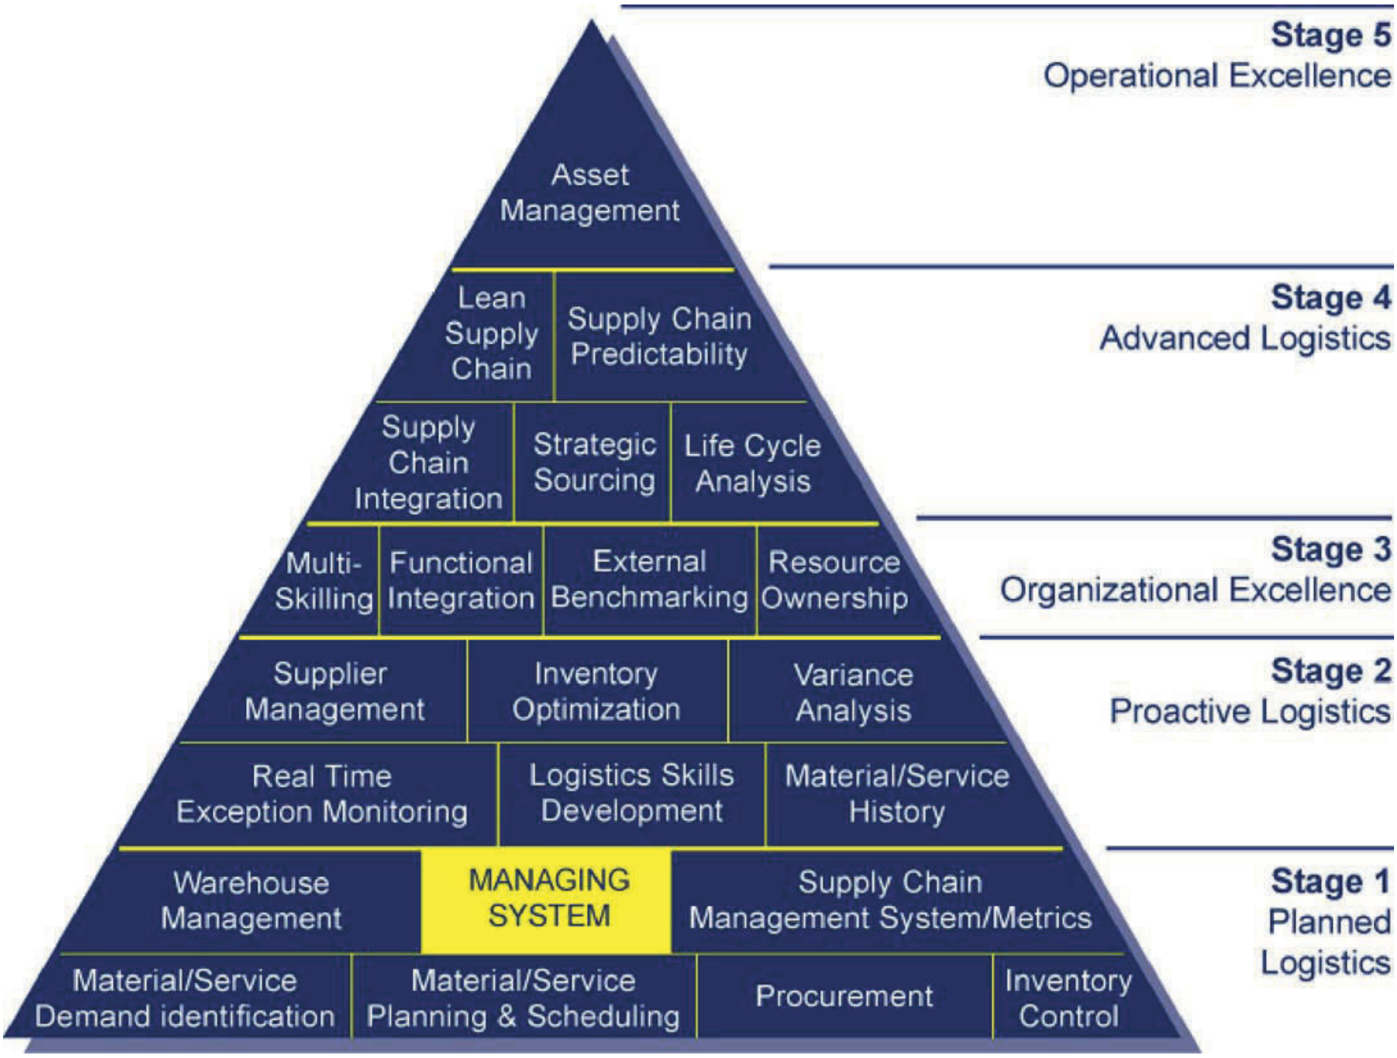

Figure 5: Logistics Triangle Model

Stage \ Class	Low Performing	Competent	High Performing
Stage 1 Planned Logistics	• Frequent reschedules of requirements •Excess of some items/frequent stock outs on others •Product/equipmentBOM's nonexistent or inaccurate • Unexecuted/inaccurate system transactions • Poor documentation/off-spec material a way of life • Frequent expediting • Delivery commitments often missed without notice • Inadequate security and control of inventory • Non-existent/inadequate performance indicators	• Most material requirements planned and stable • Controlled inventory levels with occasional stock outs •100% accurate BOM's for critical equipment/material • All material movement tracked in the system • Missed deliveries/incoming quality issues documented and resolved quickly • Supplier delivery dates usually satisfied on time/early • Some inventory counting routines in place • Occasional expediting • Performance indicators established and measured	• Requirements firm • Supplier delivery dates met >95% of the time • Early warming provided for missed deliveries • Storeroom improvement opportunities and implementation plans identified • Service improvement/inventory reduction opportunities and implementation plans identified • Formal Cycle Counting program in place to identify and resolve process issues; accuracy >95% • Expediting done proactively based on system data
Stage 2 Proactive Logistics	• Logistics personnel not trained in the process • No Supplier performance data available • Unavailable/inadequate supply chain planning and performance data • Supplier proliferation; suppliers selected randomly • Inventory managed strictly to assure service • Capabilities of the system not known/not understood • Planning data/reports unavailable or not being used	• Adequate job-related training, primarily OJT • Some data/reports available to track performance to plan • Supplier based controlled; suppliers selected primarily based on price and/or delivery • All materials purchased and stored using traditional methods • Inventory managed to balance services and investments • System capabilities understood but underutilized	• Required knowledge, skills and abilities identified and verified through formal training • Certification criteria in place to monitor and manage supplier base and performance; suppliers selected from qualified list based on criteria • Alternative procurement and stocking methods implemented to optimize service and costs • The system is capable of extracting required data and producing real-time exception notices
Stage 3 Organizational Excellence	• Unclear definition of roles and responsibilities • Focus on internal and individual performance • Nonexistent goals and objectives • Silo mindset • Resistance to change • No ownership processes	• Documented roles and responsibilities • Team-based work effective with focus on organizational goals and objectives • Acceptance of change • Individuals understand roles and responsibilities of personnel with other functions/from other departments • Multi-skilling implemented	• Cross-functional teams take ownership for resources/ processes and focus on plant/corporate goals and objectives as well as individual • Continuous improvement embraced, effective • Reward/recognition support best practices • Skills predominate over functions • Individuals can perform duties of personnel with other functions/from other departments
Stage 4 Advanced Logistics	• Suppliers are adversaries • Supply Chain/Logistics activities driven by reactive tactics • Numerous handoffs result in inefficiency and delays • Material specifications don't follow form, fit and functional needs • Equipment/process output unpredictable; customer requirements frequently missed without warning	• Suppliers are at arm's length • Supply Chain/Logistics activities driven by proactive planning • Material and transactions follow logical plan • Material specifications meet specific needs • Most customer requirements met on time or early	• Suppliers are strategic partners • Supply Chain/Logistic activities driven by strategic evaluation of total life cycle cost • Supply Chain extends to the Customer, and non-value-added functions have been eliminated • Material interchangeable in different applications without impacting quality, reliability or safety • Commitments met >95% of the time with early warning for potential missed deliveries
Stage 5 Asset Management	• Management unclear about goals and methods • Established processes circumvented in reaction to changing priorities • Commitments changed based on "squeaky wheel"	• Clear organizational alignment • Goals cascaded from plant/corporate level to individual • Commitments made based on supply chain capability and established plan • Logistics employees help establish goals and improvement plans • Supply Chain reliability is part of product marketing	• Each employee knows and is rewarded for his role • Established processes used to manage/align conflicting priorities • All decisions based on facts, models, and strategic business rules • Plant is lowest cost producer and becomes the benchmark for other sites

Figure 6: Logistics Maturity Matrix Model

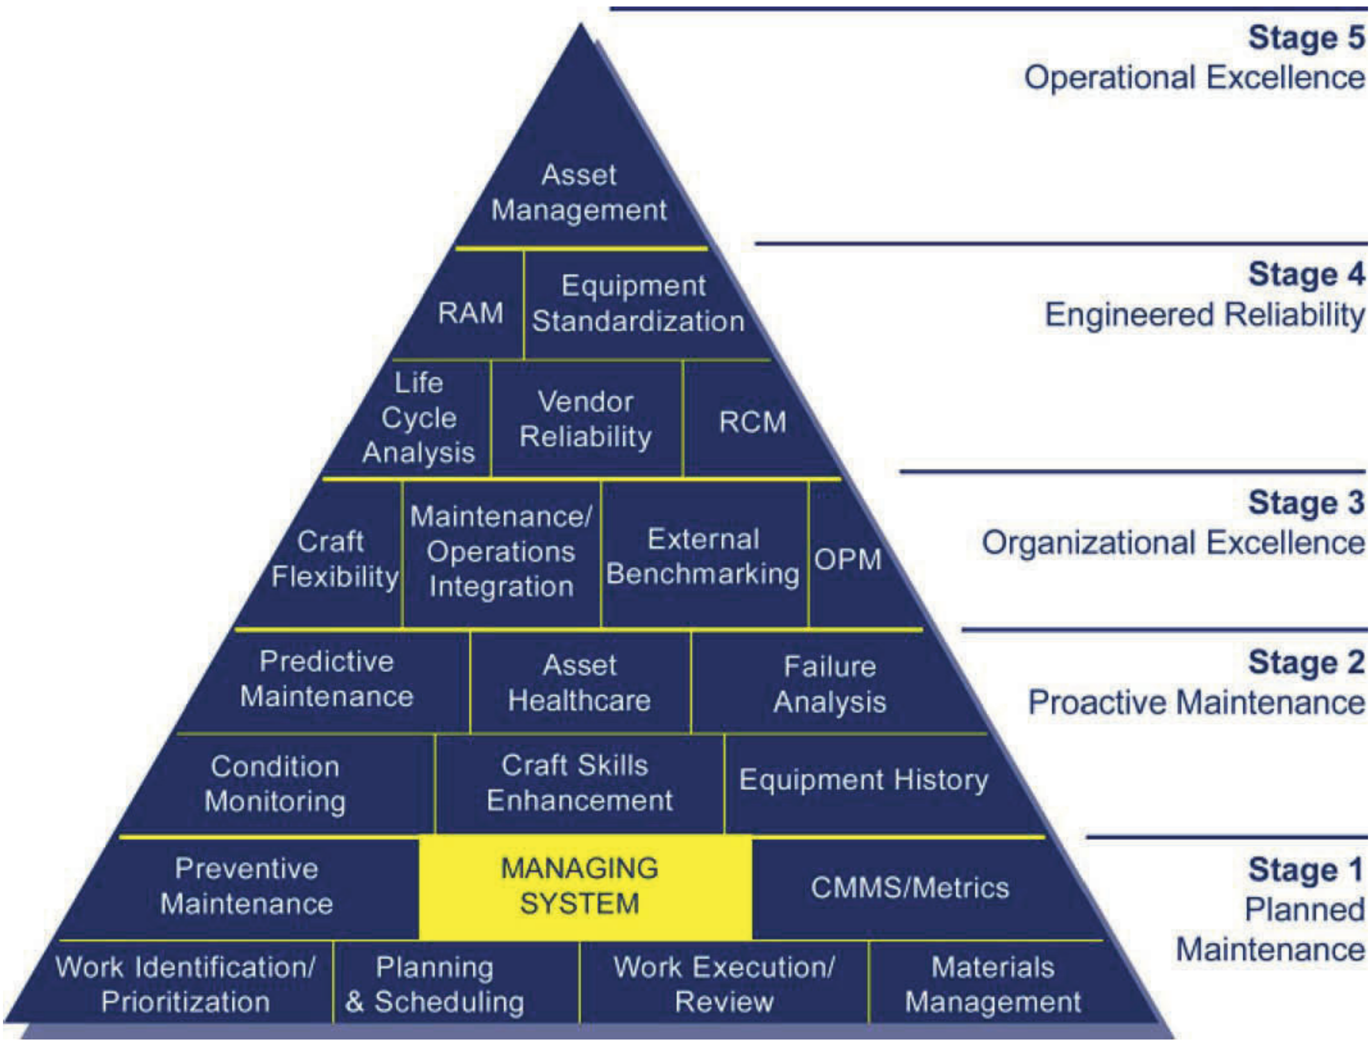

Figure 7: Asset Healthcare Triangle Model

Stage / Class	Low Performing	Competent	High Performing
Stage 1 Planned Maintenance	• "Fires" determine priorities • Breakdowns frequent • Maintenance equates to repair • Ineffective work orders, plans, controls • Stores service levels low • Poor operator/ maintenance relationships • Unable to meet production budgets	• Most work planned, scheduled • PM implemented, defects identified & corrected • Trades competent at most repairs • Computerized work system implemented • Stores service levels support operation • Operators prep for repairs • Maintenance goals & KPI's in place, reported	• All work prioritized, scheduled w/ prod's • PM hours and WO's exceed repairs • CMMS fully utilized • Parts kitted for jobs, 2x annual turns • Operators inspect, create WO's • Long-range scheduling implemented • Turnarounds well planned, executed
Stage 2 Proactive Maintenance	• Equipment history unusable • Failure analysis infrequent, ineffective • PM's don't match equipment or need • Inspections don't get done • Equipment criticality based on emotion • Condition monitoring sporadic, ignored • No comprehensive asset care program	• Equipment history is accurate and used • Critical assets have clear prevention plans • High percentage of PM compliance • Inspections yield WRs, scheduled & done • Condition monitoring widely used, trusted • Trades competent at most repairs • Failure analysis system established, effective	• Asset healthcare program for all equipment • Predictive techniques minimize downtime • Failure analysis done for 80% of failures • Results of RCFAs implemented routinely • Condition monitoring based on cost & risk • Prevention is a cultural imperative • Trades work on designing out failure
Stage 3 Organizational Excellence	• Training unconnected to real work practice • "Team" implementation causes confusion • Supervisors lack authority, accountability • Unclear roles and responsibilities • Skills flexibility in contract, not implemented • Operators don't inspect or maintain equipment • No individual performance targets/goals	• Supervisors have clear roles & accountability • Operators inspect, lube, prep equipment • Task teams form, identify solutions, disband • Most work is directly by a priority system • Natural work team effective at routine maintenance • Service contract exists between maint. & ops • Craft multi-skilling and flexibility implementation	• Work teams flexible, self-directed • Supervisors coach & advise • Continuous improvement embraced, effective • Clear priorities established for work • Reward/Recognition support best practices • Skills predominate over functions • All staff systems competent
Stage 4 Engineered Reliability	• RCM implementation creates confusion, results not implemented • Jobs changed on paper, not in reality • Stages 1&2 are ignored to "eliminate work" • Emphasis on analysis, not implementation • Vendor reduction brings lower service levels	• Reliability models run for critical systems • Component MTBF specifications defined • Equipment standards implemented • Critical equipment assessed via RCM • Projects get input from maintenance, ops • Equipment types, models rationalized • Purchasing buys by lifecycle cost, not price	• Concurrent engineering assures RAMBO • Reliability tied to financial results • Lifecycle costs are the basis for decisions • Vendor contracts pay for function reliability • Production targets set by reliability models • Equipment failures are a rare occurrence
Stage 5 Operational Excellence	• Management unclear re: goals & methods • Equipment condition not factored into goals • Equipment run parameters changed daily to respond to market pressures • Too many priorities prevent focus • Poor understanding of plant potential/ liabilities	• Clear organizational alignment • Goals cascaded from plant level to individual • Production goals based on plant capability • Most work identified and planned prior year • Hourly help set unit goals & work improvements • Activity-Based Management implemented • Production reliability is part of product marketing	• Each employee knows & is rewarded for role • All decisions based on facts and models • 80% of work is preventive or project, & is identified prior to the start of the year • Production is 98% predictable • Lowest cost producer • Plant becomes corporate expansion site

RAMBO=Reliability, availability, maintainability, buildability, operability **WR=**Work request **RCFA=**Root Cause Failure Analysis **KPI=**Key Performance Indicator **OUE=**Overall Unit Effectives (OEE)

A DATA QUALITY FRAMEWORK FOR ENGINEERING ASSET MANAGEMENT

Shien Lin [a], Jing Gao [a] and Andy Koronios [a]

[a] *School of Computer and Information Science, University of South Australia, Mawson Lakes Boulevard, MAWSON LAKES SA 5095, Australia.*

Abstract: Data Quality (DQ) is a critical issue for effective engineering asset management (AM). DQ problems can result in severe negative consequences for an organisation. Several research studies have indicated that most organizations have DQ problems. This research aims to explore DQ issues associated with asset management in engineering organisations. The study first develops an AM specific DQ framework, and then tests it in a preliminary case study of two large Australian engineering organisations. The empirical findings of the DQ issues from the research are used to validate the proposed AM DQ framework. This study provides a better understanding of DQ issues for engineering asset management. This in turn will assist in providing useful advice for improving DQ in this area, leading to activities which will help ensure DQ. The research suggests that the importance of DQ issues for engineering asset management is often overlooked; thus, there is a need for more scrutinised studies in order to raise general awareness.

Key Words: Data Quality, Engineering Asset Management

1 INTRODUCTION

Industry has recently put a strong emphasis on to the area of asset management (AM). In order for organizations to generate revenue they need to utilize assets in an effective and efficient way. Often the success of an enterprise depends largely on its ability to utilize assets efficiently. Therefore, asset management has been regarded as an essential business process in many organizations. Furthermore, as companies today are running leaner than ever before, physical assets are being pushed to their limits, as engineering enterprises attempt to continuously drive more productivity out of their equipment, in order to improve their bottom lines. Consequently, physical asset management is moving to the forefront of contributing to an organization's financial objectives.

Nevertheless, there is strong evidence that most organisations have far more data than they possibly use; yet, at the same time, they do not have the data they really need (Levitan and Redman, 1998). Modern organizations, both public and private, are continually generating large volumes of data. On a personal level, according to Gartner Research (2005), each person on the planet generates an average of 250 Mbytes of data per annum, with this volume doubling each year. At the organizational level, there are incredibly large amounts of data, including structured and unstructured, enduring and temporal, content data, and an increasing amount of structural and discovery metadata. According to Hall (2005) of Computerworld, the situation will only get worse with the introduction of new data-generating technologies, such as Radio Frequency Identification (RFID), which will balloon the amount of data that has generated and accelerate this growth well beyond what IT organizations have experienced. And the trend of massive growth in data volumes will continue with no end in sight. Outside the business environment, there is an increasing number of embedded systems such as condition monitoring systems in ships, aircraft, process plants and other engineering assets, all producing gargantuan amounts of data. Despite this apparent explosion in the generation of data it appears that, at the management level, executives are not confident that they have enough correct, reliable, consistent and timely data upon which to make decisions. Many say “we are drowning in data and are starved of information”.

This lack of data visibility and control often leads to decisions being made more on the basis of judgment rather than being data driven (Koronios, Lin & Gao 2005). This can lead to less effective strategic business decisions, an inability to reengineer, mistrust between internal organizational units, increased costs, customer dissatisfaction, and loss of revenue. In some cases, it could also lead to catastrophic consequences such massive power failures, industrial or aviation disasters. Without good data, organisations are running blind and make any decision a gamble (ARC, 2004). They can’t make good decisions because they have no accurate understanding of what is happening within their company or the marketplace. They rely on intuition, which is dangerous in a fast-moving market with nimble competitors and finicky customers. Data and information are often used synonymously. In practice, managers differentiate information from data intuitively, and describe information as data that has been processed. Unless specified otherwise, this paper will use data interchangeably with information.

2 DATA QUALITY (DQ)

Numerous researchers have attempted to define data quality and to identify its dimensions (Kriebel, 1979; Ives, Olson, & Baroudi, 1983; Wang & Kon, 1993; Fox, Levitin & Redman, 1994; Wand & Wang, 1996; Wang & Strong, 1996; Shanks & Darke, 1998; Kahn, Strong & Wang, 2002). Traditionally, data quality has been described from the perspective of accuracy. However, this description has been challenged by a number of researchers (Strong, 1997; English, 1999; Salaun & Flores, 2001; Wang, Strong & Guauascio, 1994; Ballou, Wang, Pazer & Tayi, 1998; Orr, 1998), from the point of view that data quality should be defined beyond the accuracy dimension. Although there is no universal agreement on the meaning of "quality data", a common understanding found in the literature is that: "*quality data are data that are fit for use by the data consumer*" - Wang and Strong (1996). Orr (1998) also suggests that the issue of data quality is intertwined with how users actually use the data in the system, since the users are the ultimate judges of the quality of the data produced for them. With the aim of improving data quality, Wang (1998) suggests a Total Data Quality Management (TDQM) framework (define, measure, analyze and improve) for continuously managing data quality problems.

Dimensions of data quality typically include accuracy, reliability, importance, consistency, precision, timeliness, fineness, understandability, conciseness, and usefulness. Wand and Wang (1996) use ontological concepts to define data quality dimensions: completeness, unambiguousness, meaningfulness, and correctness. Wang and Strong (1996) categorize data quality into four dimensions: intrinsic, contextual, representational, and through accessibility. Shanks and Darke (1998) use semiotic theory to divide data quality into four levels: syntactic, semantic, pragmatic, and social. Recently, Kahn et al. (2002) have used product and service quality theory to categorize information quality into four categories: sound, useful, dependable, and usable.

Maintaining the quality of data is often acknowledged as problematic, but is also seen as critical to effective decision-making. Examples of the many factors that can impede data quality are identified within various elements of the data quality literature. These include: inadequate management structures for ensuring complete, timely and accurate reporting of data; inadequate rules, training, and procedural guidelines for those involved in data collection; fragmentation and inconsistencies among the services associated with data collection; and the requirement for new management methods which utilize accurate and relevant data to support the dynamic management environment.

Clearly, personnel management and organizational factors, as well as effective technological mechanisms, affect the ability to maintain data quality. Wang (1998) clarifies this relationship by drawing an analogy between manufacturing and the production of data. In this way they derive a hierarchy of responsibilities for data quality, ranging from management processes down to individual procedures and mechanisms. Their framework specifies a top management role for data quality policy, and a data quality management function to determine how that policy is to be implemented. This, in turn, should result in a data quality system for implementing data quality management, within which data quality control is enforced through operational techniques and activities. Data quality assurance then comprises all of the planned and systematic actions required to provide confidence that data meet the quality requirements.

3 ENGINEERING ASSET MANAGEMENT

Manufacturing assets are complex and expensive with multi-stage lifecycles. They begin as simple concepts to address an organization's needs and rapidly become physical entities that must be acquired, installed and handed-over to operating departments for use in generating revenues. During operation they must be carefully maintained to get maximum performance and longevity. Eventually they become obsolete and must be retired. Achieving maximum return-on-assets requires use of asset information and best practices for every activity, across all of these stages. In order to provide an in-depth understanding of the complex lifecycle asset management processes, the collaborative asset lifecycle management model (ARC Advisory Group, 2004) is adopted and illustrated in Figure 1.

There are three domains focused on the creation, use and management of the manufacturing assets in the model. The *Asset Lifecycle Domain* captures the processes related to asset creation, improvement and retirement. It includes key processes like design, manufacture, installation and decommissioning of complex facilities. The primary stakeholders in this domain are the asset owner and their Engineer, Procure and Construct (EPC) contractor. Once assets have been installed, they are operated and maintained by the respective groups in the owner/operator's organization. The *Asset Operation Domain* recognizes that operations consumes an asset's capabilities and these are restored periodically with parts and services acquired from the Original Equipment Manufacturers (OEM). The *Asset Performance Management Domain* includes those processes that occur during operation to monitor an asset's condition and manage the performance of the asset and the maintenance processes. Key players in this domain are the condition monitoring systems, Supervisory Control and Data Acquisition (SCADA) systems, the maintenance and technical staff and management. Asset management is at the heart of this model. This is a collaborative activity which includes the maintenance technicians, engineers and operators charged with the care and improvement of the manufacturing assets. And these stakeholders depend upon a reliable service network of service and parts providers.

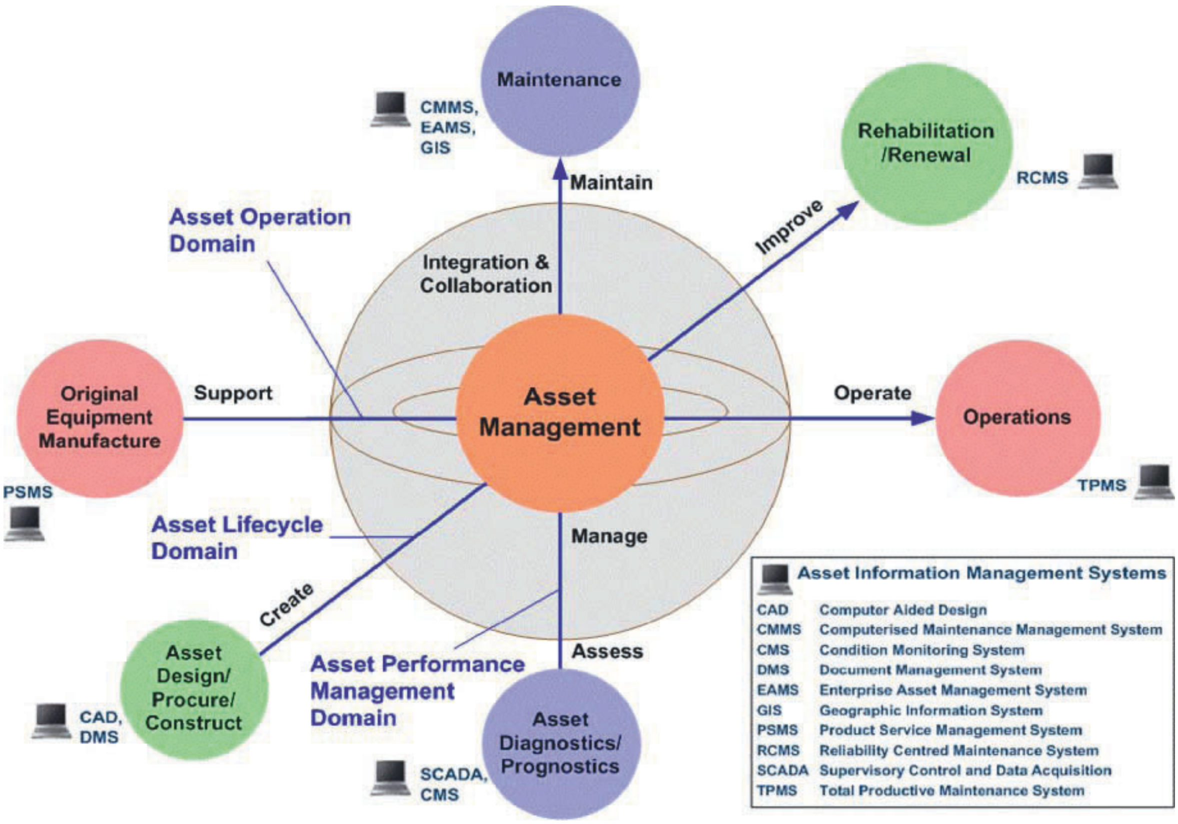

Figure 1: Collaborative asset lifecycle management and asset information management

(Source: Adopted and modified from ARC Advisory Group, 2004)

As discussed before, engineering assets have a unique set of characteristics as well as a sophisticated long process with different lifecycle stages. The process itself requires substantial information to be collected, processed, stored, analysed and further used throughout all stages of a typical asset's lifecycle. Because of the distinctive differences with regard to information systems and data requirements between general business environment and engineering asset management environment as discussed from previous research (Lin, Gao & Koronios, 2006), there is a need for an AM specific DQ framework to help obtain an insightful and overall understanding about what DQ issues are in AM, where the DQ problems are, why they have emerged, and where improvements can be made.

4 THE AM DQ FRAMEWORK

Based on the discussions on various data quality issues (Wang, Storey & Firth, 1995; Gelle, & Karhu, 2003; Xu et al., 2002; Xu et al., 2003; GAO, 2004) and the unique characteristics of asset management, an AM DQ framework was developed as shown in Figure 2. This framework is useful to guide the research into DQ issues in asset management, because it highlights the three root perspectives on data quality problems, illustrates how they emerge during the process of asset management; and outlines the basic data quality management criteria.

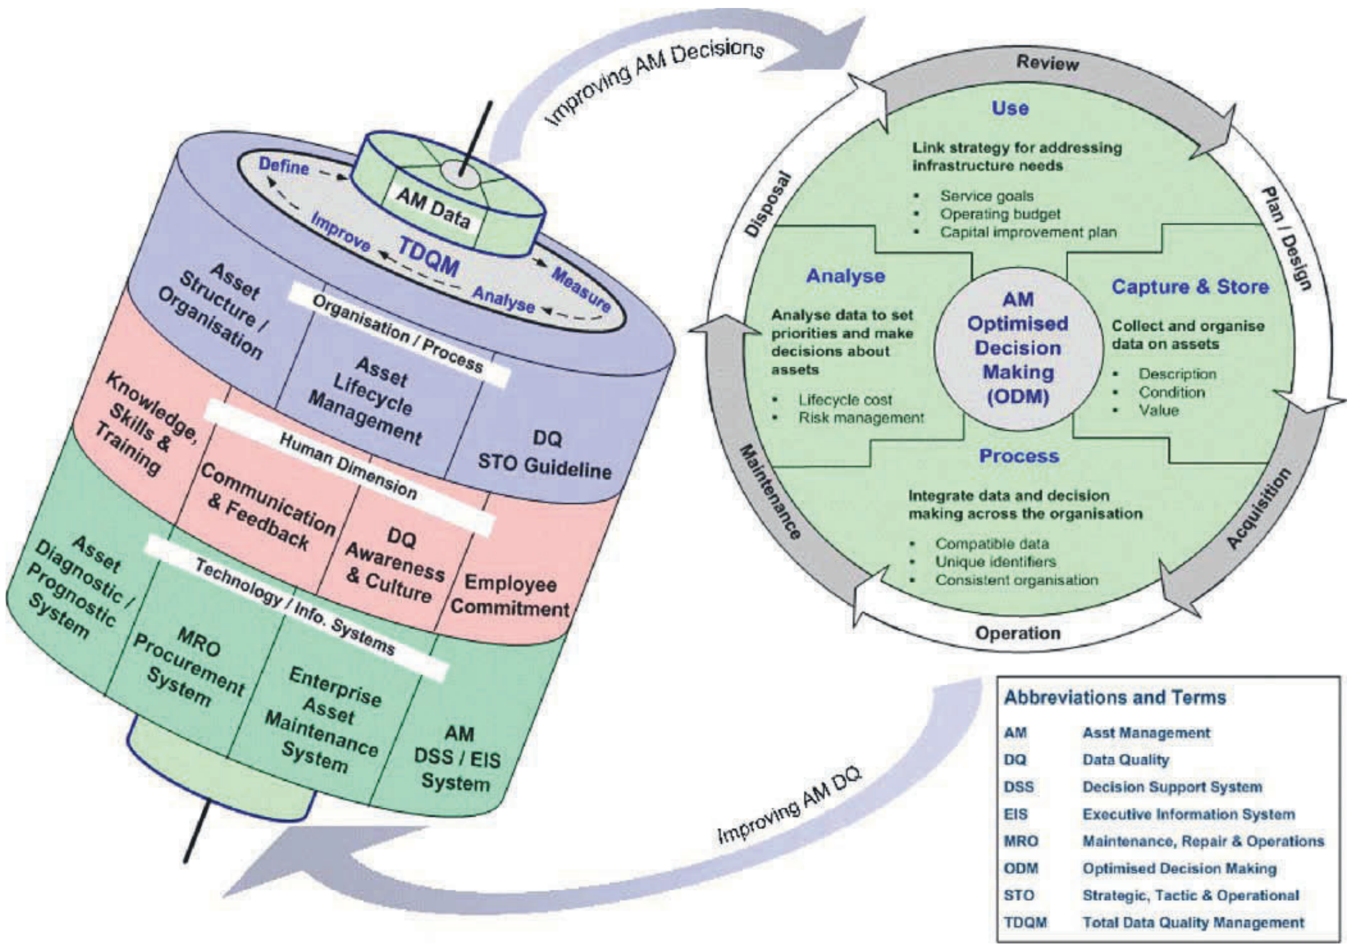

Figure 2: The AM DQ Framework (Source: Developed by the authors)

TOP Perspectives

Due to the uniqueness of engineering assets together with sophisticated long AM processes, engineering asset management demands total technological, organizational and personnel (TOP) supports. Mitroff and Linstone (1993) argue that any phenomenon, subsystem or system needs to be analysed from what they call a Multiple Perspective method – employing different ways of seeing, to seek perspectives on the problem. These different ways of seeing are demonstrated in the TOP model of Linstone (1999) and Mitroff and Linstone (1993). The TOP model allows analysts to look at the problem context from either Technical or Organizational or Personal points of view:

- The technical perspective (T) sees organizations as hierarchical structures or networks of interrelationships between individuals, groups, organizations and systems
- The organisational perspective (O) considers an organization's performance in terms of effectiveness and efficiencies. For example, leadership is one of the concerns.
- The personal perspective (P) focuses on the individual's concerns. For example, the issues of job description and job security are main concerns in this perspective.

Mitroff and Linstone (1993) suggest that these three perspectives can be applied as "three ways of seeing" any problems arising for or within a given phenomenon or system. Werhane (2002) further notes that the dynamic exchanges of ideas which emerge from using the TOP perspectives are essential, because they take into account "the fact that each of us individually, or as groups, organizations, or systems, creates and frames the world through a series of mental models, each of which, by itself, is incomplete". In other words, a single perspective on the problem context is not sufficient to elicit an insightful appreciation of it.

It is found that AM DQ requirements can be best described by using the TOP multiple-perspectives approach, which has close conformability with the key DQ research framework proposed by Wang, Storey & Firth (1995). Based on the previous discussion, it is felt that the process of modern asset management consists of the adoption of enterprise-wide information systems, various business processes, participants (e.g. maintenance people, managers, etc) and organizational policies (and business goals, structures, etc). It is thought that Linstone's TOP approach can be used to establish a building block for this framework (as a mean of identifying emerging DQ issues from AM).

4.1 Asset Lifecycle Process

An asset lifecycle starts at the time of designing the manufacturing system, and involves such activities as asset acquisition, operation, maintenance, decommissioning and replacement (Grobholz, 1988). Steed (1998) indicates that during its lifetime, the asset is subjected to a host of external factors: environmental conditions, system events, normal and abnormal loads, even changes brought about for whatever reason to the dielectric balance. At several critical stages, information is required on the condition of the assets. Knowing what to measure, how to measure it, and then what to do with the information becomes very important. Sandberg (1994) argues that contemporary asset management demands an elevated ability and knowledge to incessantly support asset management process, in terms of data acquisition, real-time monitoring, and computer supported categorization and recording of divergences from standard operations.

4.1.1 Technology

A variety of specialized technical, operational and administrative systems exist in asset management, which not only manage the operation of asset equipment but also provide maintenance support throughout the entire asset lifecycle. Most engineering organisations today purchase specialized systems from many suppliers. Some of these technical systems include asset diagnostic/prognostic systems, Supervisory Control and Data Acquisition (SCADA) systems, Computerized Maintenance Management Systems (CMMS), and Enterprise Asset Management systems. Normally these systems are bought from multiple vendors and each is specialized to accomplish its task. Unfortunately, this leads to an extremely difficult integration job for the end-user.

4.1.2 Organisation

The process of asset management is complicated. The lifecycle for a typical engineering asset involves several interdependent stages. Coordinating these processes as well as collaborating among other organizational processes affected by asset performance is vital to the effective management of engineering assets. Asset information is a key enabler in gaining control of assets. In order to facilitate AM data capture, process, storage, use and analysis, an asset hierarchy is essential. The objective of constructing an asset hierarchy is to provide a suitable framework for assets, which segments an asset base into appropriate classifications. The intent of the asset structure/organisation is to provide the business with the framework in which data are collected, information is reported, and decisions are made. In most cases, organizations work with an informal asset hierarchy. This often leads to data being collected to inappropriate levels, either creating situations where costs escalate with minimal increases in benefits, or insufficient information is available to make informed decisions (IPWEA, 2002). The information needs of the organization vary throughout the management structure. At the workface the key elements are operations, maintenance, and resource management, at a component level. At higher management levels this information needs to be aggregated to provide details on assets, facilities and systems as a whole in terms of finance, strategic and policy. The development of the asset identification needs to be appropriate for the asset hierarchy and complement the data/information needs of the organization (IPWEA, 2002).

4.1.3 People

In addition to the requirements for specialized IT/IS supporting systems, the AM process also require the involvement of assorted engineering and business stakeholders, internally and externally (Snitkin 2003). Because the impact of asset lifecycle management is too broad to be the sole responsibility of a single enterprise department, focusing only on the needs of AM personnel severely restricts the value that engineering asset management can bring to the organization. Supporting the needs of other stakeholders like management, finance & accounting, purchasing, product design, plant engineering, operations, sales, compliance, original equipment manufacturers (OEMs), and external service providers, has synergistic benefits that amplify the impact of all engineering asset management activities. As asset information is created, analysed and used throughout the whole asset lifecycle process by a variety of stakeholders, all stakeholders involved must be educated with regard to the impact of their actions and their roles, and take responsibility for supporting the collaborative asset management within the organization. Because of the diversity and high turnover of AM stakeholders, asset management outcome is also greatly associated with staff competency, communication & feedback, organizational culture, employee commitment.

4.2 Data Lifecycle Process

The sophisticated long AM process itself also requires substantial information support. Asset information is created throughout all stages of a typical asset's lifecycle, and underlies all the business processes in each domain. As data is a dynamic, fluid resource, it actually flows in a data lifecycle process. The major stages in the data lifecycle process include data acquisition, exchange and integration, storage and analysis. The DQ problems that may arise at each stage are different, and require different metrics as well as solutions [9]. Because of the continuum nature of data, DQ is not a one-time, fix-it-and-forget-it practice [13]. Building and keeping good quality corporate data takes constant vigilance and feedbacks in the context of the entire data lifecycle.

4.2.1 Data Acquisition

In increasingly rare cases, the data acquisition stage is preceded by a planning stage, where the amount of data gathered are planned and provided for. More often than not, however, it is the constraints on measuring devices and business exigencies that determine the kind of data that is collected, without the pre-planning stage. A major source of error at the data acquisition stage is the manual acquisition/entry of data. Manual entry can result in mis-typed data or lead to incomplete and missing data, non-standard entry, or duplicate entry. The lack of a pre-planning stage often introduces intractable DQ errors such as a mismatch between the scale of the problem and the scale of the hardware/software used. It can lead to short sighted or uninformed decisions that constrain the functionality of the data.

4.2.2 Data Integration

The most intractable DQ problems arise during data integration, the process by which multiple data feeds are brought together to create a rich and complete dataset. Most organizations are creating federated data, where data from different sources are stitched together to form a whole. The major DQ challenges during data integration are multiple data sources, different definitions, time synchronization, unconventional data, legacy systems, and sociological factors.

4.2.3 Data Storage

Once the data have been collected, they must be stored on devices in some format and with some storage management software. Physical storage is generally not a problem in these days. There are more concerns with the logical storage of the data – whether in a collection of files, in a database, or in some other structure. In any case, a schema must be developed, storage conventions decided upon, and metadata developed for the end user. The major DQ problems that arise during storage are: lack of awareness and planning, paucity of metadata, inappropriate data models, ad hoc modifications and changes, software and hardware constraints.

4.3 Total Data Quality Management (TDQM)

The process of engineering asset management is sophisticated, which requires gargantuan amounts of data to be collected from many different parts of the organization throughout all stages of a typical asset's lifecycle. This information must be maintained for many years in order to identify long-term trends. The AM engineering and planning processes use this information to plan and schedule asset maintenance, rehabilitation, and replacement activities. More asset data, however, does not necessarily mean better information, or more informed AM decisions. Many are finding it difficult to use this data. Most users are unable to translate the vast amounts of available asset data into meaningful management information to optimize their operation and control the total asset base. Researches found that although very large amounts of data is being generated from AM systems, little thought has been given to the quality of such generated data (Saunders 2004). Thus the quality of data from such systems may suffer from severe quality limitations. Miklovic (1998) reported that there are disconnects between the transaction-driven, product-centric business data environment and the continuous data, process-centric open control system and manufacturing data environments. The lack of process-to-product data transformation capabilities in linking business systems and plant floor AM applications have significant DQ consequences and thus negatively affect data-driven decision-making.

To achieve a state of high DQ, an organisation needs to take the approach of implementing Total Data Quality Management (TDQM) for understanding the DQ problems, identifying the causes, and developing the DQ improvement solutions. Wang (1998) adapted W. E. Deming's method of defining, measuring, analyzing, and improving products to the information manufacturing environment, and proposed TDQM, which emphasizes the importance of continuous improvement and delivery of high-quality information products. The defining component of the TDQM cycle identifies important IQ dimensions (Wang & Strong 1996) and corresponding DQ requirements. The measurement component produces DQ metrics. The analysis component identifies the root causes for DQ problems and calculates the impact of poor-quality information. Finally, the improvement component provides techniques for improving DQ. Different industries with different goals and environments can develop more specific and customized programs for DQ management to suit their own needs. Kovac, Lee & Pipino (1997) argue that regardless of differences organisations must develop a set of measures for their important DQ dimensions that can be linked to the organisational general goals and objectives. In the realms of improving data quality in engineering asset management, organisations need to focus on DQ control, DQ assurance and DQ management.

5 RESEARCH DESIGN

Based on the previous discussion about the EAM problems, an interview-based case study was designed to explore the DQ issues emerging within the chosen organizations. The organizations included two large Australian water utilities, as well as several of their subcontractors. A number of stakeholders at all levels of the organizations were interviewed, chosen on the basis of their experience in the use and management of engineering assets. The target organisations used a variety of information systems for EAM (e.g. GIS for asset location, Maximo for asset maintenance). Thirty interviews were conducted involving senior executives, asset managers, maintenance engineers, technicians, and data operators. In functional these stakeholders came from different position levels with different data roles at various office locations, including data provider, data custodian, data user, and data manager. In cases of conflicting issues, crosschecking for interviews was also conducted to validate the results.

Responses to our research questions were collated, stored, and analysed using qualitative data analysis software. This analysis allowed us to explore the raw data, identify and code the common themes, and identify relationships between themes in a rigorous manner. In analysing the collected data, an extensive examination of the viewpoints of various stakeholders was conducted. The views and actions of various interviewees in terms of their organizational interests were also examined. A very preliminary validation of the DQ for asset management model was achieved. While there may be some limitations in the approach used, we feel that the richness of the data collected far outweighed the methodological shortcomings of such an approach.

6 FINDINGS

The followings represent some of the preliminary findings based on using the TOP model. The integration of AM-related technical systems, as well as the integration between business systems and technical systems, is particularly important.

6.1 Integration of Technical Systems in Asset Management

A variety of specialized AM technical systems exist including reliability assessment systems, asset condition monitoring systems, asset maintenance systems. Such specialized systems are quite disparate, and acquired from multiple vendors, they often lead significant integration problems. There appears to be little cognizance when adopting business systems such as financial, human resource information systems of the need to ensure compatibility with technical systems such as asset register systems, condition monitoring systems. Most users are unable to translate the vast amounts of available asset data into meaningful management information to optimize their operation and control the total asset base. This has led to the notion of ‘islands of information’.

There are disconnects between the transaction-driven, product-centric business data environment and the continuous data, process-centric open control system and manufacturing data environments. Such disconnects make it extremely difficult to bring real-time information from the plant into business systems. The lack of process-to-product data transformation capabilities in linking business systems and plant floor EAM applications have significant DQ consequences and thus negatively affect data-driven decision-making.

6.2 Sensor Calibration and Integrity Check for Condition Monitoring

Interviews with asset maintenance field workers indicate that data captured by intelligent sensors may not always be accurate. Data capturing devices typically used in condition monitoring are electronic sensors or transducers, which convert numerous types of mechanical behavior into proportional electronic signals, usually voltage-sensitive signals, producing analog signals which in turn are processed in a number of ways using various electronic instruments. As signals are generally very weak, a charge amplifier is connected to the sensor or transducer to minimize noise interference and prevent signal loss. The amplified analogue signal can then be sent to filtering devices to remove or reduce noise, before being routed to a signal conditioner and/or analogue-to-digital converters for digital storage and analysis. To ensure the data received by the SCADA system conforms to the original signal data captured by sensors, integrity checks for signal transmission process and sensor calibration need to be performed and maintained. However, as the sensor calibration and integrity checks are often neglected in asset maintenance, the extent to which acquired data is correct and reliable was shown to be of concern with respondents.

6.3 Data Standard for Condition Monitoring Systems

Although it appears that condition monitoring equipment and systems are proliferating, an apparent lack of dialogue among vendors has led to incompatibilities among hardware, software and instrumentation. Data collected by current outdated equipment could become obsolete and inaccessible to new upgraded systems. To fully realize the integration of systems over the various levels of asset maintenance and management, new standards and protocols are needed. A focus on standardization of condition monitoring data modelling and exchange tools and methodologies, such as Standard for the Exchange of Product model data (STEP) is critical.

6.4 Database Synchronization

The capability of EAM systems can be enhanced through a link with GIS to provide the ability to access, use, display, and manage spatial data. The ability to effectively use spatial asset data is important for utilities with geographically dispersed utility networks. However, it was found that one of the most critical activities is to establish synchronization between the two database environments. One asset manager indicated that there has been an issue existed for overcoming the synchronization of asset register in a very common work management system with GIS in the company. Both automated and manual processes needed to be defined and implemented to maintain synchronization between the GIS and EAM databases. Database triggers and stored procedures need to be defined to automate the attribute update process maintaining synchronization between the GIS and EAM databases. Workflows and business rules must be developed for GIS and EAM data editing, to ensure synchronization from both applications.

6.5 Business Process Reengineering

Organisational fit and adaptation are important to implementation of modern large-scale enterprise systems. Like enterprise resource planning systems, EAM systems are also built with a pre-determined business process methodology that requires a fairly rigid business structure in order for it to work successfully. They are only as effective as the processes in which they operate. Companies that place faith in EAM systems often do so without reengineering their processes to fit the system requirements. Consequently, this often results in negative impacts on the effectiveness of both the EAM system and the AM practices. It was found that a mismatch existed between the business processes requirements of the EAM and actual practice in the organisation.

6.6 Data Recording

Research in data collection has found that DQ and validation effectiveness improve, the sooner the collected data is entered and the nearer the data entry is to the asset and its work. If a data entry point is remote from the asset, then the capability for accurately confirming the data is considerably reduced and the temptation to enter something - anything that the system will accept - is great. One manager said in the interview that “I feel that most of the (data) errors over time have been because of the lag between the field data and being continued in the computer somewhere….they (field staff) might wait a week before they complete their work order (entry)”. It was found that the longer the time lag between using the entered data and the time it was initially created, the less chance of cleaning up the data to make it useful.

6.7 Training

AM requires all aspects of training as well as appropriate documentation of the system. It was found that organisations tended to focus more on the “hardware” part of the systems development process, putting less effort on the “soft” part, that is, the training of how to operate and manage the system. Several respondents indicated that the training was tailored for the specific areas but the same for everyone and thus of limited use to some. Many respondents contended that what they knew about the system was in fact ‘self taught’. Awareness of issues such as how the data being collected was going to be used was not existent; yet they agreed that such knowledge would increase motivation and performance by the asset operators/technicians. Lack of training can have an adverse impact on information quality. It is easy for organisations to find reasons/excuses for avoiding adequate training for the staff and management.

6.8 Communication & Management Feedback

Competitive asset-intensive companies have reported that most of their asset improvements come from their workforce. Despite the fact that “people are our greatest asset”, evidence of the opposite is often found. People’s problems, relationships, aspirations and their personal agendas are seldom given any consideration. In the implementation and management of EAM systems it appears that this is not different and was quite evident in the responses. Respondents were quite convinced that the system implementation neglected the human dimensions and thus contributed to the partial failure of these systems.

“year after year they (field workers) filled out field data without feedback……if we did nothing, nothing happens so why bother?”

7 CONCLUSION

Several researches have indicated that maintaining the quality of data is often acknowledged as problematic, but is also seen as critical to effective decision-making in engineering asset management. Managing data quality is essential to any asset management programme. This research develops an AM DQ framework in order to help organisations and practitioners understand DQ problems, identify causes, and develop solutions in the realms of engineering asset management. The framework proposed in this paper provides a useful tool for planning the establishment of an awareness of DQ issues in managing assets. With the adoption of the DQ framework, researchers can obtain an insightful and overall understanding about what DQ issues are in engineering asset management, where the DQ problems are, why they have emerged, and where improvements can be made. Future research will further develop the framework and identify DQ toolkit (e.g. guidelines, functional requirements for asset data cleansing software) for the improvement of data quality associated with engineering asset management.

Abstract: Localization (determination of the position of each sensor node) of a large scale sensor network is an important issue for applying network sensing technique to the health monitoring of the infrastructures. This paper presents an implementation of acoustic ranging and proposes a distributed algorithm for localization of sensor network. Relative positions between sensor nodes are estimated based on acoustic ranging through the inverse Delaunay algorithm. This algorithm localizes all the nodes simultaneously, thus, the accumulation of the error in the localization is suppressed. The robustness and the scalability of this algorithm are examined through numerical simulations. Noise tolerant acoustic ranging algorithm that employs digital signal processing techniques is implemented in an off-the-shelf sensor platform (Mica2). Experiments show that this acoustic ranging algorithm is sufficient to give average range estimation error below 10 cm. Together with this acoustic ranging algorithm, the inverse Delaunay algorithm is also implemented in Mica2. This enables automatic localization of sensor network. Field experiment was conducted to evaluate the accuracy of the localization of the system.

Key Words: Robust localization, Sensor network, Acoustic Ranging, Delaunay

1 INTRODUCTION

Recent developments in sensor and wireless communication technologies make it possible to distribute sensor platform in the environment[1]. One of the final targets to apply this network sensing system is civil infrastructures. High resolution sensing and on-site simulation using dense sensor network on civil infrastructures can be regarded as a typical example of sensor embedded society. The sensor network applied to civil infrastructures should cover wide area with high spatial resolution. This results in the requirement for numerous sensor nodes with low cost. This cost consists of cost for sensor itself and the installation cost. Especially to reduce the installation cost, automatic localization of the sensor nodes is needed. Although the required accuracy of localization depends on the application, we aim at the accuracy of less than 10cm for all the sensor nodes distributed over the space of the size of a whole city. Installation of GPS receivers on all the sensor nodes is not a realistic option because of the cost of available GPS receivers with the accuracy under consideration[2]. Motivated by this background, this paper presents an algorithm and an implementation of the sensor network system for robust localization. Localization of the sensor nodes in the network is achieved by a distributed algorithm called “Inverse Delaunay Algorithm.”

Localization of the sensor nodes presented in this paper uses relative distance between neighboring nodes measured by the acoustic ranging as input data. Direct application of the techniques in surveying (i.e., starting from reference nodes, localization is done on the nodes consecutively through the triangulation) does not work in this case because of the noisy measurement on the relative distance and the accumulation of the error. It seems that the distributed algorithm consisting of i) construction of local cluster of nodes with relative positions identified in the local coordinates for the cluster and ii) inter-cluster patching algorithm, works better for localization based on noisy measurement on the relative distance between nodes. Existing work based on this approach is summarized in Moore *et al.* [3] as attempts for graph realization problem. In this problem, reduction of the flexibility of the local cluster of the nodes (e.g., flip ambiguity, discontinuous flex ambiguity) is the major concern. The inverse Delaunay algorithm presented in this paper is categorized in the attempts for graph realization problem.

2 RELATIVE LOCALIZATION BASED ON INVERSE DELAUNAY ALGORITHM

Each and every sensor node in the randomly distributed sensor network is localized by the algorithm discussed in this section. Localization is achieved by clustering the neighbouring set of nodes with Delaunay polygons using the observed relative distance between sensor nodes as input data. This is opposite from Delaunay tessellation of a space for given arrangement of points. In this sense, this localization algorithm is called inverse Delaunay algorithm. Before discussing the details of the inverse Delaunay algorithm, mathematical definition and characteristics of the Delaunay tessellation/polygons are given in this section[4].

For a set of finite number of points $X = \{\mathbf{x}^1, \mathbf{x}^2, \cdots, \mathbf{x}^n\}$ on 2D real space ($\Re^2$) with Euclid distance $d(\mathbf{x}, \mathbf{y})$ between points $\mathbf{x}$ and $\mathbf{y}$, define

$$V(\mathbf{x}^i) = \{\mathbf{x} \mid \mathbf{x} \in \Re^2, d(\mathbf{x}, \mathbf{x}^i) < d(\mathbf{x}, \mathbf{x}^j), i \neq j\}. \tag{1}$$

Then, $V(\mathbf{x}^i)$ becomes a convex polygon containing a point $\mathbf{x}^i$ and a set $\{V(\mathbf{x}^1), V(\mathbf{x}^2), \cdots, V(\mathbf{x}^n)\}$ gives a tessellation on $\Re^2$. This tessellation is called Voronoi tessellation for a set X and denoted as $V(X)$. Points in a set X are called mother points of $V(X)$, and $V(\mathbf{x}^i)$ is called a Voronoi cell for a mother point $\mathbf{x}^i$.

When $V(\mathbf{x}^i)$ and $V(\mathbf{x}^j)$ share a Voronoi edge (i.e., edge of the Voronoi polygons), conjugate geometry to Voronoi diagram can be obtained by connecting $\mathbf{x}^i$ and $\mathbf{x}^j$. This diagram is called Delaunay diagram and the tessellation using Delaunay diagram is called Delaunay tessellation. The vertices and the circumcenters of the Delaunay polygon correspond to the mother points in Voronoi tessellation and vertices of the Voronoi cells, respectively (see Fig. 1). The following characteristic holds for a Delaunay diagram in 2D space:

Polygons in the Delaunay diagram on $\Re^2$ are triangles with no mother point of $V(X)$ in their circumscribed circle

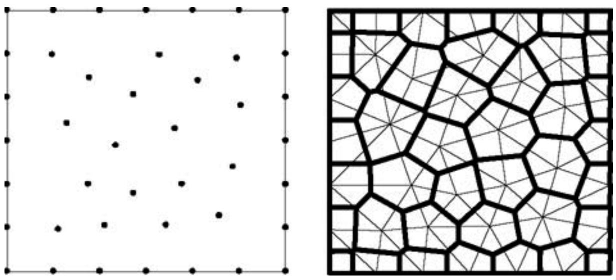

Figure 1 left: mother points (corresponding to the sensor nodes to be localized), right: Voronoi (thick) and Delaunay (thin)

The inverse Delaunay algorithm discussed in the following subsections consists of two steps, namely, 1) construction of local clusters (Delaunay clusters), and 2) merging procedure of local clusters. The characteristic of Delaunay diagram shown above is extensively used to increase the robustness of the first step (i.e., toughness of the local clusters against the measurement error).

Note that the whole discussion in this section can be easily applied to 3D real space by extending Eqn. (1) and the corresponding Euclid distance to those for $\Re^3$. In that case, a Voronoi cell, $V(\mathbf{x}^i)$ becomes a polyhedron and the Delaunay tessellation becomes a tessellation consisting of tetrahedrons. However, for the sake of simplicity, description of the algorithm is given for 2D problem setting henceforth.

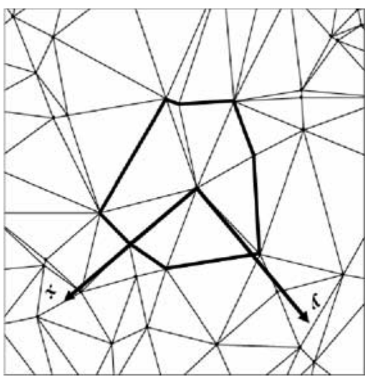

Figure 2 Typical example of the local cluster

2.1 Construction of local Delaunay cluster

In the first step of the inverse Delaunay algorithm, a local cluster is made for each sensor node (which results in a mother point in the Voronoi diagram made by localized sensor nodes). Figure 2 shows a typical example of a local cluster. The area surrounded by thick solid lines is a local cluster. In this local cluster, the center node is surrounded by the Delaunay triangles hence this cluster is called Delaunay cluster. All the nodes are localized in the local Euclidean coordinate system with the center node set as the origin. Also, the nodes surrounding the center node (satellite nodes) are numbered counter-clockwise in the local coordinate system. This numbering determines the direction of the face of the local cluster.

Each local cluster is generated in the manner as shown in Fig. 3.

1. A node is picked up as a center node (filled circle in the figure) and the closest neighboring node is identified based on the measurement of the relative distance. (Fig. 3 (a))
2. Form a triangle using above-mentioned nodes and another neighboring node. Examine this triangle to see whether it is Delaunay or not. Triangle with dotted line in Fig. 3 (b) is not Delaunay since other node is located in the circumscribed circle.
3. Local cluster is expanded by adding another Delaunay triangle which has a center node as one of the vertices (Fig. 3 (c)).
4. After surrounding the center node by Delaunay triangles, the satellite nodes are numbered. The Delaunay cluster shown in Fig. 3 (d) has the clockwise numbering. This means the local coordinate for this Delaunay cluster is flipped with respect to the global coordinate (which can be identified after the global localization is done).

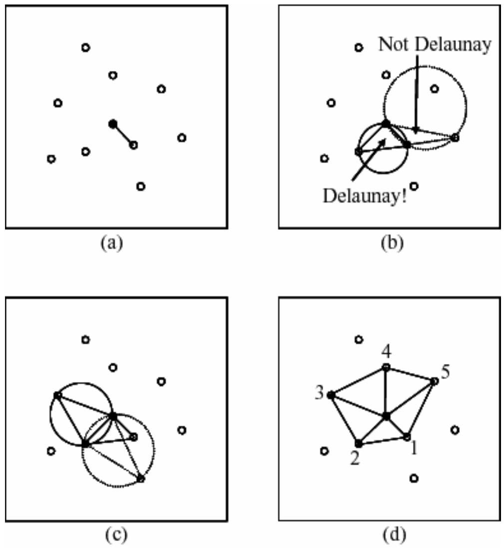

Figure 3 Construction of the Delaunay cluster

Note that Fig. 3 shows a conceptual view of the arrangement of the nodes and the local cluster. In reality, position of each node has not been identified before localization is done. All we have is the relative distance between nodes. Delaunay examination and expansion of local cluster solely depend on relative distance.

2.2 Merging procedure of local Delaunay cluster

Once the local Delaunay clusters are identified for all the nodes, those clusters should be merged together. Merging is achieved by identifying the necessary translation, rotation and flip for each cluster to satisfy consistency among local clusters with common set of nodes. The details of the merging procedure are as follows:

1. Clusters are divided into two groups, i.e., the atomic clusters and the bridging clusters. The atomic clusters are those with satellite nodes not being occupied by other clusters (i.e., polygons depicted by the edges with thick lines in Fig. 4). The bridging clusters are others. This categorization is done by first-come-first-serve basis in the current version of our source code. However, the categorization based on the reliability or the shape of the Delaunay cluster can be implemented.
2. Connect the atomic clusters (or groups) by the bridging clusters. If the order of numbering of the corresponding satellite nodes of both clusters (or groups) coincides, direction of the faces of these clusters (or groups) are different. Either one of them should be flipped. In Fig. 4, corresponding nodes in the atomic and the bridging cluster are numbered as $1 \rightarrow 2$ and $2 \rightarrow 3$, respectively, i.e., both have the ascending order. Therefore, the bridging cluster is flipped.
3. Apply the necessary translation, rotation and flip to the cluster or group to be consolidated.
4. Continue the second and the third process until all the clusters are merged into a group.

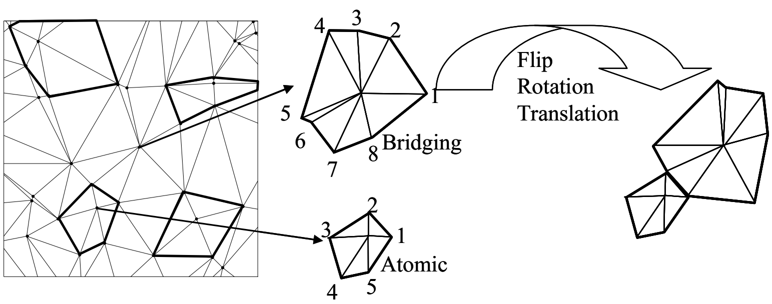

Figure 4 Cluster merging procedure

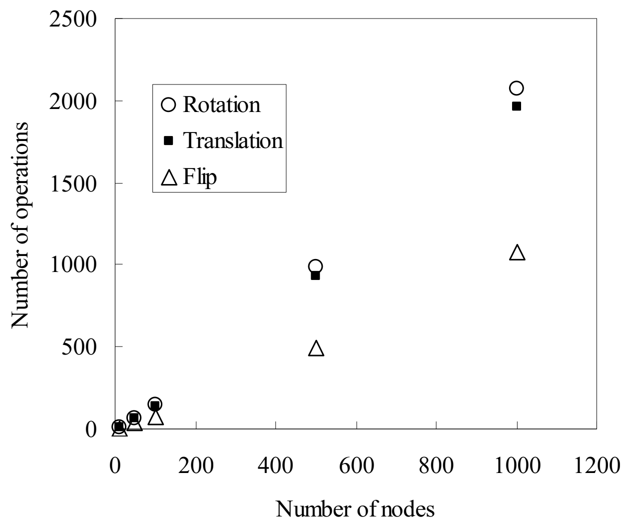
2.3 Computational complexity and robustness of the inverse Delaunay algorithm



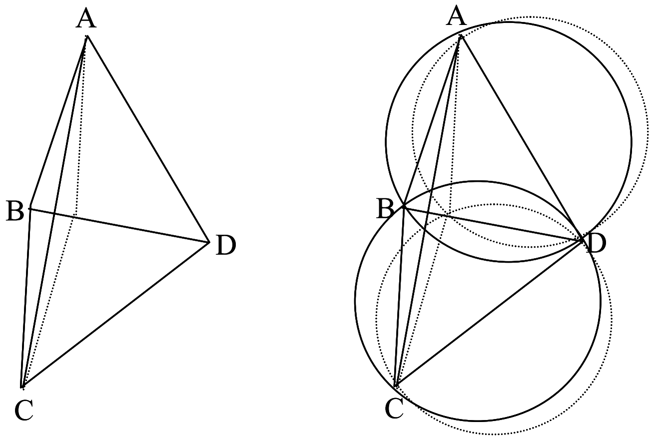


Figure 6 Robustness of the Delaunay cluster
left: the quadrilateral is not robust because of the measurement noise in the length BD
right: regardless of the position of node B, Delaunay is robust

Localization of sensor nodes based on relative distance between nodes is categorized in graph representation problem in computational geometry. As shown in the previous subsections, the proposed localization algorithm gives the relative location of the nodes using local clusters consisting of the Delaunay triangles. Thus, the algorithm is named as the inverse Delaunay algorithm.

One of the major advantages of the inverse Dealunay algorithm is its small computational complexity. Obviously, the construction of the local Delaunay clusters has the complexity of $O(n)$ where n is the number of the nodes. Figure 5 shows the total number of operation (i.e., translation, rotation and flip) in the merging procedure with respect to number of nodes. Figure 5 proves that computational complexity is $O(n)$ for merging procedure at least upto n=1000. This suppression of the complexity could due to the sparse arrangement of the atomic and bridging clusters.

Another major advantage of the inverse Delaunay algorithm is its robustness against the measurement error in ranging. To close the discussion on this algorithm, consider the situation shown in Fig. 6 as a typical example. In this situation, most of the localization algorithms based on robust quadrilaterals regard this quadrilateral as a potential source of the flip ambiguity and discards this quadrilateral. As a result, failure in localization of some nodes in the network is often observed. On the other hand, as shown in Fig. 6, this situation does not cause any problem to the inverse Dealunay algorithm. This is due to the bigger margin allowed in checking the Delaunay condition than that for robustness of the quadrilateral.

3 IMPLEMENTATION OF ACOUSTIC RANGING ON A SENSOR PLATFORM (MICA2 MOTE)

Relative distance between sensor nodes is one of the key information for localization. Recently, many algorithms have been developed for ranging. RSSI (Received Signal Strength Indicator) based on attenuation of strength of electromagnetic wave is one of the well-known ranging algorithm for localization with relatively low accuracy applied for sparsely arranged sensor network. On the other hand, for applications with a requirement for precise localization of densely arranged sensor network, more accurate ranging method is utterly needed. For this purpose, ranging based on travelling time of electromagnetic and/or acoustic signals, so called time of arrival (TOA) methods are considered to be effective. Especially, research activities on acoustic ranging are active. This is mainly due to the limited resources in the hardware of currently available sensor nodes which is not enough for implementing ranging devices/algorithms based on TOA of electromagnetic signals. Typical sensor node (Mica2) has only 4kB RAM and 12kB ROM with 7.3MHz microcontroller (Amtel ATmega 128L)[1]. This little capacity shows requirement for algorithms with minimum consumption of memory and computational resources. The ranging algorithm discussed in this section is based on TOA of acoustic signal and implemented in Mica2.

3.1 Basic principle of acoustic ranging

The concept of acoustic ranging is based on measurement of the time of flight (TOF) of the acoustic signal between the signal source and the acoustic receiver. The range is estimated from the time measurement, assuming the speed of sound is known. To accurately measure the TOF of the acoustic signal, time synchronization between transmitter and receiver should be kept. However, accurate synchronization between sensor nodes itself is a topic with numerous ongoing research projects[]. Therefore, we do not try to implement synchronization among sensor nodes. Instead, we make use of the difference between the speed of electromagnetic wave and that of acoustic wave. Since the sound propagates much slower in the air (approximately 10^6 times) than RF signals, TOF can be precisely estimated from the time difference of arrival (TDOA) of simultaneously emitted acoustic and radio signals. This can be achieved by having actuator notify the receiver via a radio message at the same time when the acoustic signal is emitted. The difference of the arrival times of the sound and radio signals is a good indicator for the estimation of TOF.

In the following subsections, implementation of this principle of acoustic ranging on a commercially available sensor node (Mica2) is discussed with a major focus on algorithms for reducing the environment noise and for estimation of TOF.

3.2 Noise Reduction

To locate the beginning of the acoustic signal, we need to increase the SNR (signal to noise ratio) of the samples. Since disturbances such as ambient noise are of Gaussian nature, they are independent for each chirp, whereas the useful signal content will be identical. The acoustic signal used in this research consists of a series of chirps, all of the same length, with difference in intervals of silence in between. As shown in Fig. 7, Delays between consecutive chirps are varied to avoid a situation when multiple samples have the same noise pattern at the same offset, which is a common phenomenon caused by acoustic multi-path effects such as echoes from a wall in indoor environment (see Fig. 8). The length of intervals and the actual emission time of each chirp are preset in sensor and actuator. Once the sensor has received the RF signal from actuator, it controls the sampling timing based on the preset timing described above. The chirps are sampled one by one, then added together and processed as a single sampled signal. Adding together the series of samples improves the SNR by 10log(N)dB, where N is the number of chirps used. Specifically, in our implementation, by using 64 consecutive chirps in an acoustic ranging signal, the SNR is improved by 18dB.

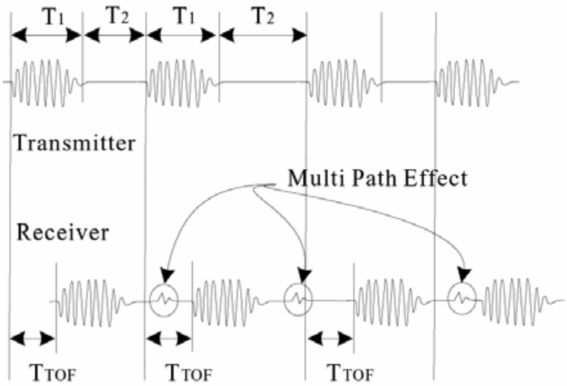

Figure 7 Reduction of the noise by data stacking
T_1=constant, T_2= random

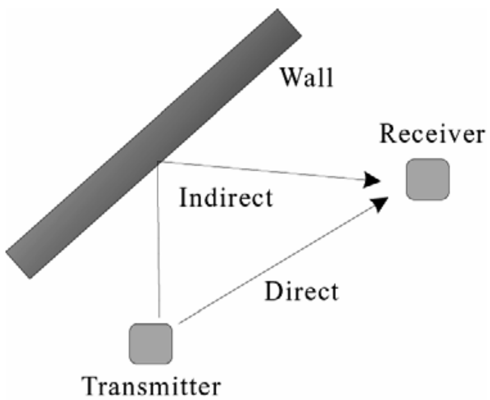

Figure 8 Multi-path caused by reflection

In addition to the external sources of the noise mentioned above (ambient and echo), analogue circuit for microphone and buzzer could contaminate the signal in low frequency range and the internal devices such as crystal oscillator could be the source of high frequency noise. Figure 9 shows the observed digital data after 64 times stacking. Remarkable noise in both low and high frequency range can be observed. To remove these noises, sampled data through ADC (analogue digital converter) is digitally processed by FIR filter and the SNR is improved. For finding integer coefficients of the band pass filter employed in this acoustic ranging application, the real acoustic signal samples containing both chirps and silence obtained by Mica2 is used as input for rectangular window functions. Rectangular window function is used in order to gain the equal weight for 4.0--4.5kHz frequency range of the sounder. By using the rectangular window function, tap number is varied. Figures 10--12 show filtered data with tap number 21, 25 and 35, respectively. We do not observe significant difference among them. Thus, FIR filter with tap number 21 is enough and we implement this filter in Mica2. Knowing the Mica2 hardware limitation, 21-tap FIR filter with integer coefficients in the [-7, 7] interval was chosen.

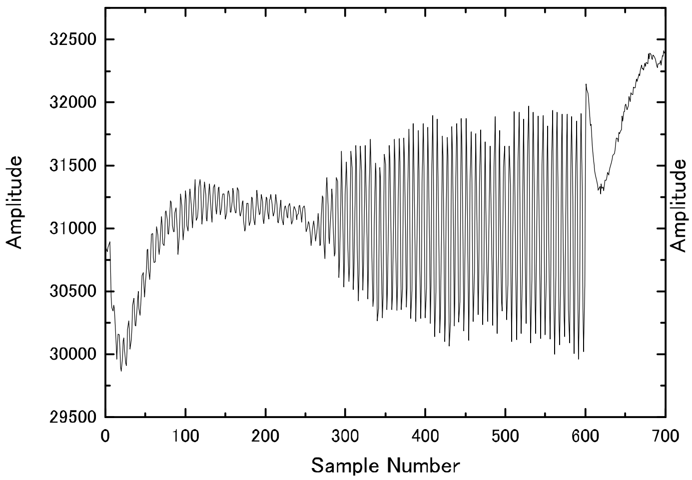

Figure 9 Stacked data without filtering

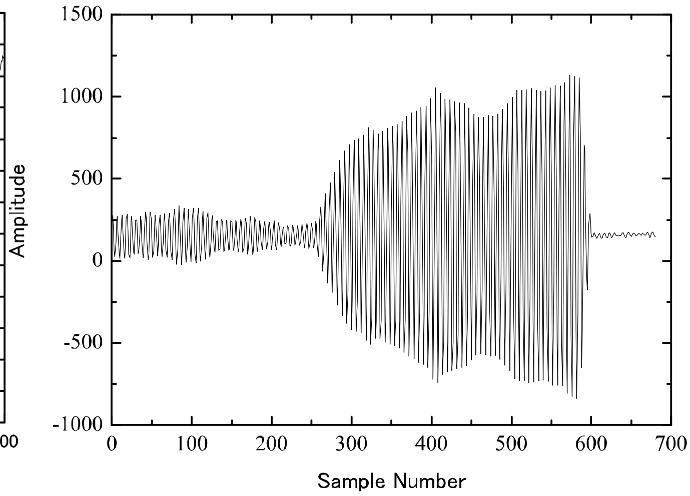

Figure 10 Filtered data with (tap number) =21

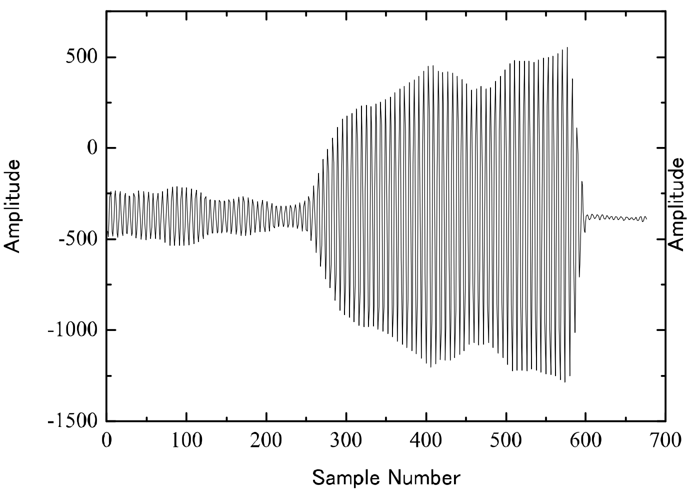

Figure 11 Filtered data with (tap number) =25

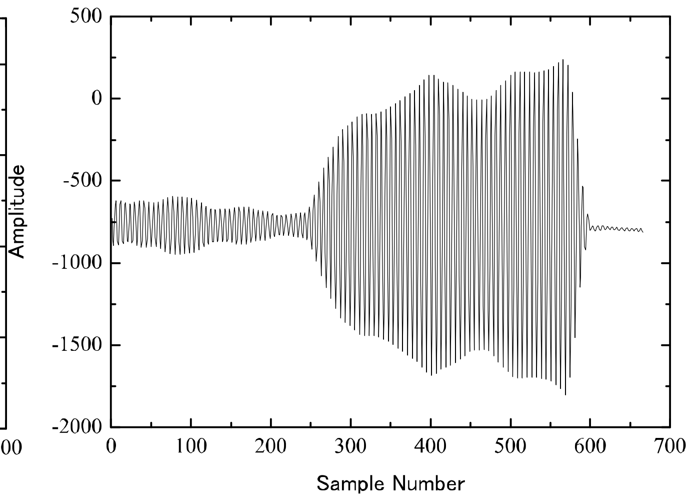

Figure 12 Filtered data with (tap number) =35

3.3 Time of flight estimation

In order to effectively locate the time of arrival, the following algorithm is proposed.

1. Locate all the peaks for the filtered signals.
2. Pick up the maximum amplitude A_{max} from the first 40 samples of the located peaks. For the frequency range between 4.0kHz and 4.5kHz, the 40th sample of the located peaks corresponds to about 100cm distance in the real space. Since the spacing between child nodes are more than 100cm in our application, the maximum amplitude A_{max} is the maximum ambient noise level.
3. Using A_{max} as a reference point, compare the following peaks with it. Locate position Ts where the following peaks are all bigger than A_{max}. This is based on the fact that, then acoustic signal arrives at the sensor, its amplitude is much bigger than the ambient noise after the filtering. Using A_{max} also speeds up the process of detecting the general position of time of arrival.

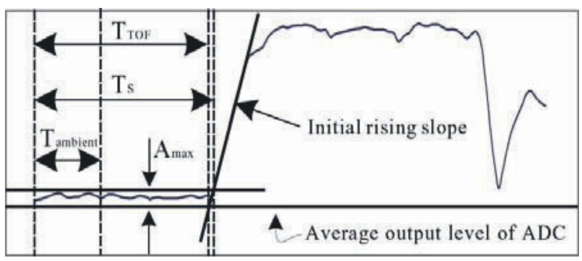

Figure 13 TOF detect algorithm.

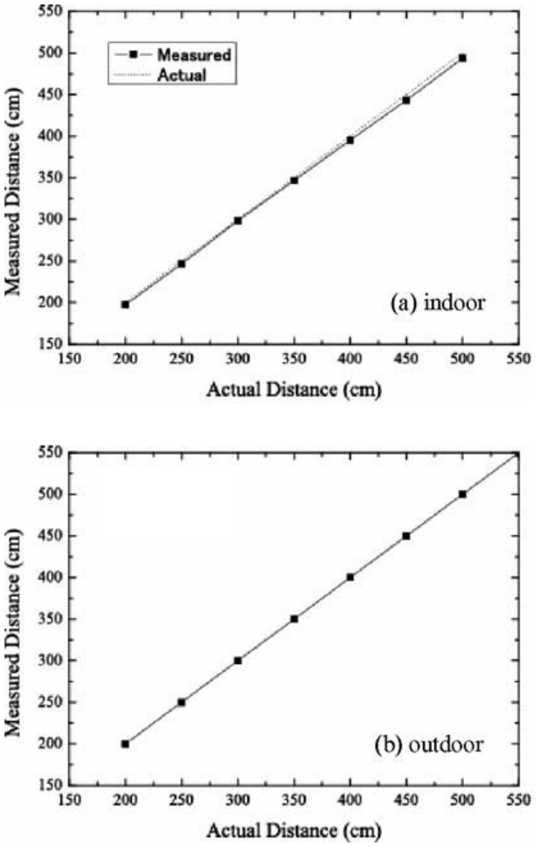
4. Perform adverse look-back to find the exact position of time of flight T_{TOF}. The exact position of time of flight is defined as a point in which the initial rising slope intersects the average output level of ADC, as shown in Fig. 13. Assuming the rising slope linear, a simple Kalman filter is adopted for extrapolating the initial rising slope.

3.4 Experiment for evaluation of acoustic ranging method

The performance of the acoustic ranging method is evaluated in the indoor environment where we observe severe echoes as well as the moderate urban noise environment. Figure 14 (a) and (b) show the comparison between actual and measured distance for the indoor and the outdoor environments, respectively and Fig.15 (a) and (b) show the measurement errors for the indoor and the outdoor environments, respectively. It is clearly visible that the precision of the measurement in the urban noise is better, especially around 300cm. This is because of the fact that we have conducted the indoor experiment in 6m× 6m× 8m room surrounded by hard walls which reflect acoustic wave so that the effect of the echo is severe. However, in any cases, it can be concluded that the accuracy of the present acoustic localization method is with 6cm in terms of standard deviation even in the indoor environment.

4 FIELD EXPERIMENT

Field experiment was conducted to evaluate the performance of the system for localization of sensor nodes based on the inverse Delaunay algorithm and acoustic ranging. Total of 21 sensor nodes (Mica2) with acoustic ranging devices/algorithm discussed in section 3 were spread on the plane (i.e., 2-dimensional arrangement) in a pseudo-random manner as shown in Fig. 16. Each sensor node measured the relative distance among neighboring 4 to 13 nodes depending on the local arrangement of the nodes (i.e., the nodes placed near the boundary measured relative distance among less number of nodes and the nodes at the vicinity of the center of the arrangement measured many). Localization was performed by using measured relative distance among sensor nodes as input data set for the inverse Delaunay algorithm.



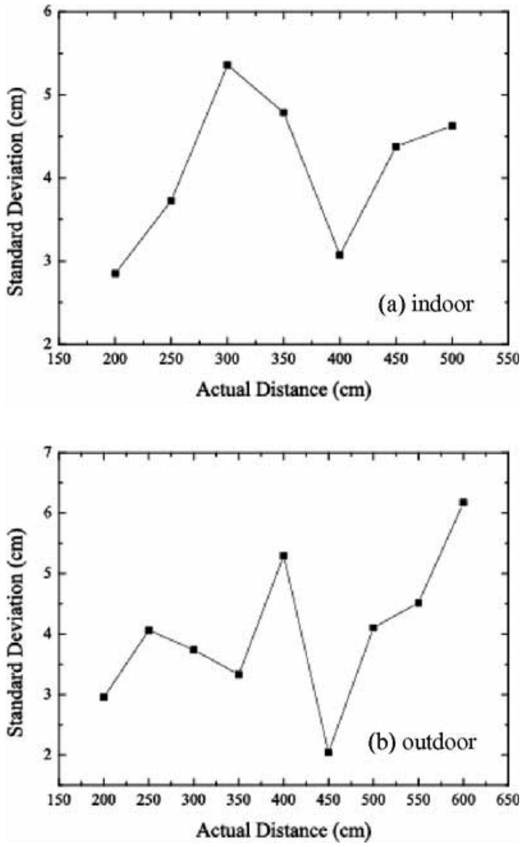


Figure 14 Comparison between actual and measured distance **Figure 15 Measurement error as a function of distance**

Figure 17 shows the estimated and the actual location of the sensor nodes. Since the inverse Delaunay algorithm determines the position of each sensor node upto rigid body motion (translation, rotation and flip) ambiguity as a whole, the global coordinate of the whole network of the sensor nodes is determined by GPS receivers deployed on three anchoring nodes as shown in Fig. 16. The measurement error in the acoustic ranging in this experiment was 3.8cm in average (maximum of 16.8cm) against average distance between nodes of 321.6cm. In spite of this noisy measurement of the relative distance, no node was missed in the localization and the error in the estimation was suppressed in the reasonable range. The error in the estimation of the location of the boundary nodes is relatively large. However, it should be noted that no attempt to redistribute the error throughout the domain, such as Laplacian smoothing or spring relaxation, were not applied in this estimation. No sign of the flip ambiguity, accumulation of the error can be observed. Although more detailed validation such as numerical simulation on the arrangement of thousands of nodes with noise in the ranging as a controlling parameter is required, this experimental result implies the robustness of the system.

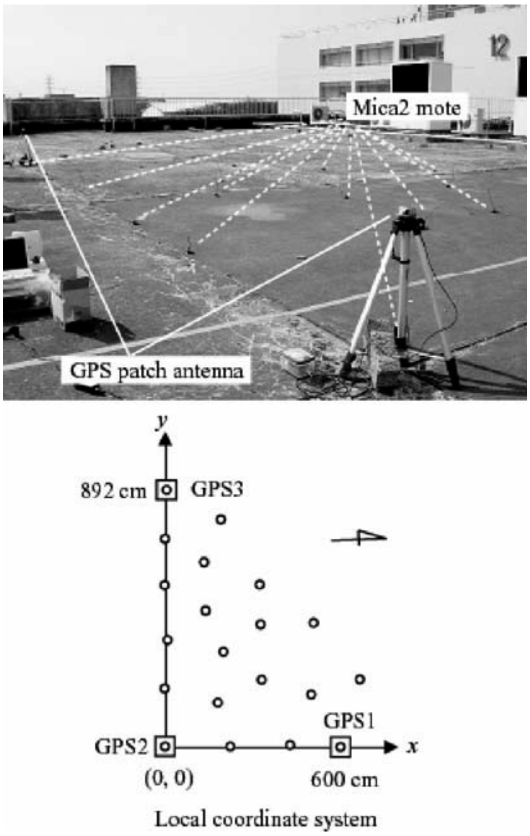

Figure 16 Schematic view of the deployment of sensor nodes

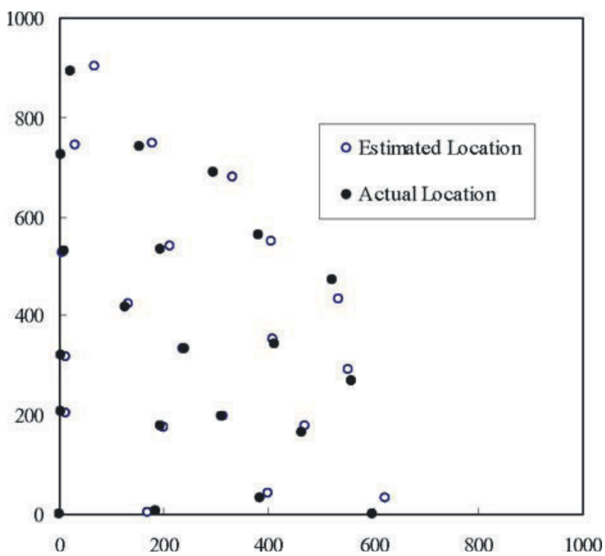

Figure 17 Comparison of the global positions of the nodes localized by our system with the actual positions of the nodes

5 CONCLUDING REMARKS

The inverse Delaunay algorithm and acoustic ranging method for localization (determination of the position of each sensor node) of a large scale sensor network are presented in this paper. Localization is an important issue for applying network sensing technique to the field of civil engineering and or earthquake engineering (e.g., more advanced health monitoring of the infrastructures).

The inverse Delaunay algorithm localizes all the nodes simultaneously, thus, the accumulation of the error in the localization is suppressed. Also, numerical simulation shows the scalability of this algorithm. In all the operation for localization, computational complexity is kept O(n). Noise tolerant acoustic ranging algorithm that employs digital signal processing techniques is implemented in an off-the-shelf sensor platform (Mica2). Experiments show that this acoustic ranging algorithm is sufficient to give average range estimation error below 10 cm. Together with this acoustic ranging algorithm, the inverse Delaunay algorithm is also implemented in Mica2. This enables automatic localization of sensor network. Field experiment was conducted to evaluate the accuracy of the localization of the system. Results from this experiment validate the robustness of the proposed method.

As future work, i) experimental validation of the robustness of the method against errors using hundreds of sensor nodes, ii) extension of the algorithm to 3D deployment of the sensor nodes, iii) improvement of the accuracy of the acoustic ranging and iv) measurement of the actual infrastructures, could be listed.

"A ship in harbour is safe - but that is not what ships are for"

~John A. Shedd, *Salt from My Attic*

Abstract: This paper presents the design of a risk management toolkit that facilitates maintenance of integrated engineering assets over a distributed operational environment. Key aspects of the tool includes impact profiling (i.e., the impact of loss of a particular system or sub-system), parametric modelling of the system-as-a-whole and business case generation. A variance based model has been developed for risk assessment. The system provides number of other features including, but not limited to, report generation, alert and flash messaging, testing/testability considerations and other such records. The system also offers a limited degree of visualisation capabilities in order to view risks at various layers and types.

Key Words: Risk management, Impact profiling, Parametric modelling, Risk visualisation, Variance modelling.

1 INTRODUCTION

Engineering systems typically last over 40 years, be they chemical plants, manufacturing pipelines or process industry systems. While the design of such systems are challenging, design for maintenance is something rarely attempted, unless the systems are mission-critical (e.g., heart pace makers, satellites, etc). However, maintenance takes up more than 75% of the costs of the overall system life cycle costs in almost all engineering projects [10, 33]. Indeed this is the case even with software systems too!

Even though technology changes with time and changes in design and development processes, the downstream issue of overall system/plant maintenance is fraught with considerable risks of various types. Further, the nature and severity of these risks usually compound during the maintenance phase and the costs to address or ameliorate or mitigate these risks also considerably increase – in some cases exponentially during the maintenance phase. The problem is very much akin to noting and trying to fix a stich in a sweater after it has been completely knitted [2], except by then one may have to un-do many stages of stiches in order to correct the original error. The cost of fixing an error can be 100 times as high as it would have been during the development stage and the associated risks in testing and verifying the correct operation of the modified system is also order of magnitude higher than during the original development of the system.

In this paper, we identify various types of risks during the maintenance phase through parametric attributes. For this purpose, we note the definition of the term risk as, "*Risk is the net negative impact of the exercise of a vulnerability, considering both the probability and the impact of occurrence [11]*". They include risks in testing (during maintenance), on-going risks to business and modelling the risk management capability. We develop a variance model for risk management, mitigation and minimisation during the maintenance phase and we believe that this model serves as a step in the right direction towards addressing risk related issues in large organisations.

The rest of the paper is organised as follows: the next section presents more specific details on the risks in integrated systems development, while section 3 deals with factors in engineering risk assessment and related models. Section 4 is on the development of a variance model for evaluating systems risk assessment, followed by a discussion on this model in section 5. The conclusion summarises the paper and provides further research directions.

2 RISKS IN ENGINEERING SYSTEMS DEVELOPMENT & MAINTENANCE

Typical System Development Life Cycle (SDLC) [30, 32] has a number of steps (i.e., system analysis, design, pilot development, implementation, testing and maintenance) and the steps therein vary to some degree depending on the type of system or plant being developed (e.g., manufacturing systems, chemical process engineering systems, etc). Naturally, several types of risks occur during each stage of the SDLC.

Unfortunately, the impact of costs and risks involved in plant maintenance has not permeated to financial managers, who still perceive maintenance as a necessary evil, as opposed to affirmative good. Indeed the Maintenance Hall of Shame [2] showcases several projects, which have been totally abandoned after spending budgets ranging from $11 million to $4 billion. These projects in the OECD world include BHP Billiton's Iron Brickett facility, FBI's Virtual Case File [1, 4] and Anaconda Nickel in Western Australia.

Maintenance occurs in four ways [8, 9]: corrective maintenance, adaptive maintenance, perfective maintenance and preventative maintenance. The first two issues concern fixing of systems, the latter two issues relate to enhancing the system. The corrective approach is intended to defect identification and removal of defects, the adaptive approach manages changes resulting from system changes, the perfective approach handles changes resulting from user requests and the preventative approach deals with changes made to the plant to make it more maintainable. Risks arise at all of the maintenance phases and two impact factors that we are interested in this paper include risks to business and risks to re-testability.

A short and quick literature survey relevant to this paper is as follows: Yassine et. al. [29] provide an information structured approach to designing systems, Gits [20] provides a comprehensive literature review of maintenance concept for various systems, Stewart, et. al. [22] detail probabilistic risk assessment methods and Dunthie, et. al. [23] provide risk-based approaches to maintenance. Edwards [21] provides a specific case study in the construction industry. Risks related to software systems, related frameworks [16], testability [24], cost-benefits [19], choice of test tools [26] and typical mistakes [17, 18] have also been extensively studied. The latter set of references provide an interesting dimension to risk in the all ubiquitous computer software-based systems, which will soon encompass almost all systems. Various IEEE and NIST Standards [8, 11] deal with Software Maintenance issues and analysing problems during maintenance and provides a way to go about addressing these issues.

Charette [2] list several major factors for the failure of such projects. We have amended the original list in order to generate the list of risks that occur during the plant maintenance phase (Table 1).

- Unrealistic or unarticulated project goals
- Inaccurate estimates of the needed resources for maintenance
- Badly defined maintenance requests
- Poor reporting of the system status under maintenance
- Unmanaged risks during maintenance
- Poor communication among users and maintainers
- Use of immature technology in implementation
- Complexity of the system
- Poor maintenance practices, processes and procedures
- Stakeholder politics, and
- Commercial pressure
- Lack of or improper deployment of maintenance Standards

Table 1: List of Typical Risks During Maintenance Phase

The impact of the process chosen and the cultural disposition of the technical people[1] is profoundly felt during maintenance. For instance, Cusumano et al report [5-7] that Japanese companies have applied extensive quality control procedures that they employ for manufacturing to several other industries, including software development also. As a consequence, the reported median number of defects in Japanese IT projects is one fourth of the corresponding numbers in US IT projects. When measured over 100 projects, Cumano et al [7] report that Japanese adherence to rigid software processes produced 0.02 defects per 1000 source lines of code, compared to 0.40 for corresponding US projects. Further, their rigid processes involving considerable amount of comprehensive documentation allows considerable degree of code re-use also. All these issues have a profound impact on maintenance of software systems.

3 FACTORS IN PLANT RISK ASSESSMENT DURING MAINTENANCE

Issues that occur during maintenance include the following:

- Changing priorities
- Testing methods
- Performance measurement
- Incomplete or non-existent system documentation
- Adapting to changing business requirements
- Backlog size
- Measurement of contributions
- Low morale due to lack of recognition or respect
- Lack of personnel, especially experienced
- Lack of maintenance methodology, standards, procedures and tools . . . . .

Obviously, the number and types of unresolved issues determine the level of risk [12, 25] posed by the project. However, one can use high-level estimation outputs to make critical decisions on risks only if the underlying processes can be trusted. When parametric measurements of risk prove inadequate, risks can be simply stated in terms of issues that remain to be resolved yet and their perceived impact to the plant. For example, a good indication on the maintainability of a plant can be inferred by the work of Oman [14], whose key points are brought up in Table 1.

Table 2: Effects on Maintainability of Asset Properties

Our risk models are adaptations of the Function Point models employed in software cost and effort estimations and the works of Oman [14]. The overall system interaction model (adopted and modified from the MIT-90 model for assessing and achieving change [27] and also several available at [13]) for software maintenance is captured in Fig.1, wherein we identify the following elements as having profound impact on the overall impact contributing to the vulnerability of an organisation's Asset Maintenance system:

---

[1] Glazewski [31] makes the following observation about risk management: *We have all heard the saying, "Give a man a fish, and you feed him for a day. Teach a man to fish, and you feed him for a lifetime." Let me revise that from a risk management standpoint: "Put out a manager's fires, and you help him for a day. Teach a manager fire prevention, and you help him for a career." If a manager understands good risk management, he can worry about things other than fire fighting.*

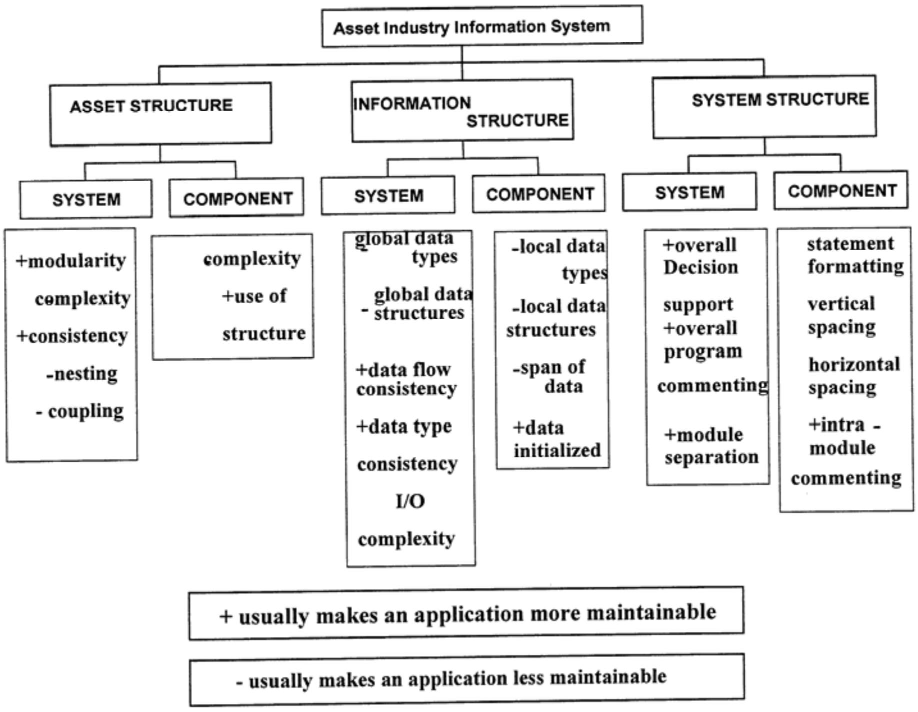

Table 2: Effects on Maintainability of Asset Properties

- Technology, which changes rapidly
- Maturity of skill-base, which is vital for maintenance
- Maturity of plant sub-systems and related entities, which is critical to the stability (which in turn depends on the percentage change in the system per day) and,
- Threat or risk to/from individuals to the IT system. Note that this is not a malicious threats, but more along the lines that "what if a key personnel leaves the organisation, then what will be the impact on plant maintenance"

One can notice that different combinations of factors influence: i) the organisational culture, ii) external technical environment and iii) external socio-economic environment. People involved in the maintenance of plants have to deal with these issues pragmatically and on a continual basis (more on our model for maintenance will be described in a forthcoming paper).

We also define the following factors as contributors to risk during software maintenance and these factors are elaborated in Tables 3-6:

- α-Risk Factors, which are system related
- β-Risk Factors, which are process related
- γ-Risk Factors, which are practice related
- δ-Risk Factors, which are testing related

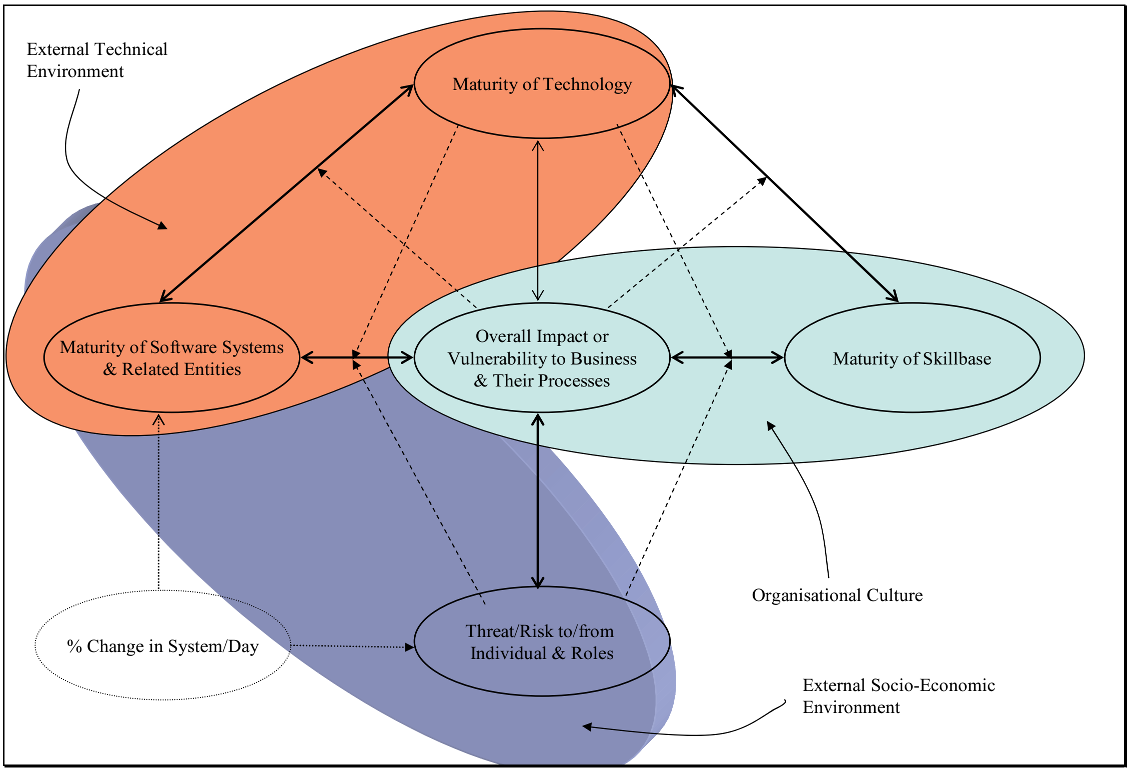

Figure 1: Overall system interaction model for Asset Maintenance

α - Risk Factors	Measurement Mechanism
Size of system	for every 10 sub-systems, add 1 point up to 8 points; for every 10 sub-systems thereafter, add 8 points
Number of systems affected	Actual value
Mean time to test	Actual value
Mean time to fix a bug	Actual value
Average cost per unit test	Actual value

Table 3: α - Risk Factors (Code Related)

β - Risk Factors	Measurement Mechanism
Volatility of development process	no process (=10), *ad hoc*, well-defined, repeatable (=1)
Perceived impact to/on organisation	On a non-linear ***multiple*** of 1 (low), 3, 7, 10, 20 (high)
Degree of clarity of plant requirements	On a scale of 1 (good clarity) – 10 (poor clarity)
Degree of clarity of testing requirements	On a scale of 1 (good clarity) – 10 (poor clarity)
Degree of reusability requirement	On a scale of 1 (low need) – 10 (high need)
Degree of availability of reusable test rigs	On a scale of 1 (poor availability) – 10 (good availability)
Degree of maintainability of reusable test rigs	On a scale of 1 (good maintainability) – 10 (poor maintainability)
Degree of comprehensiveness of the test tool & environment	life cycle toolkit (=1), … , *ad hoc toolkit* (=10)

Table 4: β - Risk Factors (Process Related)

γ - Risk Factors	Measurement Mechanism
Adherence to Standards (*a la* training time)	On a non-linear ***multiple*** of 1 (low), 3, 7, 10, 20 (high)
Time to test	Average time to test a sub-system – actual value
Remaining time to deploy	Actual value
(Efficacy) weighted number of testers	on a non-linear ***multiple*** of 1 (low), 3, 7, 10, 20 (high)
Degree of (real time) performance requirement	On a scale of 1 (low) to 10 (high)
Clarity of performance requirement	On a scale of 1 (low) to 10 (high)
Degree of data/access security constraints imposed	On a scale of 1 (low) to 10 (high)
Degree of code-level migration requirement	On a scale of 1 (low) to 10 (high)
Degree of plant-level migration requirement	On a scale of 1 (low) to 10 (high)
Percentage of full load testability requirement	Actual value

Table 5: γ - Risk Factors (Practice Related)

3.1 The δ-Risk Factors

- Number of users that use the plant
- Number of control sub-systems in the plant
- Number of external sub-systems accessible through the plant
- Number of inspections conducted per day
- Total available plant performance
- Number of approved changes per day
- Number of maintenance people
- Number of maintenance centres in the organisation (there could be a "cultural difference" between the testing centres!)
- Number of total sub-task in testing/maintenance

Table 6: δ - Risk Factors (Testing Related)

4 VARIANCE MODEL FOR ASSET MAINTENANCE RISK ASSESSMENT

We define several risk factor metrics as noted in Table 7, before we develop the variance model.

Risk Factor Metrics	Definitions
Coverage	Percentage amount of the plant tested after a maintenance cycle
Impact	Degree of effect of the maintenance operation from one cycle to another, which can be positive or negative
Time2Fix	The average time taken to fix a reported bug (does not include bug detection time)
Exposure	Degree of revelation of faults after a particular maintenance cycle that gets exposed to outside of the organisation

Fault Likelihood	Probability of a fault occurring
Consequence	The consequence of failure of a particular sub-system
Degree of Adherence	Degree of adherence to procedures, Standards or process and their perceived veracity and effectiveness towards the entire maintenance process
Probability of loss of Key People	The impact of the loss of key people
Remaining Time	The remaining time before the proposed re-start of the plant

Table 7: Risk Factor Metrics and Their Definitions

We now define the following metrics as noted in Table 8. Note that each one of the functions (F#(t)) below is unique and only the key parameters from each of the risk factors from Tables 3-6 are included in the actual calculation of the metrics; the remaining parameters are ignored. The selection of the right type of parameters is based on experience, application requirement and context in which the measurement is sought. Further the function F#(t) is a measure of the variance or changes in the parameters as the entire plant goes through various stages of its maintenance cycle at any given time t.

Risk Factor Metrics	Nature of Measurement
Coverage	F# (α-Risk Factors)
Impact	F# (δ-Risk Factors)
Time2Fix	F# (γ- and δ-Risk Factors)
Exposure	F# (α- and γ-Risk Factors)
Fault Likelihood	F# (α , γ and δ-Risk Factors)
Consequence	F# (δ-Risk Factors)
Degree of Adherence	F# (β-Risk Factors)
Probability of loss of Key People	F# (β and δ -Risk Factors)
Remaining Time	F# (γ-Risk Factors)

Table 8: Risk Factor Metrics and Their Measurement

The metrics given in Table 8 can be variably evaluated depending on which of the listed risk factors are considered to dominate a particular plant. As a further extension, one can define a number of metrics for the following terms also:

- <u>Impact Metrics:</u> Integrity, Availability, Confidentiality, Vulnerability, Threat-source Identification, Threat-action Identification.

- <u>Mitigation Action & Strategy Metrics:</u> Risk Awareness, Risk Assumptions, Risk Avoidance, Risk Limits, Risk Plans, Risk Acknowledgement, Risk Transfer or Risk Outsourcing.

- <u>Cost-benefit Metrics:</u> for the following actions - Analysis, Assigning responsibility, Priority/Rating generation, Cost of detection, Cost for correction, Targeting, Process/Standard generation, Education & adherence to process/Standards (Training), Standards/process improvement (capability maturity), identifying & evaluating residual risks.

- <u>Incident Management Metrics:</u> Incident reporting, Categorization, Incident Prioritization/Rating, Responsibility assignment, Risk isolation, Impact assessment.

5 DISCUSSION OF THE VARIANCE MODEL

We define several types of metrics for software maintenance, which include the following: risk to testability, risk to business activities and risk to business perception. These are pictorially described in Fig.2 below. The empirical implications of various TAR values are provided in Table 9.

Risk to Testability (R2T) = **A** = Area of triangle {Coverage, Impact, Time2Fix}

Business Perception Risk (BPR) = **B** = Area of triangle {Exposure, Fault Likelihood, Consequence}

Business Vulnerability Risk (BVR) = **C** = Area of triangle {Degree of Adherence, Prob. loss of key people, Remaining Time}

Total Acceptable Risk (TAR) = **A * B * C**

Other factors such as Risk to Business can be in terms of performance, time-to-market (or market conditions) and technology alternatives. For example,

Risk2Business (t) = F3 (c1, c2, c3, c4) / F4 (d1, d2, d3, d4)

C1 = perceived impact on business (visibility, loss of life,)

C2 = degree of Leadership support

C3 = degree of organisational culture to support the values of testing and testability

And, the rest are explained in the forthcoming paper.

Similarly, risks can be quantified or qualified in terms of humans and systems as noted below:

Human Terms (t) = F (easy of training test tool/environment, % change in policies, nature of project, recoverability from errors, # maintenance centres,)

System Terms (t) = F (# of sub-systems, # of controllers, # of transactions/sec, # of refreshes/day, # changes/day, degree of concurrency required,)

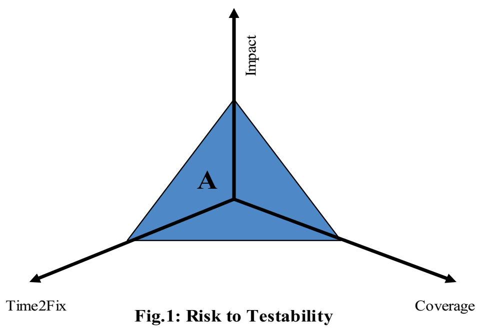

Fig.1: Risk to Testability

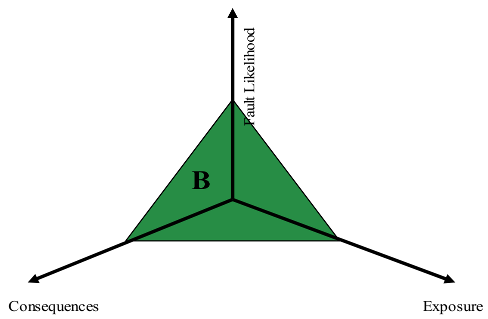

Fig.2: Business Perception Risk

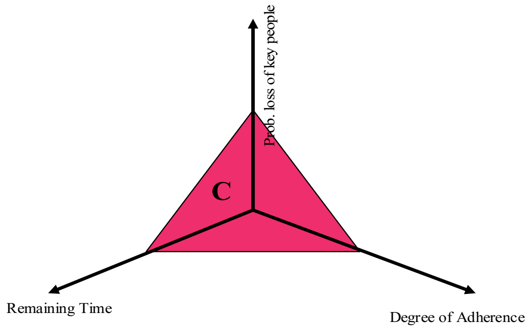

Fig.2: Business Vulnerability Risk

TAR Values	Implications	Recommended Remedial Actions
10	Fatal failures	Immediate attention with highest priority
7	Serious failures	High priority; expect consequences
4	Manageable failures	Good priority; consequences may be serious.
1	Acceptable failures	Low priority, consequences may not be serious
0.1	Virtually impossible	Well tested, rare errors with minor consequences

Table 9: TAR Values and their Implications

5.1 Development of a Risk Measurement Toolkit

We have developed a version of our Risk Measurement Toolkit using Excel Spreadsheet, whose parameters are provided in Table 10, which itself is a modified version of the NIST Standard on Maintenance Risk Analysis Matrix [11]. We also generate some recommendations automatically and further, repositories for the creation and maintenance of a repository for each of the following items:

- Risk watch-list
- Profile of typical errors, bugs, pitfalls and mistakes
- Code patterns for error corrections
- Potential impact profiles

- Key personnel impact
- Knowledge gained from correcting bugs, pitfalls and mistakes

Nature of Risk	Priority	Recommended Control Actions	Planned Controls	Required Resources	Responsible Team or Persons	Start/ End Dates	Estimated Total Costs	Residual Risk	
•									
•									
•									

Table 10: Maintenance Risk Analysis Matrix

5.2 Maturing of the Risk Model - WArm-blooded Risk Management (WARM) Model for Risk Management Maturity

We present a new model, called the WArm-blooded Risk Management (WARM) model (see Table 11), which indicates the degree of maturity of organisations in managing their risk. The WARM model is inspired by the works of Pooch [15], Capability Maturity Model Integration of Humphry [28] and discussions with various industrial experts. At the basic step, all organisations are Cows, where risk management happens by accident of serendipity. As the organisations improve their risk management profiles, they move in their maturity levels from the Cow-level, to that of elephants, hyenas, foxes and then lions, one-level at time. Along with their maturity level upward movement, their capabilities also increase profoundly. At the highest level, organisations will be able to consider their entire risk management life cycle and cost their operations in terms of costs, resources, personnel and performance requirements.

Level	Name	Attributes	Characteristics
1	Cow	Scavengers, nature fed, unfocussed; eat whatever available dead or alive, so long as you can eat!	Risk management happens by accident or serendipity.
2	Elephant	Gulp all, unfocussed irrespective of quality, no particular motivation except to fill-in.	Limited risk management is performed, but just to fill the scripts, with no planning or real load based evaluation.
3	Hyena	Acting as a team on easy target, predatory, fast.	Automated tools are used to perform risk management, but inconsistent processes employed with limited estimate on costs.
4	Fox	Group action, movement, temperate.	Near-production risk management is performed with clearly repeatable processes, control over performance requirements and costs, maintainable risk profiles.
5	Lion	Group, motivation, large-scale movement across entire available space.	Entire risk management life cycle is considered, well-articulated risk profiles maintained, costs, resources and performance requirements controlled.

Table 11: The WARM Model for Risk Management Maturity

6 CONCLUSIONS

The measurement of risks and process that must be placed to eliminate or mitigate the risks, involves the collection of data and decision support systems. In this paper, we have identified various types of risks that occur during plant maintenance. We have parameterised these attributes and developed a variance-based model for their measurement and control. We have also identified several metrics for monitoring risk during maintenance, described a toolkit and discussed the WARM Risk Maturity Model. We are currently working on the design and development of an intelligent agent based framework for comprehensive risk assessment during single and multi-plant maintenance.

DEGRADATION MONITORING OF INDUSTRIAL HEAT EXCHANGERS

BR Upadhyaya[a] and E. Eryurek[b]

[a] *Nuclear Engineering Dept., University of Tennessee, Knoxville, TN 37996-2300, USA*

[b] *Formerly with Emerson Process Management, Eden Prairie, Minnesota, USA*

Abstract: This paper presents the results of monitoring device-level and system-level faults in industrial heat exchangers. The device-level faults refer to degradation of sensors and control actuators. In the case of heat exchanger (HX) studies presented here, system-level fault refers to fouling of HX tubing during plant operation. The objective of the research performed at The University of Tennessee was to develop techniques to detect and isolate both sensor faults and fouling-related degradation in a tube-and-shell heat exchanger. This was achieved by monitoring the changes in the relationship among a set of system-bound variables for different fault types. The measurement-based models were established using experimental data of fouling progression in a tube and shell industrial heat exchanger. Direct and inferred measurements of fluid temperatures, flow rates, pressure drops, and thermal resistance were used to perform the fault diagnosis. An approach called the Group Method of Data Handling (GMDH) was developed to characterize the interrelationships among several measurements

Key Words: Heat exchanger fouling, Device faults, Data-based modelling, Diagnostics

1 INTRODUCTION

The issue of on-line monitoring of process units and the ability to detect their incipient failures is gaining high priority in many industrial processes, including power generation systems, chemical industry, pulp and paper industry, and many other process industries. Examples of process units include heat exchangers, feedwater heaters, boilers, coal pulverizers, feed water pumps, electric motors, and others. In addition, the monitoring of field devices such as instrumentation systems, controllers, and actuators is equally important. The combined effort helps in maintenance planning and optimal equipment repair and replacement. The research and the results presented here focused on the development of data-driven empirical characterization techniques with application to industrial heat exchangers. In the case of heat exchanger (HX) studies presented here, system-level fault refers to fouling of HX tubing during plant operation [1]. This is an important concern because of the degradation of thermal performance of these process units. Particulate fouling is considered in this study and is defined *as the accumulation of solid particles suspended in a fluid onto a heat transfer surface. Suspended particles can be ambient pollutants (sand, silt, clay), upstream corrosion products, or products of chemical reactions occurring within the fluid.* This was achieved by monitoring the changes in the relationship among a set of system-bound variables for different fault types in a tube-and-shell heat exchanger. The measurement-based empirical models were established using experimental data of fouling progression in the heat exchanger. Direct and inferred measurements of fluid temperatures, flow rates, pressure drops, and thermal resistance were used to perform the fault diagnosis. An approach called the Group Method of Data Handling (GMDH) [1] was developed and applied to the measurements. The GMDH performs a prediction of the process variables.

The current work is based on several earlier works on heat exchanger fouling [2-5]. We used heat exchangers with multiple tubing, and performed on-line measurements of fluid temperatures and flow rates during the entire fouling progression. In addition to experimental data, steady-state heat transfer models were developed to complement the information set, especially in cases where plant data may not be initially available.

The paper describes the analytical approach for calculating the changes in the thermal resistance, the development of the heat exchanger experiment, and the results of monitoring tube fouling and sensor degradation in the heat exchanger system. The results indicate the feasibility of applying this approach for monitoring industrial heat exchangers.

2 THEORETICAL STUDY OF THE EFFECT OF FOULING AT DIFFERENT TUBE LOCATIONS

2.1 Tube Fouling and Thermal Performance

The foulant deposition on tube surfaces results in the degradation of thermal performance in heat exchangers, fossil boilers, and nuclear plant steam generators. Furthermore, tube fouling results in a decrease in the tube internal diameter and consequently an increase in the pressure drop between the inlet and the outlet. For this reason, heat exchangers and steam generators are designed with excess heat transfer capacity in order to offset the effect of fouling. The heat transfer resistance increases with fouling and the overall heat transfer coefficient decreases. This parameter is critical in planning unit servicing and tube plugging, if necessary. Limits on the percent of tubes plugged must be established so that the process unit would perform without losing considerable thermal performance.

2.2 Fouling Behaviour at Different Tube Locations

An attempt has been made to understand the effect of fouling on the fluid temperatures at different locations along the tube. This simple model does not consider the influence of fluid temperature itself on the fouling rate. The following energy balance equation is used to characterize the steady-state heat transfer.

$$\dot{Q} = UA\Delta T_{LMTD} = \dot{m}_h C_h \Delta T_h = \dot{m}_c C_c \Delta T_c \quad \textbf{(1)}$$

$\dot{Q}$ is the heat transfer rate, A is the surface area, and U is the overall heat transfer coefficient. ΔT_{LMTD} is the logarithmic mean temperature difference (LMTD) for the heat exchanger. Note that the subscripts *h* and *c* indicate hot side (tube side) and cold side (shell side) fluids. The LMTD is defined as

$$\Delta T_{LMTD} = \frac{\Delta t_1 - \Delta t_2}{\ln(\Delta t_1 / \Delta t_2)} \quad (2)$$

For a parallel flow heat exchanger

$$\Delta t_1 = t_{h,in} - t_{c,in} \,;\; \Delta t_2 = t_{h,out} - t_{c,out} \quad (3)$$

For a counter flow heat exchanger

$$\Delta t_1 = t_{h,in} - t_{c,out} \,;\; \Delta t_2 = t_{h,out} - t_{c,in} \quad (4)$$

The model used was for a parallel flow HX to match with the experimental device. The flow rates on both the tube and the shell side were kept constant and a uniform fouling per unit area was assumed. Figure 1 shows the cold-side (shell side) coolant temperature distribution along the HX length. The graph indicates that the final cold-side outlet temperature attains the same value independent of the location of fouling. This is also the behaviour of hot-side (tube side) fluid temperature. Thus, the tracking of only the outlet temperature is not sufficient to determine the location of fouling. In practice, it is necessary to measure the temperature profile along the HX tube length by distributed sensors.

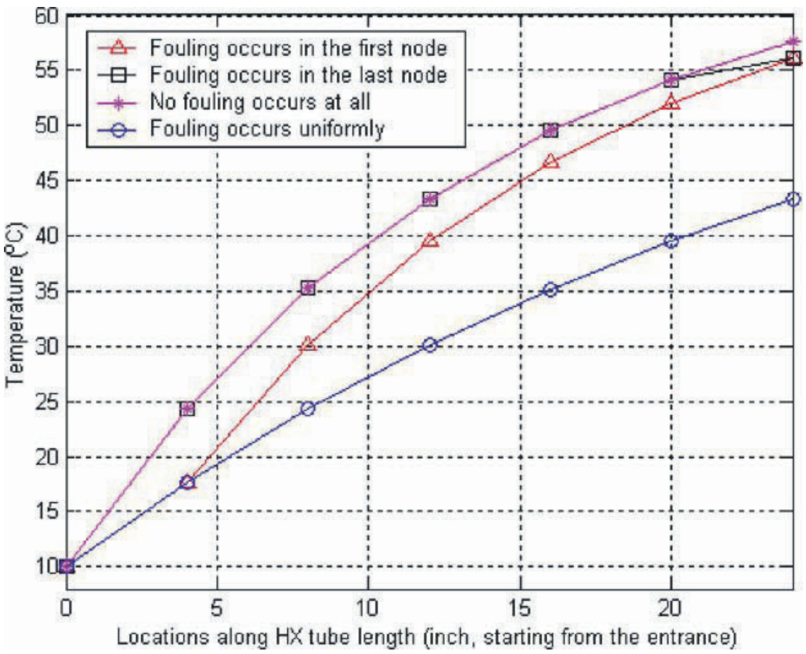

Figure 1. Cold-side coolant temperature distribution along HX tube length.

3 HEAT EXCHANGER SYSTEM DEGRADATION MONITORING

This study has focused on tracking fouling-related degradation and faults in process sensors. The process sensors of interest are measurements of fluid inlet and outlet temperatures, and differential pressure across the tubing. It is important to understand that changes in thermal resistance across the tubing may be caused by fouling, fluid flow rate fluctuations, and/or other factors. In order to separate the process effects from equipment degradation it is necessary to establish a database of normal operating conditions. In the absence of such knowledge, the desired information could be generated using physics models. The data generated from a physics model is then used to develop empirical models for future use.

The following procedure was developed to detect and isolate HX system degradation based on our knowledge of the system physics and the experimental observation.

3.1 Development of the Knowledge Base

Process data are acquired at different operating conditions. If a complete set of data is not available in the beginning, the plant database is expanded by appending information generated from the physics model. As the plant operation progresses, the need for simulated information may be reduced. The normal database is then characterized by building multivariate empirical models (GMDH models described in Section 5). These models are then used to predict one or more process variables using plant measurements.

3.2 Sensor Fault Detection

As the HX fouling progresses, this results in a change in the measured fluid temperature. This is a normal behaviour of the sensor. In this case the temperature profile follows the change in thermal resistance. Assuming that temperature measurements have redundant sensors, a cross check is performed to determine the inconsistency among the sensors. If this is detected, the faulty sensor may be isolated by verifying the heat balance by repeated computation of the heat transfer rate, $\dot{Q}$, using different combinations of hot-side and cold-side temperatures.

$$\dot{Q} = \dot{m}_h C_h \Delta T_h = \dot{m}_c C_c \Delta T_c \tag{5}$$

If sensor redundancy is not available, empirical prediction models may be used to detect one of the four defective temperature sensors: $t_{h,in}, t_{h,out}, t_{c,in}$, and $t_{c,out}$. Multiple prediction models are needed in this case. The predicted values are compared with actual measurements and the resulting residual patterns are evaluated for suspect sensor.

3.3 Heat Exchanger Fouling Detection (HXFD)

When step 2 described in Section 3.2 is successfully completed, HX fouling can be monitored using several parameters: percent change in the thermal resistance, changes in the prediction error of a selected temperature measurement, and differential pressure on the tube-side of the HX. Generally, all these parameters have similar behaviour. Calculation of thermal resistance change is performed by directly using the temperature and flow measurements. The overall thermal resistance of the heat exchanger is calculated as [1]

$$R = \frac{1}{UA} = \frac{\Delta T_{LMTD}}{\dot{m}_h C_h \Delta T_h} = \frac{\Delta T_{LMTD}}{\dot{m}_c C_c \Delta T_c} \tag{6}$$

$\dot{m}_h, \dot{m}_c$: Fluid Flow rates on the hot side and the cold side, respectively

C_h, C_c: Fluid heat capacity on the hot side and the cold side, respectively

$$\Delta T_h = t_{h,in} - t_{h,out}$$

$$\Delta T_c = t_{c,out} - t_{c,in}$$

The thermal resistance generally follows a first order asymptotic model. When fouling is predominant, both the pressure drop and the fluid outlet temperature prediction error follow a similar behaviour. Thus all the three parameters have similar time characteristics. The approach described here (see Ref [7]) is capable of detecting and isolating multiple faults in the heat exchanger system.

4 EXPERIMENTS ON PARTICULATE FOULING OF A TUBE-AND-SHELL HEAT EXCHANGER

4.1 Experimental Loop

The approaches developed for HX fouling degradation monitoring were implemented using a small-scale tube-and-shell heat exchanger. Figure 2 shows a schematic of the HX experimental loop. The process measurements include fluid inlet and outlet temperatures, differential pressure (DP) in the tube, and flow rates on the tube-side and on the shell-side. All the measuring devices were calibrated and the data acquisition was performed using the LabVIEW software.

The demonstration of fouling monitoring by tracking the overall thermal resistance was accomplished by running the experiments for different particulate concentrations and for different tube-side water flow rates. The foulant was a clay-like substance that has the trade name KAOLIN.

4.2 Particulate Concentration and Tube Fouling Degradation

Three experimental runs were made to study the effect of particulate concentration. Each experimental run was about 80-90 hours long. All the data were acquired continuously during the run. At the end of each run, the HX end plates were removed and all the 31 tubes were thoroughly cleaned with brushes and flushed with clean water. The experiment was now run with clean water to verify the normal value of the thermal resistance. If it matches with the nominal value, this is an indication that the change in the thermal resistance is due to tube fouling. The fluid flow rates were kept constant during all the runs. The following three concentrations of KAOLIN were used: 70 gm (1,647 ppm), 90 gm (2,118 ppm), and 110 gm (2,588 ppm). KAOLIN was mixed into the water tank from which the water was circulated through the loop.

Figures 3-5 show the measurements of the process variables, percent change in the thermal resistance during the experimental period, and the pressure drop between the inlet and the outlet headers on the tube side of the HX, respectively, for Run # 3 with 2,588 ppm of KAOLIN on the tube side. Figures 3 and 4 indicate that the time behaviours of the thermal resistance and the pressure drop follow approximately a first order trend, achieving asymptotic values at approximately 120 hours into the test run. It was observed that these values increase with particulate concentration, and so does the time to achieve asymptotic value. At the end of the experiment, the HX tubes were cleaned and the experiment was run with pure water to verify the initial value of the thermal resistance. Figure 6 shows a photograph of the HX tubing with the cleaning brush at the end of the fouling experiment.

5 GROUP METHOD OF DATA HANDLING (GMDH) TECHNIQUE FOR PROCESS CHARACTERIZATION

5.1 Summary of the GMDH Approach

In the absence of a detailed physics model to monitor the cause and effect relationship among system state variables, a multivariate empirical model may be developed using operational data. Even though these models do not take into account all the state variables defined by the physics, they are sufficient to track the changes in the process itself and to monitor the degradation of sensors and field devices. Such an approach is highly efficient and has seen many applications [8, 9]. These empirical models range from simple linear, single-variable to nonlinear, multivariate forms. A proven technique for a general characterization of multiple measurements is the Group Method of Data Handling (GMDH) [6, 10].

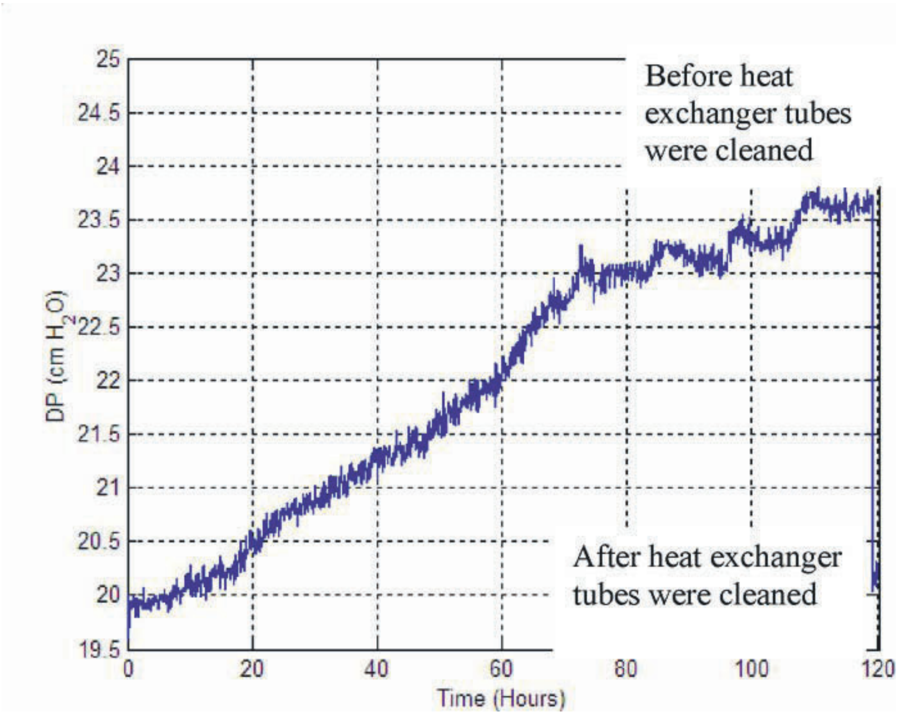

Figure 5. Trending of tube-side pressure drop for Run # 3.

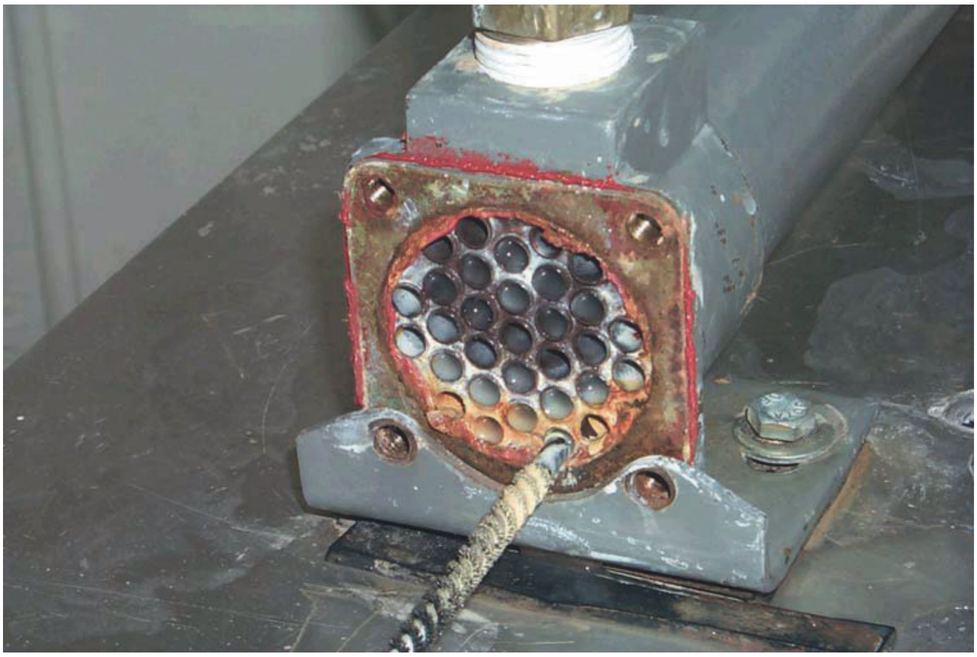

Figure 6. Photograph of the HX tubing with the cleaning brush at the end of the fouling experiment.

The GMDH is an *inductive, self-organizing algebraic model* development approach that creates an *optimal* nonlinear representation of one variable as a function of other related variables. The learning phase may use actual operational data, physics model simulated information, or a combination of the two. The goal is to model a variable *y* as a function of the input set $\{x_1, x_2, \ldots, x_n\}$. At each level of the model structure two of the n-signals, $\{x_i, x_j\}$ are used to generate a second order polynomial model of the form

$$y = A + Bx_i + Cx_j + Dx_i^2 + Ex_j^2 + Fx_i x_j \quad (7)$$

This procedure is repeated for all pairs $\{x_i, x_j\}$. The prediction of y at each layer will improve until the prediction error is within desired limits. The general approximation is called the Kolmogorov-Gabor polynomial and is given by Equation (8). The model-building algorithm is terminated at this point.

$$y = a_0 + \sum_{i=1}^{n} a_i x_i + \sum_{i=1}^{n}\sum_{j=1}^{n} a_{ij} x_i x_j + \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n} a_{ijk} x_i x_j x_k + \ldots \quad (8)$$

$\{a_0, a_i, a_{ij}, \ldots\}$ is the vector of model coefficients, which are estimated by the GMDH algorithm. The details of the algorithm and its implementation are given in Ref. [10].

5.2 Tracking Heat Exchanger Performance

The first step in implementing the GMDH for process variable prediction is to develop a normal operation model. The model structure is defined in Section 5.1. The ideal situation is to develop the model using operational database. In its absence, we suggest the use of high-fidelity physics models to generate the necessary information. In some cases operational data and physics-derived information may be used to generalize the empirical model for a wide range of situations.

In this study, a GMDH model was first developed to characterize the dynamics of the HX cold-side outlet temperature, and then used for the prediction of this variable during future operation. Inlet temperatures on the hot and cold sides of the HX were used as inputs. Figure 7 shows a comparison of the measured and GMDH-predicted values of this temperature with fouling (Run # 2). The residuals between the measured and predicted values are plotted in Figure 8. The overall time behaviour of the cold-side outlet temperature prediction error and the percent change in the thermal resistance are similar. This is an important observation that is useful in isolating the fault type. When the degradation is dominated by the fouling phenomenon, the thermal resistance and model prediction error of the outlet temperature have similar trends, eventually attaining asymptotic values.

6 CONCLUDING REMARKS

Continuous monitoring of process units in chemical industry, power industry, and other process industries is critical for economic growth and environmental protection. Early detection of anomalies in process units must be made part of the overall monitoring system and for maintenance planning, repair, replacement, and resource allocation. The results of the research presented in this paper demonstrate the successful implementation of empirical models developed from operational measurements. The technology is sufficiently advanced to the point where the implementation may be made part of the standard procedure and be incorporated into a computerized maintenance management system (CMMS). Work is currently underway in applying this technique to process units in a coal-fired power plant, with the focus on the coal pulverizer system.

Abstract: In this research, the sound source direction is decided by two angles, one is the horizontal angle α, and the other is vertical angle β. The former is presumed from the difference of the time of arrival of the sound from the source to a right and left ear, and the latter is presumed from spectrum correlation analysis using HRTF(Head Related Transfer Function). HRTF is a transfer function of spectrum modulation caused because the sound is diffracted and reflects by the ruggedness of the head and the earlobe. HRTF was measured beforehand for all directions by using a white noise in preparation for the analysis, and the HRTF database was made. Additionally, the information of the sound for the localization is prepared as knowledge under assumption of having heard it. When the sound is observed, the directional information of the sound is taken out by using information that system has as knowledge. The direction location experiment was done in the anechoic chamber for some sources, therefore the correct presumption rate became about 90% on the average, and was able to show the possibility of the sound localization by this technique.

Key Words: Sound Localization, Binaural Model, Transfer Function, Head Related Transfer Function

1 INTRODUCTION

The robot (electric machine and machine) has evolved to meet various needs in the industrial world and the home flexibly today. However, most of them are still moves by a one-sided instruction of man. In the future, the robot that will think for myself, judges, and acts is needed. It is demanded for the robot to be able to recognize surrounding circumstances by oneself, and to decide the action that should be taken based on the information. It is thought that corresponds to man's sense, sight, aural, sense of smell, and the function of the sense of touch etc. are necessary to recognize surrounding circumstances. In aural, when man listens to a certain sound, the direction of coming, the distance, and the kind of sound can be roughly presumed. It is said, "Sound Localization" to presume the direction of coming among these. The researches on the sound localization were advanced than before by many fields. However, it is usually a technique that uses a lot of microphone arrays. Moreover, the one to need additional movement to rotate for them even if it's with two microphones. It aims at the achievement of three dimension sound localization with two fixed microphones that assume the application of the humanoid robot to the auditory system in this research. Then, binaural model using dummy head (model with built-in mike that imitated man's head) was made as man's auditory model.

In this research, the sound source direction is decided by two angles, one is the horizontal angle α, and the other is vertical angle β. The former is presumed from the difference of the time of arrival of the sound from the source to a right and left ear, and the latter is presumed from spectrum correlation analysis using HRTF (Head Related Transfer Function). HRTF is a transfer function of the sound that changes depending on the direction of coming, and spectrum modulation caused because the sound is diffracted and reflects by the ruggedness of the head and the earlobe. As the mechanism of the human body has the element of uncertainty, it is difficult to evaluate human senses. The observation of human's information processing is indispensable to do the study of human senses. Our research of sound localization is one in aural mechanism. This is the signal processing system by the pinna model which uses two microphones to apply to the auditory system of robots.

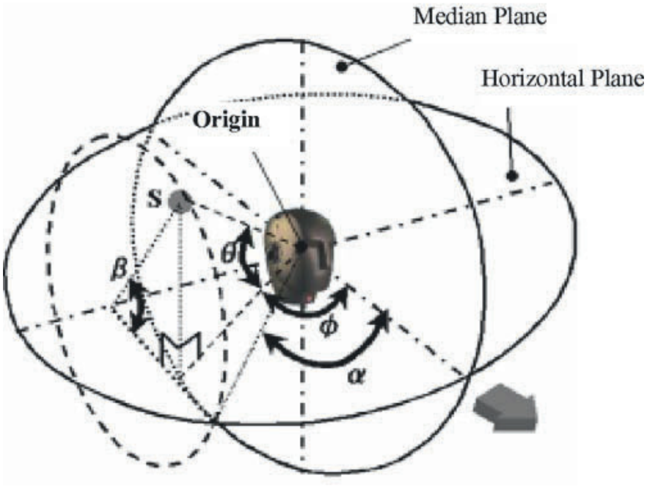
Our researches are shown in the following.

2 3-D SOUND LOCALIZATION USING TRANSFER FUNCTION OF THE BINAURAL MODEL

When we hear a sound, we are able to guess the direction and the position of the sound source. This ability we have is called "sound localization". If this ability is mechanically engineered, this can be applied to aural of robots. And it is possible to use this system as assistance of the physically handicapped person. The Principle of sound direction localizations is shown below.

Up to this time, only some studies about sound localization have been done. In these studies, the array of 3 or more microphones has usually been used, but is not suitable to apply to the auditory system of robots. On the other hand, using 2 microphones is not general and is limited in robotic usage, but is a better option. The purpose of this study is the realization of sound localization using two microphones. The ear model is designed to have different acoustical characteristics (HRTF; Head Related Transfer Function) in every direction. We measured the HRTF in each direction, and have made a database about it. If we can select the direction of the observed sound by using signals of each microphone from the HRTF database, we will be able to know the direction of each sound source. The practicality of this system is being examined by sound localization experimental apparatus including a dummy head. The coordinates of sound source location are decided by an azimuthal angle φ and elevation angle θ. In our system, the horizontal angle α and the vertical angle β are used. The relation between (φ, θ) and (α, β) is shown by Fig.1 and the following equation.

$$\varphi = \tan^{-1}\left(\frac{\tan\alpha}{\cos\beta}\right) \quad , \quad \theta = \cos^{-1}\left(\frac{\sin\alpha}{\sin\varphi}\right) \tag{1}$$



φ: Azimuthal angle, θ: Elevation angle,

α: Horizontal angle, β: Vertical angle

Fig.1 Direction of sound.

The horizontal angle α can be presumed by calculating the time that the sound travel from the sound source to the left and right microphones. This is called Binaural Time Difference (BTD). The vertical angle β is presumed by frequency response of HRTF. In this study, we've made the HRTF database in the anechoic room using white noise practically. We assume that the observed sound has been heard before. And the sound is recorded on a data base as knowledge. In an analysis, α is calculated from BTD of the observation signal, and a group which should refer to the HRTF data base is decided. Next, ratio, *Rhr*, of the standard HRTF and referred HRTF are calculated respectively. On the other hand, ratio, *Rsr*, of an observed signal's spectrum and the standard spectrum is calculated. And, the correlation coefficient γ of *Rhr* and *Rsr* is calculated by the following equation.

$$\gamma = \frac{\int_{-\infty}^{\infty}(Rsr(f)-\overline{Rsr}))(Rhr(f)-\overline{Rhr})df}{\sqrt{\int_{-\infty}^{\infty}(Rsr(f)-\overline{Rsr})^2 df}\sqrt{\int_{-\infty}^{\infty}(Rhr(f)-\overline{Rhr})^2 df}} \tag{2}$$

From the maximum value of γ, the vertical angle β is presumed.

Table.1 Sound source direction of HRTF data base

		[deg]
[deg]	0 20	0, 30, 60, 90, 120, 150, 180, 210, 240, 270, 300, 330
	30 40	0, 36, 72, 108, 144, 180, 216, 252, 288, 324
	50	0, 45, 90, 135, 180, 225, 270, 315
	60	0, 60, 120, 180, 240, 300
	70 80	0, 90, 180, 270

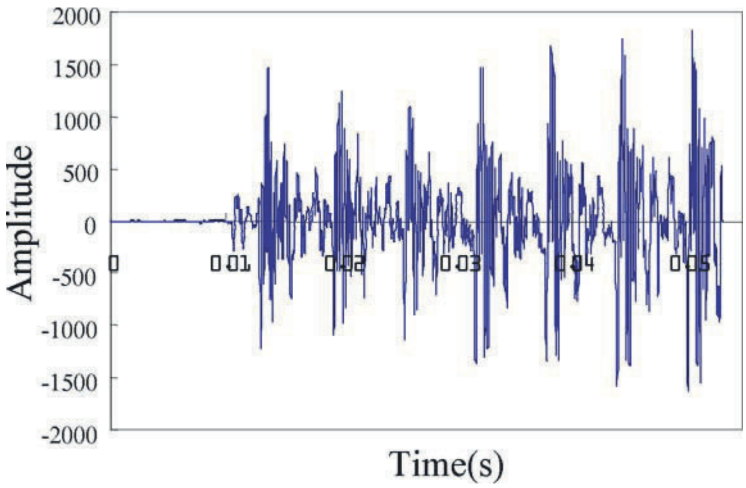


Fig.2 Wave form of vowel /a/ of Japan.

Then we did experiments of sound localization using a man's voice /a/ as the sound source. About experimental conditions, the distance from the starting point to the sound source is 2m and the sampling frequency is 25.6 kHz. The distance between the dummy head's both ears is 14cm. The angle α at the interval of 10°is measured from 0°to 80°. Figure shows the interval of β corresponding to each α. The total of the observation points is 78 points. Table 1 shows observation points of HRTF data base. In this research, Japanese vowels are used as a sound source. Here, we show the analytical result of vowel /a/ of Japan. The wave form of vowel /a/ of Japanese is shown in Fig.2.

3 ANALYTICA RESULTS

3.1 Presumption of horizontal angle

Fig.3 shows the relation between α and BTD obtained by the experiment. Here, α is presumed by a half-adjust at intervals of 10°. In this study, we obtain approximation straight line from the curve that has been obtained because of the experiment in Fig.3. The obtained equation is $\alpha=1.031\times10^5\times$BTD. The correct answers of α are very high in our system.

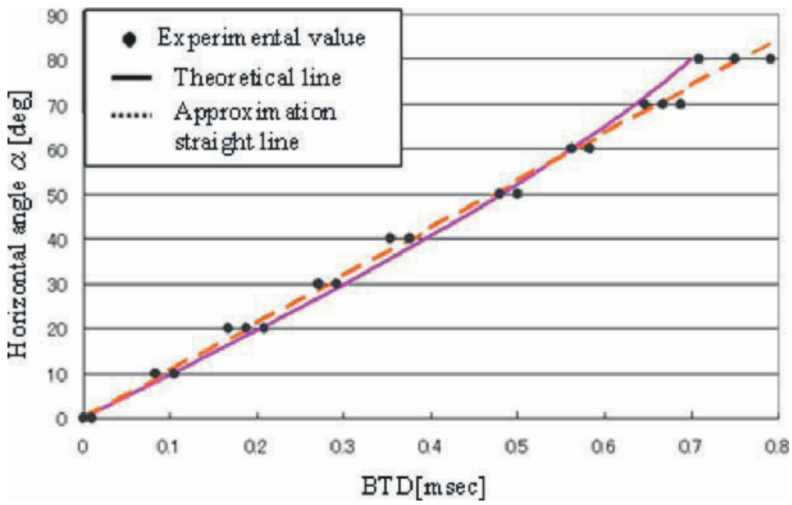

Fig.3α - BTD curve.

3.2 Presumption of vertical corner β

HRTF was measured beforehand for all directions by using a white noise in preparation for the analysis, and the HRTF database was made. Additionally, the information of the sound for the localization is prepared as knowledge under assumption of having heard it. When the sound is observed, the directional information included in the sound is taken out by using information that has it as knowledge. The direction of the source is presumed by collating this HRTF with the database.

Fig.4 shows the presumption result of β obtained by the correlation analysis in the case of α=60° and β=90°. Because the calculation result of the correlation value was the highest in β=90°, it can be said that β will be correctly presumed. Figure 5 shows the correct answer rate of the vertical angle β of the sound of the direction of each α. The range of frequency to obtain correlation value is 234.375-4687.5Hz.

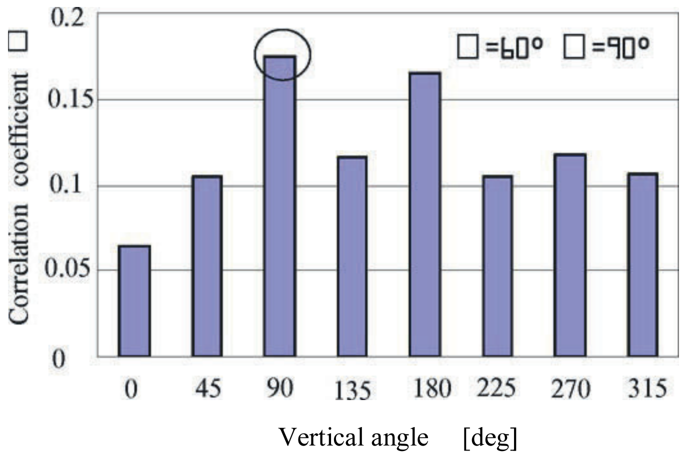

Fig.4 Comparison of correlation coefficient.

Figure 5(a) is an analytical result of the /a/ continuously generated. The average presumption rates obtained about 92%. Now, we are examining the reason why the miss-presumption increases when α is small. As a result, when the sound source was near the median plane of the binaural system, the percentages of correct answers of β were very high. As the sound source was far away from the median plane, the percentages of correct answers of β had decreased. The reason is that the difference of each HRTF data is small. Figure 5(b) is an analytical result of the /a/ intermittently generated. The average presumption rates obtained about 97%. From this result, it has been understood that intermittent sounds are more suitable for the sound direction localization than continuous sounds. Because information on the sound source increased, the accuracy of the location is assumed to be improved.

We were able to show the possibility of the sound localization by this technique. In the future, the three dimension sound direction localization system is constructed by the spectrum analysis including voice recognition.

(b) Result of intermittently generated /a/.

Fig.5 Localization result of each direction.

4 CONCLUSIONS

In this report, we showed the 3-D sound localization method that used transfer function of the binaural model. As a result of the sound direction localization experiment by the dummy head, we were able to show effectiveness of our system. In the future, we want to solve some problems, and to improve our system to a more practicable system.

The direction location experiment was done in the anechoic chamber for some sources; therefore the correct presumption rate became about 90% on the average, and was able to show the possibility of the sound localization by this technique. These accurately locate as a problem in the future about a specific direction because there are a lot of miss-presumptions. Correspondence to another source that builds in sound source recognition and the localization in real time, etc. are raised.

Abstract: In this study, in order to improve the problem of abnormal signal selection, the technique of constituting an Average Real signal Mother Wavelet (A-RMW) from two or more real signals is proposed and its effectiveness is confirmed. The main results obtained can be summarized as follows: (1) For constructing A-RMW from two or more signals, the Symmetric Complex Real signal Mother Wavelet (SCRMW) first was constructed for each signal and then the average SCRMW was obtained by adding them. Finally the average SCRMW obtained above was normalized and the A-RMW was obtained. (2) The proposed construction method of the SCRMW is different to that of the CRMW [9] in that the phase information of all the frequency components has been cut off and symmetry can be obtained.

Key Words: Wavelet transform, Wavelet, Real signal mother wavelet, Abnormal signal detection

1 INTRODUCTION

It is well known that the Short Time Fourier Transform (STFT) and the Wavelet Transform (WT) are used widely as time-frequency analysis methods since they express the features of an unsteady signal clearly on the time and frequency plane [1]. However the STFT has fixed time resolution and frequency resolution at all frequencies and the determination of window width is difficult. Compared to this, the WT has a suitable resolution at each frequency because it carries out expansion reduction of the function called the Mother Wavelet (MW) and changes the time and frequency resolution according to frequency. Therefore, the WT has been applied to signal processing in various fields, and has received attention [2, 3].

For the MT, all functions can be used as the MW if they satisfy the admissibility condition and many types of MWs, for example, the complex type and real type and so on have been proposed [4]. Understandably, analysis results obtained using different MWs are different. So in signal analysis, one often has to first examine the characteristics of the MWs, and then choose one. For example, when analyzing an unfamiliar signal, the Gabor function [6] and the RI-Spline wavelet [5] generally produce better results than other wavelets since they have good localization in the frequency and time domain, and easily matche the frequency and scale of the signal. However, for detecting abnormal signals which appear unsteady, the Gabor function and the RI-Spline wavelet cannot always give satisfactory results.

In addition, the WT can be considered a kind of similarity transform [7, 8]. A signal $f(t)$ is measured by using the wavelet functions $\psi_{a,b}(t)$ that are defined from the MW $\psi(t)$ as a scale, and the similarity between the signal $f(t)$ and wavelet functions $\psi_{a,b}(t)$ is evaluated by the coefficient of the WT. The authors [7] took advantage of this feature and constituted a Real signal Mother Wavelet (RMW) from an abnormal signal. Then the WT was carried out by using the RMW and the abnormal signal was detected by evaluating the correlation between the RMW and the abnormal signal using the wavelet coefficient. This method was very useful for detecting the abnormal signal although it had the following two problems: 1) The signal's phase information could not be obtained since the RMW constructed was a real type MW and the wavelet coefficients oscillated. 2) The RMW is difficult to form when it is not clear what portion of the signal is suitable for the RMW. In this case, it was difficult to narrow down to one with the WT using the Gabor function and the RI-Spline wavelet.

In order to suppress oscillation of the analysis results, the authors proposed a Complex Real signal Mother Wavelet (CRMW) [9] and confirmed its effectiveness by applying it to abnormal vibration detection. In this study, in order to ease the difficult problem of the signal selection, the technique of constituting an average RMW from two or more real signals is proposed. The important technique of this method is the construction of a Symmetric Complex Real signal Mother Wavelet (SCRMW), in which the phase information of all the frequency components has been cut off. Furthermore, the proposal method is applied to the abnormal sound source detection of a car, and its effectiveness is examined.

2 RMW AND WAVELET INSTANTANEOUS CORRELATION

The WT transforms the signal $f(t)$ which has a finite energy into a function which has two variables, frequency ($1/a$, a : scale) and time b . The WT is defined by the following formula.

$$W(a,b) = \int_{-\infty}^{\infty} f(t)\overline{\psi_{a,b}(t)}dt, \quad (1)$$

$$\psi_{a,b}(t) = a^{-1/2}\psi(\frac{t-b}{a}),$$

where $\overline{\psi_{a,b}(t)}$ and $\psi_{a,b}(t)$ are conjugate complex functions of each other. Here, the function $\psi(t)$ is the MW which satisfies the following admissibility condition.

$$C_\psi = \int_{-\infty}^{\infty} \frac{|\hat{\psi}(\omega)|^2}{|\omega|} d\omega < \infty. \quad (2)$$

Here, $\hat{\psi}(\omega)$ means the Fourier transform of $\psi(t)$, ω denotes the angular frequency ($\omega = 2\pi f$), and f the frequency. This condition can be simplified to the next equation when $\psi(t)$ tends to zero as t approaches infinity.

$$\int_{-\infty}^{\infty} \psi(t)dt = 0. \quad (3)$$

Formula (1) shows that the wavelet transform achieves the time-frequency analysis by transforming the signal $f(t)$ into the function $W(a,b)$ which has two variables, frequency ($1/a$) and time b . Generally, the abnormal signal consists of many components, its strength is various and its generating time is irregular. The WT can show these features clearly in the time-frequency plane, but it cannot detect and evaluate its features at the same time because the common MW performs band pass filtering. Therefore, creating a technique for the detection and evaluation of abnormal signals is still a very difficult task.

Moreover, as is shown in Eq. (3), all functions can be used as the MW if they are functions such that their average value is zero and the amplitude becomes zero sufficiently quickly at a distant point. Therefore, the real RMW can be constructed by multiplying the real signal with a window function and removing the average which makes it approach zero sufficiently quickly at a distant point [7]. Furthermore, the authors proposed the method for constructing a CRMW using the frequency characteristic of the complex wavelet function [9] and defined the Wavelet Instantaneous Correlation Value (WICV) $R(b)$, which is a value $|w(a,b)|$ obtained by the CRMW in scale a =1 was shown as follows:

$$R(b) = |w(a=1,b)|. \quad (4)$$

By using $R(b)$, the detection and evaluation of the abnormal signal's strength and generating time can be achieved at the same time.

The procedure for constructing the CRMW can be summarized as follows: 1) First the characteristic portion of the real signal is isolated and then the real signal is multiplied with a window function. Next the average is removed thereby making it approach zero sufficiently quickly at a distant point and obtaining the RMW $\psi_R(t)$. 2) The RMW is normalized so that the norm $\|\psi_R\|$ =1.

$$\|\psi_R\| = \left[\int_{-\infty}^{\infty} \psi_R(t)^2 dt\right]^{1/2} = 1. \quad (5)$$

3) The Fourier transform of the RMW $\psi_R(t)$ is performed and its frequency spectrum $\hat{\psi}_R(f)$ is obtained. 4) In the negative frequency domain, $\hat{\psi}_R(f)$ is set to 0, in the positive frequency domain, $\hat{\psi}_R(f)$ is set to $2\hat{\psi}_R(f)$ and the reverse Fourier transform is performed. Finally the CRMW $\psi(t)$ = $\psi_R(t) + i\psi_I(t)$ can then be obtained.

Figure 1(a) shows an example of the RMW $\psi_R(t)$, which was constructed by a model signal, where the Hanning window function has been used. The model signal consists of three sine waves with 400Hz, 800Hz and 1600Hz which can be shown as follows:

$$f(t) = \sin(2\pi 400t) + 0.7\sin(2\pi 800t) + 0.7\sin(2\pi 1600t) \qquad (6)$$

Where t denotes time. Figure 1(b) shows an example of the CRMW $\psi(t)$ that was constructed by the method shown above using the RMW $\psi_R(t)$ shown in Fig. 1(a) and Fig. 1(c) shows their power spectrum $E(f)$. Moreover, the norm of the real component and the imaginary component of the CRMW are set to 1, respectively. As is shown in Fig. 1(b), construction of the CRMW was successful.

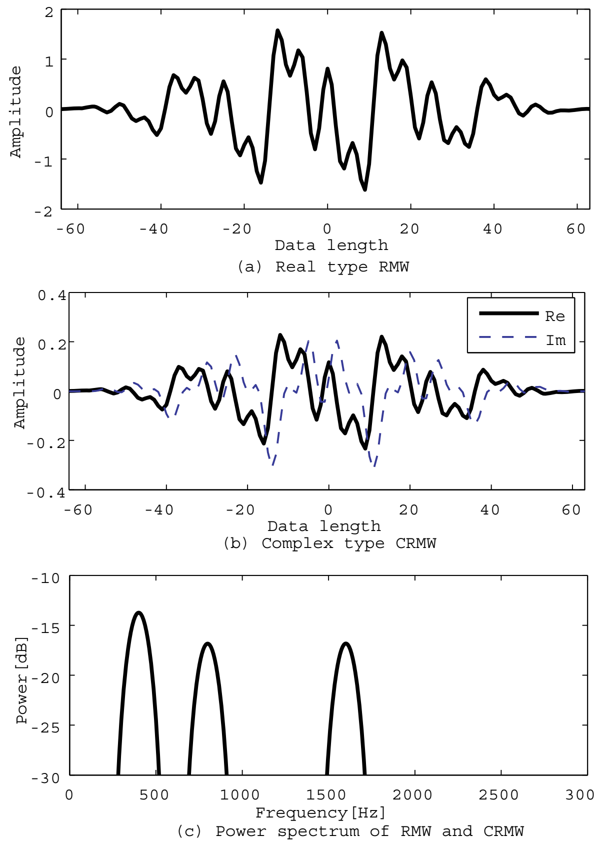

Figure 1 Example of the RMW and CRMW constructed by the model signal.

3 CONSTRUCTION OF AVERAGE REAL SIGNAL MOTHER WAVELET (A-RMW)

When constructing the RMW, there is a difficult problem in that one can not always narrow down the location of an abnormal signal if it is not clear what portion of the signal is suitable for the RMW. Therefore, it is possible that if the selection of the portion of an abnormal signal is not correct, then the abnormal signals can not be detected correctly by using the RMW constructed above. In this case, it was thought that if the RMW was first constructed from multiple locations of the abnormal signal (or multiple abnormal signals) and then the abnormal signal could be detected correctly. Therefore, the construction method shown below of the A-RMW was proposed and the construction technique of the Symmetric Complex Real signal Mother Wavelet (SCRMW) plays an important role in the A-RMW construction.

3.1 Construction method of the SCRMW

Figure 2 shows the flow chart of the construction method of the SCRMW. In the figure, steps 1 to 4 are the same as the process of CRMW [9]. However step 5 is different from the CRMW in that the real part of $\hat{\psi}(f)$ is set to $\sqrt{(\hat{\psi}_R(f))^2 + (\hat{\psi}_I(f))^2}$, and the imaginary part is set zero. As a result, the phase information of all the frequency components has been cut off. In step 6, the inverse Fourier transform was carried out and the SCRMW $\psi(t) = \psi_R(t) + i\psi_I(t)$ can be obtained.

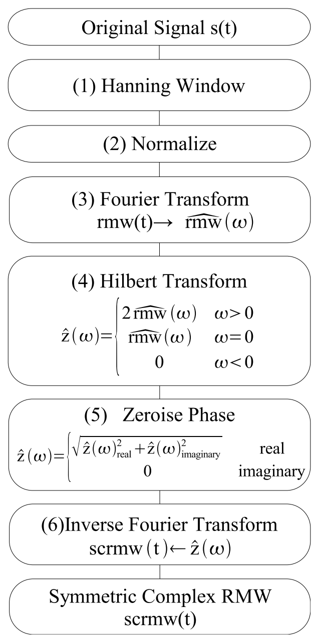

Figure 2. The method of constructing the SCRMW

Figure 3(a) shows the SCRMW constructed using the model signal shown in Eq. (6) and (b) shows the CRMW constructed using the same model signal for comparison. From Fig. 3(a) it is clear that the energy of the SCRMW is concentrated around the center of the SCRMW. In addition, the real component of the SCRMW has symmetry and the imaginary component has anti-symmetry. Compared to the SCRMW, the CRMW holds the original signal's phase information and does not have symmetry.

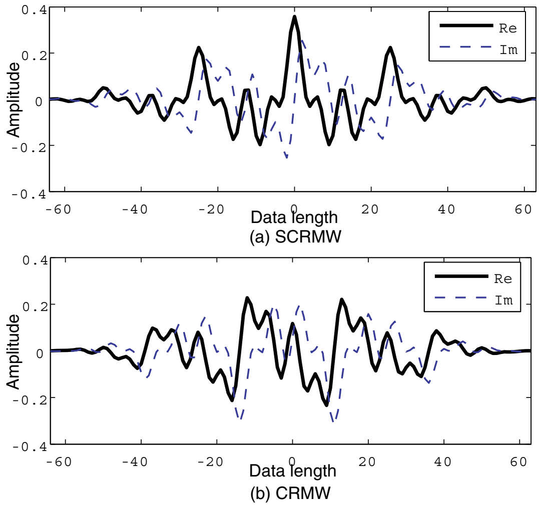

Figure 3. Example of the SCRMW and the CRMW

3.2 Construction method of the A-RMW

For construction of the A-RMW, the method proposed by authors, which connecting multiple signals in the time domain was used [10]. Figure 4(a) shows the average RMW obtained by connecting two signals. In this figure, we use two model signals, one with the components of 400, 800, and 1600Hz shown in Eq. 6 and another one with the components of 300, 600, and 1200Hz shown in the next equation.

$$f(k) = \sin(2\pi 300t) + 0.7\sin(2\pi 900t) + 0.7\sin(2\pi 1200t) \tag{7}$$

In the construction of the average CMRW, first two data sets with 128 points in which one was extracted from the signal shown in Eq. (6) and another one was extracted from the signal shown in Eq. (7), respectively, were arranged continuously and a synthetic signal shown in Fig. 4(a) was obtained. Then multiplying the synthetic signal with the window function, and removing the average yielded the average RMW. Figure 4(b) shows an example of the average RMW constructed. An average CRMW finally was obtained by the construction method of the CRMW using the average RMW as the original signal and is shown in Figure 4(c). As is shown in Fig. 4(c), the average characteristic of the two signals can not be obtained from the average CMRW since using the construction method of CMRW, the phase information of the two signals were held and a discontinuity arose in the connection portion.

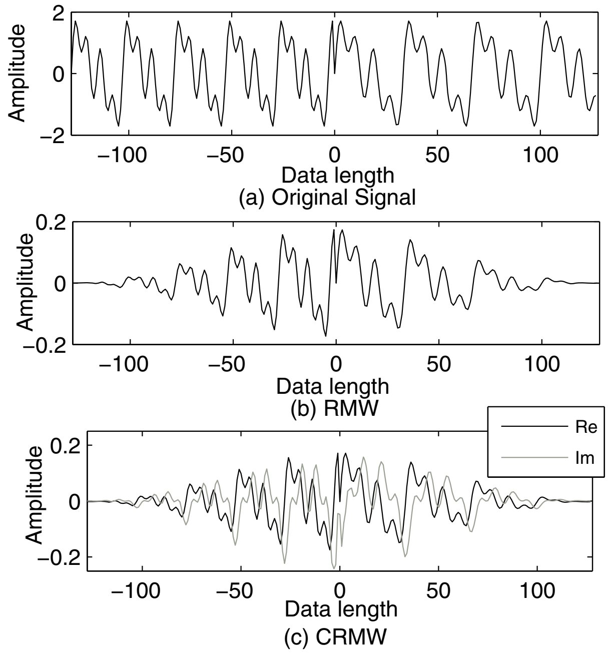

Figure 4. Example of the average CRMW

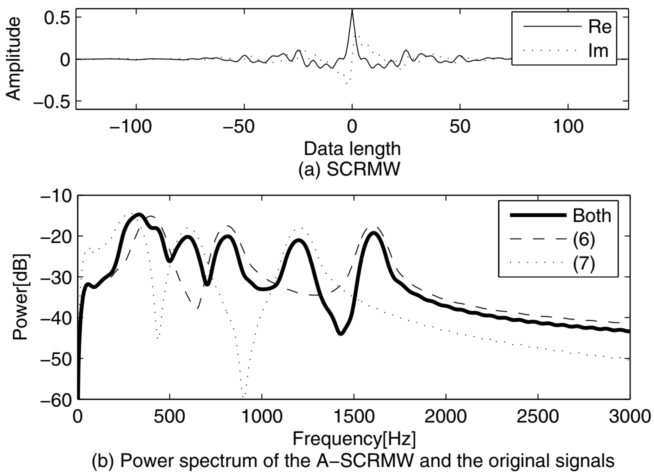

Figure 5. Example of the Average SCRMW

In order to improve the discontinuity problem in the connection portion, the constructing method of the SCRMW was used instead of the construction method of the CRMW and the results are shown in Fig. 5. Here, Fig. 5(a) shows the average SCRMW and (b) its power spectrum. As is shown in Fig. 5, the average SCRMW has the SCRMW's property that the real component has symmetry and the imaginary component is anti-symmetric, and the wave of an average SCRMW becomes smoother than an average CRMW although the frequency property which high frequency components have been increased is not good because the average RMW shown in Fig.4 (a) has a discontinuous part in the connection portion.

3.3 Problems and improving method

Regarding the average SCRMW shown above, the following problems can be observed. 1) The data length of an average SCRMW becomes longer than the data quarried out. 2) The average SCRMW's frequency property is not good because the discontinuity is in the connection part of two (or more) signals. Especially for problem 2, improvement is very difficult because the original data of the average RMW shown in Fig.4 (b) is discontinuous. In order to overcome the above drawbacks, a new construction method that uses the SCRMW's features was developed and it is shown in Fig. 6. That is, for two or more signals, the SCRMW first were constructed for each signal and then the average SCRMW was obtained by adding them. Finally the average SCRMW obtained above was normalized and the A-RMW was obtained. Figure 7 shows an example of the A-RMW, where (a) is an example of the A-RMW constituted, and (b) is its frequency characteristic. By comparing Fig. 7 and Fig. 5, it is clear that in the case of the average SCRMW shown in Fig. 5, it has some frequency components which the original model signal does not have. However, in the case of the A-RMW, this phenomenon has been improved.

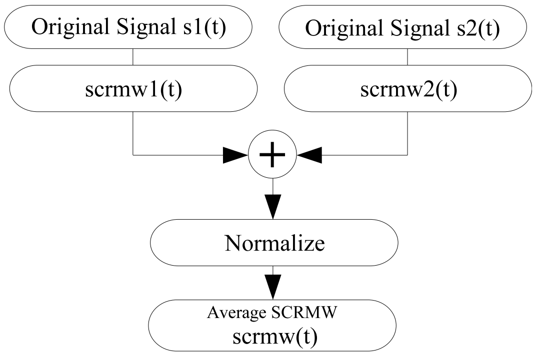

Figure 6. Method of generating the A-RMW

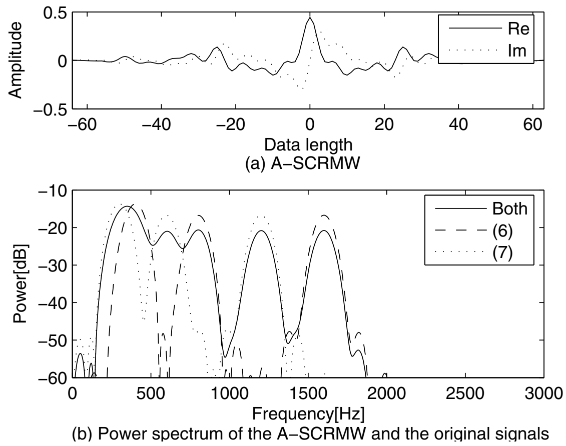

Figure 7. Example of the A-RMW constructed from the SCRMW

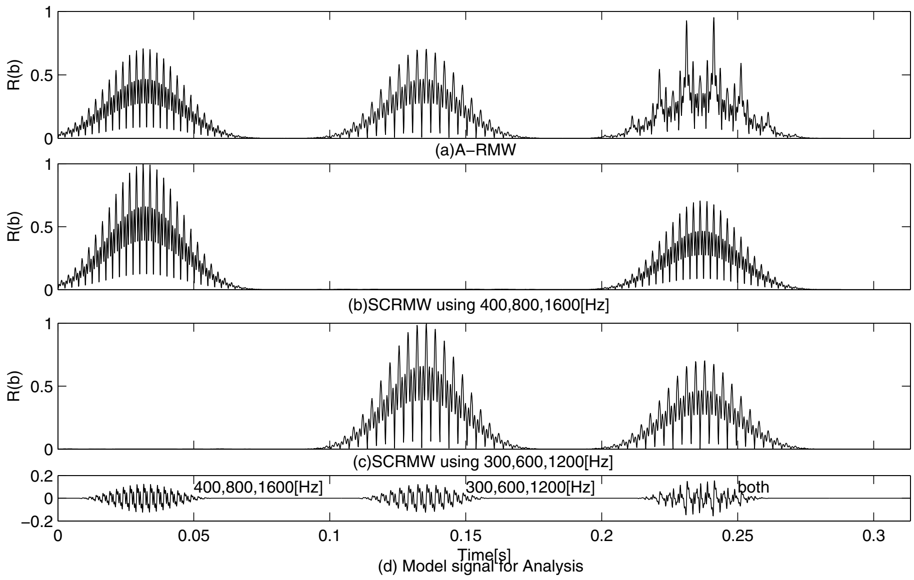

Figure 8. Example of analysis results by using the A-RMWs

3.4 Test of the A-RMW by Simulation

To confirm the features of the A-RMW, a simulation using the model signals was carried out. Figure 8 shows a model signal for analysis and the results obtained by the WICV. The model signal shown in (d) has three parts, which can be shown in Eq. (6), Eq. (7) and Eq. (6) + Eq. (7), respectively. The simulation results obtained by using the A-RMW and the SCRMW are shown in Fig. 8(a), (b) and (c), where (a) shows the results obtained by the A-RMW constructed using the model signal Eq. (6)+Eq. (7), (b) obtained by the SCRMW using the model signal Eq. (6) and (c) obtained by the SCRMW using the model signal Eq. (7). Furthermore, in order to show the results clearly, the length of those A-RMW and SCRMW are 512 points. As is shown in Fig. 8, in the case of (b), the signal of Eq. (7) was not detected and in the case of (c), the signal of Eq. (6) was not detected. Compared to this, in the case of (a), both signals have been detected. Therefore, we can conclude that the construction method of the A-RMW shown in Fig. 6 is successful.

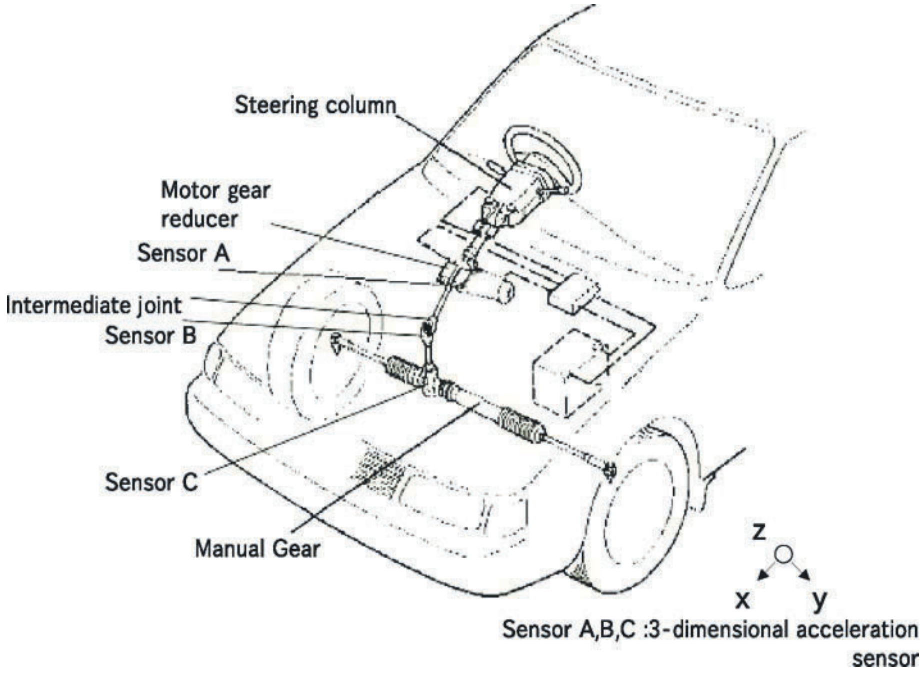

Figure 9. The position of acceleration sensors

4 APPLICATION ON RATTLE NOISE SOURCE DETECTION

Recently, an Electric Power Steering (EPS), in which the motor is driven only when the steering wheel is turned, has been increasingly adopted in the cars, because it greatly improves fuel performance over conventional hydraulic power steering. However, a rattle noise and a joint noise are occurred from front of vehicle while driving over rough roads when vehicle equipped with the EPS system and these noises become problem now. The EPS has the vibration sources such as motor gear reducer, manual gear, intermediate joint, and so on. In order to improve the rattle noises, it is very important to evaluate rattle noises and identify the correct noise source that occurred by the vibration in the EPS, although it is very difficult since the vehicle interior noise generated by the engine, suspension and tires, does not only by the EPS. Therefore, one of the main problems related to identifying the rattle noises in EPS is how do detect the rattle noises from the many kinds of noises. In this section, we will discuss the rattle noises detection by using the A-RMW.

4.1 A-RMW Constructed by Real Sound Signals

Figure 9 shows the position in which the acceleration sensors were installed. As is shown in Fig. 9, three 3-dimension acceleration sensors were installed in each position. A microphone was set up under the steering wheel. The experiments were carried out when a car was driven on a road, and nine vibration data (three sensors and three directions) and a sound data were obtained.

Figure 10 shows example of the sound signals and the A-RMW constructed, where (a) and (b) are the sound signals, (c) is the A-RMW constructed from (a) and (b) by extracting the portion of the rattle noise, which shown in square area of the sound signals. Here, notes that the low-pass filters which cutoff frequency 1kHz for the sound signal has been used. Figure 11 shows the averaged spectrum obtained by the sound signals shown in Fig. 10(a) and (b), and the spectrum obtained from A-RMW shown in Fig. 10(c). From Fig. 11 it is clear that the spectrums are almost same although the wave shape of the A-RMW is different from that of the sound signals. That is, the average property of the rattle noise has been obtained by using A-RMW. Furthermore, in the next section, the A-RMW would be used to the sound source detection of the rattle noise.

4.2 Results and Discussion

Figure 12 (a) shows the example of the vibration signal, which obtained by acceleration sensor C and direction Z (Z direction of Manual Gear), (b) shows the example of analysis result obtained by the WICV $R(b)$ using the A-RMW, where the A-RMW was constructed by using eight signals of the rattle noises that extracted from sound signals. As is shown in Fig. 12(b), the bigger values than 2 of the $R(b)$ can be obtained at 0.35ms, 0.4ms, 0.75ms and 0.9ms. It means the vibration at these time has same frequency characteristic as the A-RMW that constructed by the rattle noise.

Figure 13 shows the mean values of the $R(b)$ obtained in the calculation range, where horizontal axes shows the number of samples which are the seeds of the A-RMW and vertical axes shows $R(b)$ value. Here, the rattle noise is correctly detected, so that average value is high. As is shown in Fig. 13, the vibrations obtained from the motor gear reducer in the direction of X and Y have bigger WICV $R(b)$ than that of the other vibration signals, that is, these vibrations have the large contribution to the rattle noise. Furthermore, the values of the $R(b)$ become large as the number of samples of the rattle noise increase when the number of samples are small than 6 and the values of the $R(b)$ are almost same when the number of samples are bigger than 6. It predicts that an optimal number of the samples exist for the A-RMW and it is almost six.

Figure 14 shows the mean values of the $R(b)$ that included an error signal, where the error signal was shown as "sample 0" in the figure. The example of the error signal was shown in Fig. 15. Where Fig. 15(a) shows the original error signal which selected from sound signal and (b) shows its power spectrum. By comparing Fig. 15(b) and Fig. 11, it is clear that the spectrum of the error signal and the rattle noise are difference.

The influence of the error signal decreases when a lot of the samples of the rattle noise were used although the selection of the rattle noise for the A-RMW is mistake.

Therefore, we can conclude that the A-RMW constructed from two or more real signals is successful for improving the difficult problem of the signal selection.

5 SUMMARY

In this study, in order to ease the difficult problem of signal selection, the technique of constituting A-RMW from two or more real signals has been proposed and its effectiveness has been confirmed. The main results obtained can be summarized as follows:

1. For constructing the A-RMW from two or more signals, the method in which the SCRMW first was constructed for each signal and then the average SCRMW was obtained by adding them, and finally the average SCRMW obtained was normalized and the A-RMW was obtained was effective.
2. The proposed construction method of the SCRMW is different to the CRMW in that the real part of $\hat{\psi}(f)$ is set to $\sqrt{(\hat{\psi}_R(f))^2 + (\hat{\psi}_I(f))^2}$, and the imaginary part is set to zero. As a result, the phase information of all the frequency components has been cut off and symmetry can be obtained.
3. Furthermore, the proposed method was applied to the rattle noise detection of the EPS, and its effectiveness was examined.

FLOW VISUALISATION IN DENSE PHASE PNEUMATIC CONVEYING OF ALUMINA

Cenna AA, Williams KC, Jones MG and Page NW

The University of Newcastle, Australia

Abstract: Pipeline wear is a very complex problem and at present there is limited understanding of the wear mechanisms responsible for the reduction of pipe wall thickness in critical wear areas. The ability to determine the wear mechanisms in these areas holds the key in determining the service life of pneumatic conveying pipelines in industry. In this paper design and construction of a visualisation test rig is presented which enables better understanding of the flow process in pneumatic conveying pipelines. Results from the flow visualisation have been analysed and presented for an insight to the flow patterns in the critical wear areas of pneumatic conveying pipelines.

Wear samples from an industrial pipeline have also been analysed in relation to the flow patterns in the pipelines and bends. The flow patterns observed through the visualization test rig clearly demonstrate its capability to establish the critical wear areas on the pipeline and the bends depending on the pneumatic conveying parameters. Possibility of the development of a realistic predictive model for wear in these critical wear areas have been discussed and presented.

High speed video was used to record the flow patterns inside the bends and immediately after the bends (reacceleration zone). Visualization of flow patterns in the bend clearly showed the complex nature of the flow development in the bends. Impact and sliding of the particle stream on different surfaces clearly showed the critical wear areas in the pipeline and bends. Scanning Electron Microscopy was used to analyse the wear samples from the industrial pipeline. Finally a conceptual model for the wear process is presented.

Key Words: Critical wear, service life, visualisation test, flow patterns, Predictive model, Electron Microscopy, Conceptual model.

1 INTRODUCTION

Pneumatic conveying is a very complex problem of two phase flow and at present there is limited understanding of the flow characteristics in the pipeline, especially through and immediately after the bends. Currently researchers and professionals in the field of pneumatic conveying depend on the concepts and models developed on the basis of steady state conveying conditions. Although these models can be used to estimate the conveying gas pressure and air mass flow rate through the pipeline which provide information on the motive force energy available, the solids (or particle) flow information is limited to a mass flow value prediction which provides no information of the geometric flow structure of the particle stream.

Wear is surface damage that involves progressive material loss due to relative motion between the surface and the contacting substance or substances. Wear poses serious consequences in pneumatic conveying systems with respect to the service life as well as maintenance management. The ability to determine the effects of conveying parameters on wear mechanisms calls for a systematic study of the evolution of the wear profiles on the pipelines due to the particle stream.

In this paper, the design and construction of a visualisation test rig for pneumatic conveying is described. Flow visualization tests were conducted by controlling the solid and air mass flow rates into the system. A high speed video has been used to analyse the flow structure, specifically the flow patterns inside and at the exit of the bends. Using high speed video, the particle stream velocity and associated impact angles in the critical wear area were determined.

2 PNEUMATIC CONVEYING

Pneumatic conveying has gained popularity because it offers a flexible line layout, containment of the conveyed solids and ease of automation. For the case of classification, pneumatic conveying can be categorised into two modes of flow; 1) Dilute phase flow and 2) Dense phase flow. For simplicity, each phase can be categorised in terms of the mass flow ratio (m*), which is defined as the ratio of the mass flow rates of solids to the mass flow rates of conveying air. Thus in terms of the above definition we have (1):

Mode	Mass Flow Ratio
Dilute Phase	0-15
Dense Phase	<15

In dilute phase systems, material is conveyed in suspension in air through the pipeline. Dilute phase (sometimes referred to as lean phase) systems in general employ large volumes of gas at high velocities. The gas stream carries the discrete particles by means of lift and drag forces acting on the individual particles. Dilute phase systems constitute the most widely used of all pneumatic conveying systems. Almost any material can be conveyed in dilute phase, suspension flow through a pipeline, regardless of the particle size, shape or density [2].

In dense phase systems material is in a non-suspension mode in which the particles are generally in contact with each other. Depending upon the major characteristics of the solids and air mass flow rates and the pressure drop through the pipeline, the flow patterns in the dense phase mode can vary from being unstable to stable or an intermediate unstable/stable regime. Figure 1 shows the two modes of dense phase flow diagrammatically as (a) fluidized dense phase or fluidised moving bed type flow and (b) slug or plug flow.

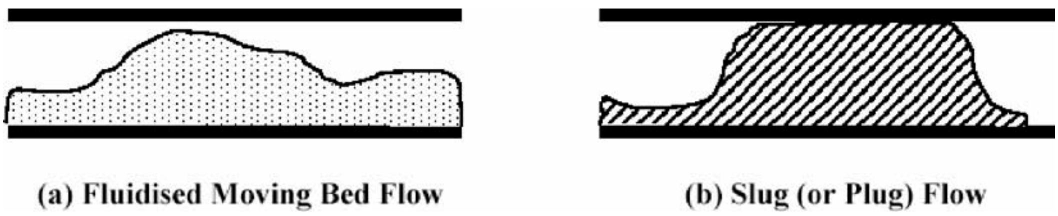

Figure 1: Two Major Modes of Dense Phase

The fluidised dense phase mode is exhibited largely by powdered materials which have good air retention capabilities, whereas, the slug flow mode is generally exhibited by coarse granular materials which have a high level of permeability to the conveying gas. Hence, it is useful to be able to distinguish between those materials capable of dense phase in a conventional pipeline and those restricted to dilute phase only. Furthermore, an ability to identify which mode of dense phase is most suitable for the material is also an advantage.

The boundary between dilute phase flow and dense phase flow is not well defined. For a fixed solids loading ratio, as the superficial gas velocity is increased, the flow condition shifts from a steady dense phase to an unsteady phase and finally to a steady dilute phase as shown in the Zenz diagram (Figure 2) [3]. This shift from stable to unstable transport is marked by a characteristic point called the critical velocity, which has been defined as the transition between dense phase flow and slug flow or plug flow transport. In this paper fluidized dense phase flow conditions for conveying alumina is the focus of the work.

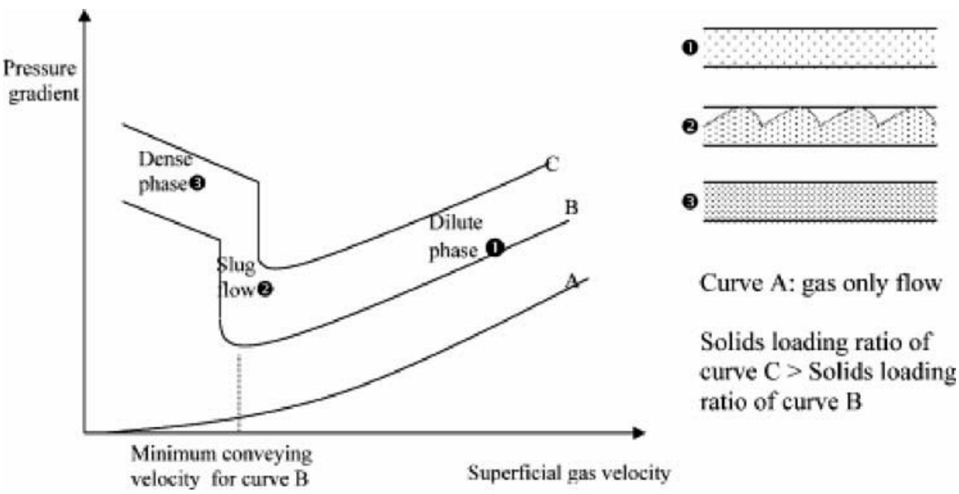

Figure 2: Zenz diagram showing the different phases of pneumatic conveying.

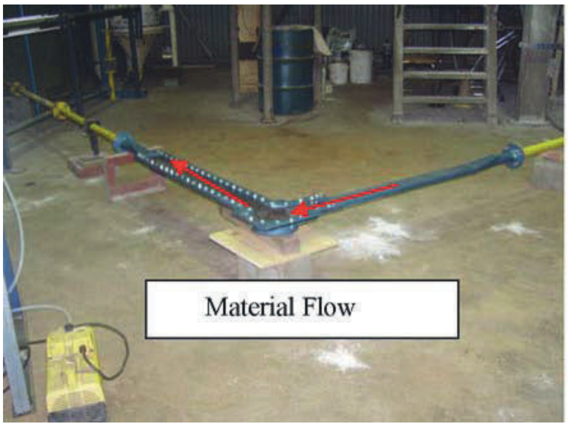
3 VISUALISATION TEST RIG

For a better understanding of the dense phase flow characteristics and its behaviour with changes in conveying parameters, a visualization test rig was designed and constructed at the University of Newcastle. The primary aim of this development was to study the flow patterns in different bends as well as in the particles reacceleration zone after the bends. Another objective of the test rig was to provide a basis for the determination of the critical wear areas with respect to the pipeline configuration and conveying parameters. Although the dense phase conveying was the main focus of the current project, the test rig is designed to study the flow characteristics of both the lean phase and dense phase conveying systems. The following figure (Figure 3) shows the visualization test rig with a circular bend (Botswana bend) installed.



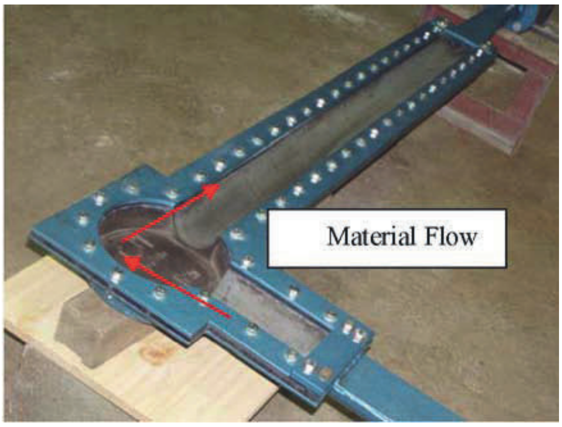


Figure 3: Visualisation test rig with a circular Bend (Botswana Bend) installed.

Alumina with an average particle size of 70 µm was used for the flow analysis in the test rig with varying solids and air mass flow rates used. Changes in the flow patterns inside the bend as well as in the reacceleration zone after the bends were observed and recorded utilising a high speed video at 500 frames per second. The videos were then studied and analysed to investigate the flow patterns and critical wear areas of the flow in the pipeline. In the Figure 4, the flow directions for two different conveying parameters are presented. Flow directions are shown with arrow heads and critical wear areas are shown in solid lines (the right picture has higher gas velocity and no critical wear area).

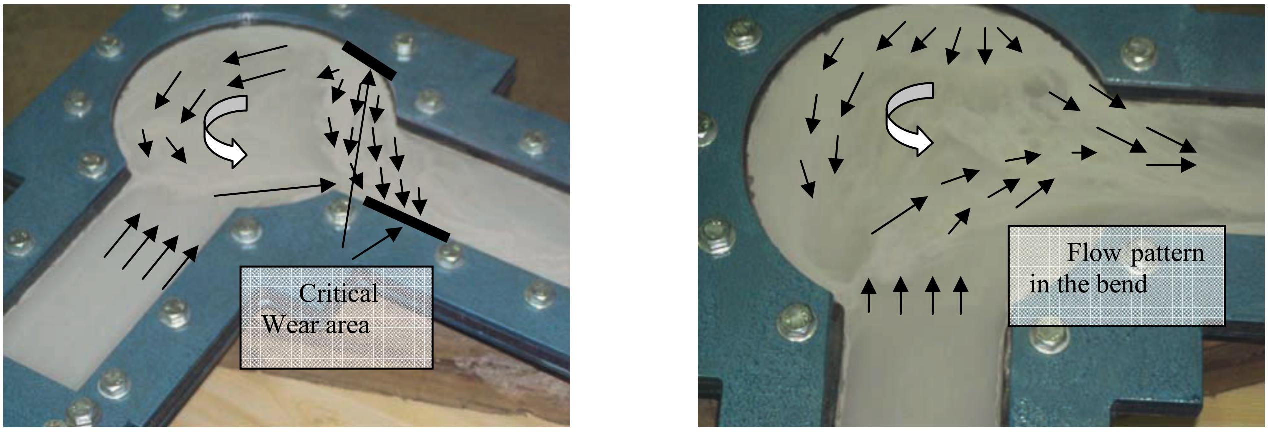

Figure 4: Visualisation test rig and flow patterns in a specific bend.

The two pictures shown in Figure 4 describe the bulk material flow structure for two different sets of conveying parameters. The particle flow in the left picture shows impact on the pipe wall after the bend as well as the particles impact on the bend opposite to the entry. On the other hand, the right picture shows particle streaming through the centre of the pipe with material piled up at the impact point (stagnation point) inside the bend. As the materials impact on the pipeline is reduced in the right picture, the wear in this section is expected to be reduced. This analysis demonstrates the possibility of optimization of the conveying parameters to reduce the wear in the reacceleration zone of the pipeline.

4 FLOW ANALYSIS FOR DETERMINING THE CRITICAL WEAR AREAS IN PNEUMATIC CONVEYING PIPELINE

The visualization test rig clearly showed the structure of the bulk material flow during pneumatic transport through the bends. It was also found that the amount of material that piled up in the bends depended on the solids and air mass flow rates. With higher solid mass flow rate, material piled up in the bend particularly around the impact area which protected the bend from direct impact or erosive wear. On the other hand with increased air mass flow rate, little or no material remained stationary in the bend, which leads to erosive wear due to particle impacts on the bend. After the impact on the bend, the material rebounds and is reaccelerated towards the exit pipe. The flow pattern in the bend clearly shows two different stream paths of the particles; one stream towards the exit and the other in the opposite direction (shown in Figure 4). It is also understood that the reverse flow created in the bend plays an important role in the resultant exit flow from the bend.

From the visualisation analysis, important geometrical features were determined and are modelled as is shown in Figure 5. The geometrical parameters represent the flow patterns in the bend as well as the position of the critical wear areas. The 1st critical wear area occurs directly opposite to the entry pipeline and at higher solid mass flow rates this area is protected by the bulk material build up. On the other hand, if the air velocity is increased, even with the same solid mass flow rate, the material may not build up in this area which will allow erosive wear to occur. The particle stream towards the exit tends to impact on the pipe wall immediately after the bend (2nd critical wear area). The geometrical parameters of distance X and the angles α and β primarily depend on the solid and air mass flow rates in the conveying process. Pressure at the location of the pipeline may also affect the location of the critical wear point due to the variation of the gas velocity.

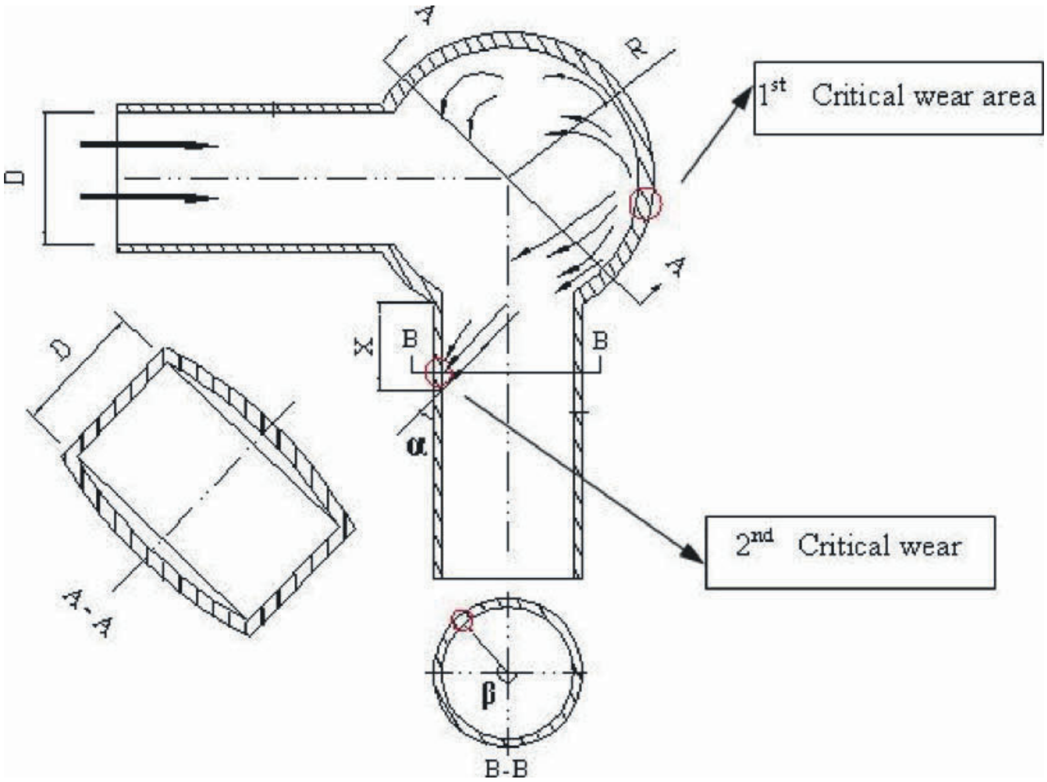

Figure 5: Flow model in the bend based on the high speed video analysis.

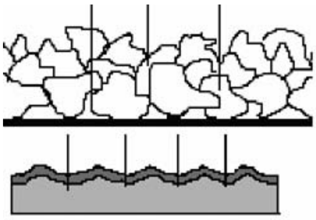
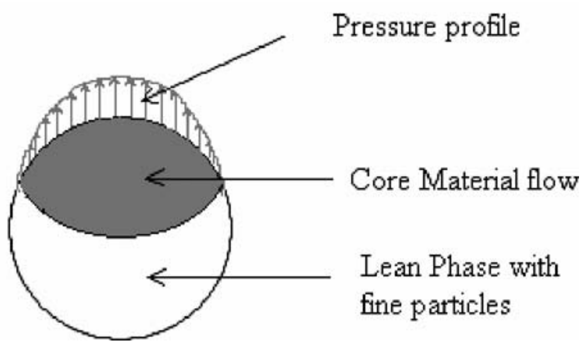
From the analysis of the high speed videos of the flow at different conveying parameters it was clear that the material impact in the 1st critical wear area can be reduced through increased material flow in the bend which increases the material build up in the bend. On the other hand, increased air flow velocity reduced the stagnation material inside the bend which will increase the wear in this critical wear area. Increased air mass flow rate also increases the impact on the 2nd critical wear area which increases the overall wear in the pipeline. With opimisation of the conveying parameters, it is possible to obtain a set of parameters which reduce the impacts on both the pipeline and the bend in order to reduce wear.

5 PARTICLES SEGREGATION

Particle segregation after the bends is a well known phenomenon in pneumatic conveying of particulate materials. Generally a particle jet is formed after the impact in the bend and reaccelerated towards the exit of the bend. In this process, smaller particles mostly follow a stream line with the air flow and larger particles form the particle jet. The particle jet forms a dense core which contains the majority of the material and mostly flows along the pipe wall until being evenly distributed across the pipe cross section further downstream of the bend.

The important aspect of the dense core flow is the associated loading condition that occurs on the pipe wall. The expected surface loading condition (Figure 6) in critical wear area 2 is also an important factor in understanding the severe nature of the wear in this area. This is because as the dense core of bulk material impacts on the pipe surface immediately after the bend, a close packing of the particles generally occurs in the contact area. Although the impacts are within the elastic range, due to the continuous nature of the material flow, the surface does not have enough time to recover from its previous impacts. As a result the surface will accumulate plastic deformation within the individual elastic impacts and cause the surface to work hardened. As the surface is continuously subjected to the impact of the particles as well as sliding of the bulk material, the wear behaviour can be described as impact sliding due to the impact wear superimposed by the sliding. The surface loading and pressure profile in the critical area can be schematically represented as shown in Figure 6.





a) b)

Figure 6. Schematic representation of a) particle loading and surface deformation and b) pressure profile due to bulk material on the internal pipe wall.

The thickness of the work hardened surface layer due to impact sliding depends on the particle size and shape, as well as the pressure fluctuation in the contact area. Work hardening reduces cutting and deformation wear rate but due to the inclusion of alumina into the pipe material from the sliding wear process a transfer film is generated on the surface. The transfer film is characterised by a hardened brittle layer with the effect on the wear characteristics recently discussed detailed in a journal paper [4]. The complex stress cycles in sliding abrasion and impact sliding result in significant alterations of the surface and the subsurface. The changes in material properties in the subsurface layer govern the wear behaviour in the critical wear areas of the pneumatic conveying pipeline. This sub-surface modification of the material was presented by Glardin and Finnie [5] as shown schematically in Figure 7. The fragmented (or transfer) layer (FL) plays a crucial role in the material removal in this region. The transfer layer consists of ultrafine crystallites of the surface material as well as materials from the conveyed bulk material. Once the layer is formed and subjected to rolling fatigue, it is removed through sub surface delamination and cracking.

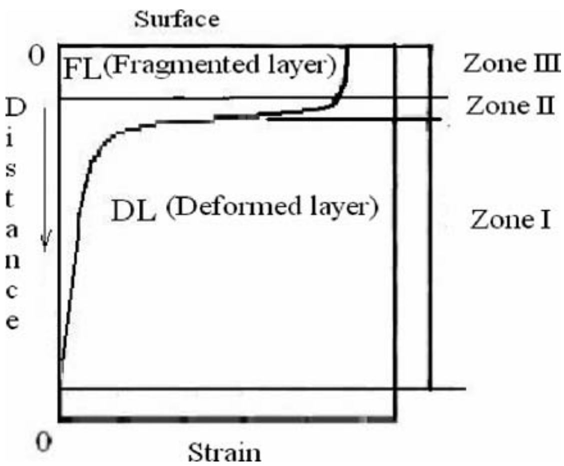


Figure 7. Schematic diagram of the strain distribution below the wear surface and regions defined as 'deformed layer' (DL) and 'fragment layer' (FL).

Particle rolling and sliding has a serious effect on the transfer layer formed on the wear surface. Due to the repeated loading and unloading cycles as a result of the particles rolling, the hardened surface delaminates from the substrate. The particles rolling and sliding conditions can be explained by considering the surface friction and the bulk material internal friction as described in Figure 8 [6]. If the surface friction is higher than the internal friction of the fluidized bulk material, as the case in pneumatic conveying, particle rolling is expected in the critical areas of the pipeline. Fluctuation of pressure and the material flow causes the micro cracks to appear on the delaminated surface layer which is removed through spalling. It is believed that this is the most severe of the material removal mechanisms in the critical wear areas in the pipelines after the bends.

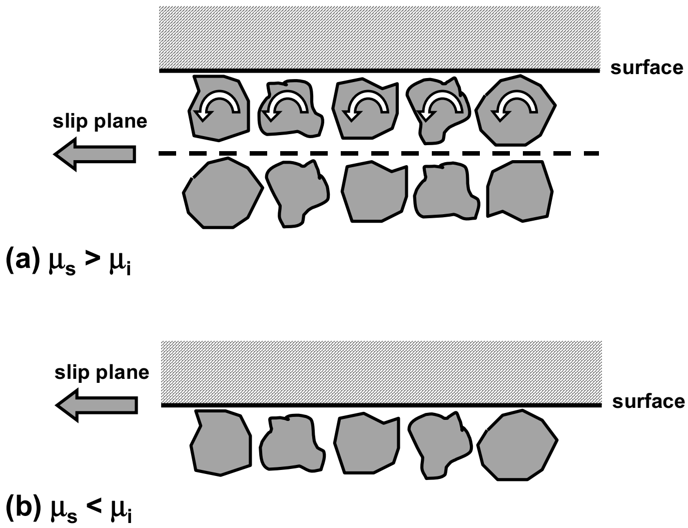

Figure 8. Particle rolling and sliding conditions based on the internal friction (μ_i) and surface friction (μ_s) [6].

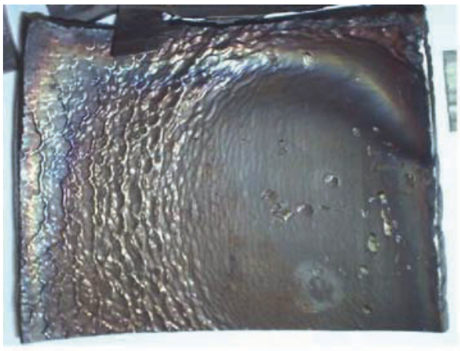
6 WEAR MECHANISMS IN INDUSTRIAL PIPELINES

In this section the severe wear areas from an industrial pipeline are discussed and compared with the flow profiles from the visualization test rig. Wear patterns on the samples agreed well with the flow patterns observed during the visualization studies. The locations of the two critical wear areas on the pipeline were also confirmed by the flow analysis in the bends and the straight sections after the bends. Figure 9a and 9b show the bend sections from the dense phase industrial conveying pipeline. The smooth section (figure 9b) represents the area directly opposite to the material entry (stagnation area). The upper right corner of the sample shows a wear groove which represents the area where particles reaccelerate towards the exit of the bend. The wave pattern surrounding the smooth area represent the deformation of surface due to the bulk material movement as seen in the reverse flow during visualization tests. Both the stagnation area and the deformation reverse flow area suffer minimum wear loss from the surface.

Figure 9a shows sections from bends towards the end of the conveying pipeline. In this case, the bend was not protected from the inlet material jet. This is the case when the material does not build up in the bend either due to lower solid mass flow rate or the higher air velocity. In dense phase conveying, although the solid loading ratio remains constant for the whole length of the pipeline, the increase in the air velocity through the pipeline generally means that material does not build up in the bends located towards the end of the pipeline. As a result, the surface opposite to the inlet pipe is subjected to increasing amounts of erosive wear from the particle jet.

a)



b) c)

Figure 9: Critical wear areas as seen on the industrial pipeline and bend samples a) Bend section b) straight pipe section after the bend.

Figure 9c represents the pipe section after the bend showing the critical wear area after the bends. In this case the critical wear area is away from the bend compared to the critical wear area immediately after the bend represented by the patching of the pipe (critical area 2). Figure 9c also shows the spiral nature of the material flow after the bend.

Wear surfaces from the critical wear areas have been studied to investigate the dominant wear mechanisms responsible for material removal in these areas. Detailed study of the wear mechanisms can be found in [5]. One of the very unique characteristics of the wear surfaces observed in this study is the surface cracking and generation of crack network on the wear surface. These features are seen primarily along the bottom of the wear grooves in the severe wear areas in the straight section of pipeline after the bends. Figure 10 shows such a crack network seen on the wear surface.

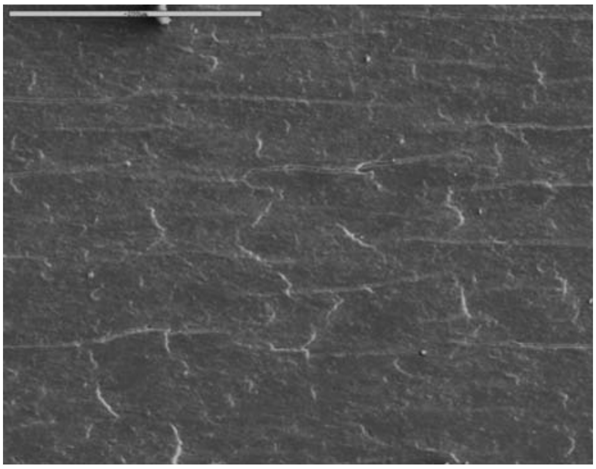


Figure 10. Formation of lateral and longitudinal cracks (material flow from left to right, length bar = 200 μm) [5].

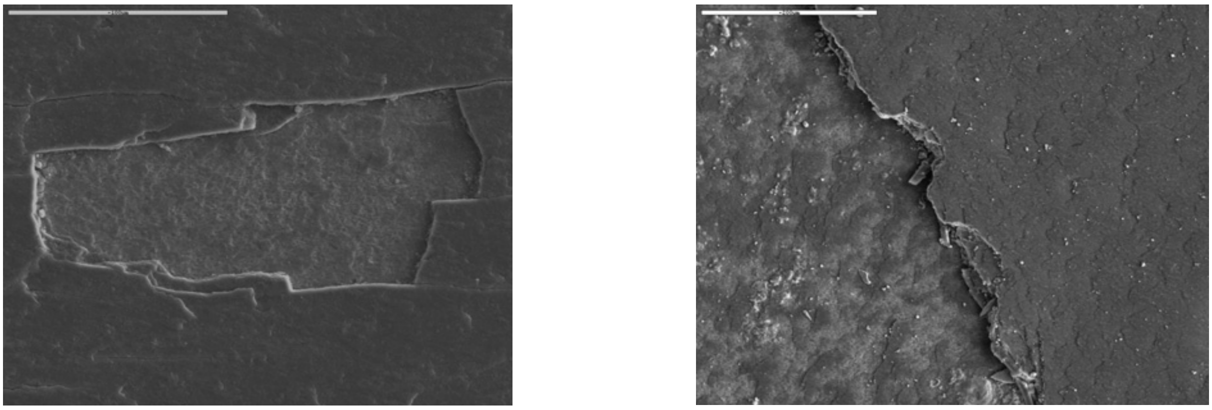
Although surface hardening due to abrasive and erosive wear have been investigated before, these cracking phenomena have not been mentioned in any earlier literature. With careful observation it was found that the cracks are generated preferentially surrounding the rippled structures. One of the possible causes of these cracks can be the surface hardening and the fluctuation of conveying pressure in the pipeline. The cutting and ploughing mechanisms together with the fluctuation of conveying pressure as well as the fluctuation of the rope structured (core flow) material flow causes the surface hardening. The fluctuating pressure may also create a hoop stress condition causing the longitudinal cracks on the surface. As the wall thickness is reduced, any pressure fluctuation in the pipeline can generate a significant amount of hoop stress fluctuation. The effectiveness of the hoop stress increases according to the following formula:

$$\sigma_h = \frac{pr}{t}$$

where σ_h is the hoop stress, p is the pressure inside the pipeline, r is the radius and t in the pipe wall thickness.

It is also possible that a transfer layer is formed on the wear surface which is harder and brittle compared to the substrate material. This transfer layer may also be responsible for the crack formations and material removal through delamination and spalling. Spalling occurs when abrasives flow over the delaminated surface and produce a shear traction force greater than the shear strength between the hardened delaminated layer and the ductile substrate.

Figure 11a shows the delamination characteristics of the surface layer where a cracked surface fragment has been removed. Once one of the surface segments is removed, the surrounding segments are removed relative ease with the new undamaged surface subsequently revealed. Figure 11b shows an area where both the new revealed and the hardened surface is evident from the fracture pattern of the layer. As the material is removed in large fragments, the rate of material removal at this stage is extremely high compared to cutting and deformation mechanisms.



a) b)

Figure 11. a) Formation of cracks around ripples and loss of surface fragment, length scale: 100 μm. b) formation of ripples after removal of the fragmented layer, length scale: 200 μm [4].

The behaviour of a hardened layer on top of a relatively softer substrate had been explained through the characteristics particular to a thin hard coating on a softer substrate. It was shown that if the hard coating is not sufficiently supported by the substrate, it will fail at relatively low contact stress because it can not follow the deformation of the substrate (so called eggshell effect) [7]. Although the hard layer tends to protect the softer substrate from cutting and deformation wear, it fails due to the delamination and subsequent cracking and chipping of the hard layer. Cyclic loading and unloading of the surface causes fracture or fatigue cracks, which ultimately destroys the harder surface layer [8]. Bell *et al* [9] demonstrated that under cyclic loading conditions, fatigue failure is initiated at the coating substrate interface (interfacial fatigue). The mechanism for delaminations and surface cracking was also supported by Jiang et al [10] in the case of hard coating.

From the observation of the industrial pipe wear sections together with the flow patterns from the visualization test rig, it became clear that there is a strong correlation between the conveying parameters and critical wear areas in the pneumatic conveying pipelines. By changing the conveying parameters, different flow patterns have been studied which has enhanced our understanding of the wear situations in the pneumatic conveying pipelines. Based on the visualization studies, and the conceptual model of wear in pneumatic conveying, a cyclic model of wear has been proposed which can predict and material removal rate for optimised process parameters and subsequently predict the remnant life of the pipeline.

7 PROPOSED MODELS FOR WEAR IN PNEUMATIC CONVEYING

With careful consideration of the flow structures in the bends and in the reacceleration zone of the pipeline, the critical wear areas have been defined. Although it is established knowledge that the primary wear mechanisms in pneumatic conveying is erosive (cutting and deformation) wear, work hardening and subsequent delamination and cracking of the surface layer plays a significant role in material removal process. Based on the understanding of the material removal process as supported by the wear mechanism studies from the conveying pipelines, a conceptual model for the wear process has been proposed [6]. The model can be described as follows:

- Step 1: Wear process begins on the ductile surface with impact-sliding: material is removed primarily by cutting and deformation.

- Step 2: Work hardening and transfer film formation of the pipe material takes place according to the particle-wall interaction process: at this stage material removal is restricted to the deformation wear giving rise to the surface hardening effects.

- Step 3: Surface delamination of work hardened surface: due to the surface loading and surface material interaction, subsurface damage accumulation occurs. No material is removed in this stage.

- Step 4: Lateral and longitudinal cracking: as the hardened layer is less supported due to delamination, cracks are initiated around the weak surrounding of the ripples that are formed during the cutting and deformation processes.

- Step 5: Removal of delaminated surface layer exposing the ductile surface underneath: material is removed at a higher rate to remove the layer of harder surface.

- Step 6: Cycle repeats to Step 1.

The reduction in pipeline wall thickness can be determined based on the reduction of wall thickness in three different stages, erosion, sliding and the removal of the hardened layer through crack propagation and spalling. The thickness of material removed during a cycle can be expressed as:

$$t = t_s + t_e + t_c$$

t_s = thickness reduction due to sliding

t_e = thickness reduction due to erosion

t_c = hardened layer thickness due to work hardening

These three events form a cycle in the wear process and *t* (total thickness reduced per cycle) can be associated with a frequency depending on the flow characteristics of the conveying system. Material removal through sliding and erosion can be determined by the established wear models based on mass flow rate, flow velocity and material parameters. The work hardening and transfer film thicknesses can be modelled by material characteristics and the contact process.

8 CONCLUSION

A visulisation test rig was designed for a better understanding of the flow characteristics in pneumatic conveying systems. Analysis of the flow characteristics in the bends as well as the reacceleration zone has been presented with respect in relation to severe wear characteristics of the pipeline. A technique for measurement of particle velocity in the reacceleration zone and impact angles in the critical wear areas has been developed and presented. Finally a technique for a predictive model of wear in the critical region based on a conceptual model for the wear process is also presented.

Possibility of optimisating the conveying process parameters to minimise wear in the critical wear areas has been demonstrated. Although in pneumatic conveying, the solid loading ratio (mass of solids to mass of air) remains constant for the entire length of the pipeline, wear behaviour changes through the pipeline due to the changes in pressure and the particle velocity at different points. As a result, the optimum operating condition at the beginning of the pipeline may be altered towards the end of the pipeline.

Abstract: This paper develops a new approach to stochastic modelling of asset renewal timing decisions using net present value derived from attributable revenue and total cost of ownership. This renewal decision model proposed has the advantage of aligning the efforts of asset custodians to the financial needs of the infrastructure management business. Secondly, we identify the option to perform Front End Engineering (FEE) as part of the asset renewal decision process and use the Black Scholes [1] call option formula to calculate the value of an option to perform FEE. The ratio of option value to option cost is suggested as a means of prioritising front end engineering for renewal projects.

Key Words: Asset renewal, Decision modelling, Real options

1 BACKGROUND

When considering the renewal of public infrastructure assets, we are faced with a unique and challenging scenario. The life of a typical asset is usually in excess of 30 years and sometimes more than 100 years. There is an expectation that the asset custodians will ensure the total cost of ownership of these assets is kept to a minimum whilst simultaneously ensuring agreed service standards are maintained and risks to health and safety and the environment are kept to acceptable levels. Yet this must be achieved against a backdrop of:

- Deterioration of asset reliability and maintainability
- Changing customer service level expectations
- Changing customer demographics and hence fluctuations in demand for service
- Decreasing levels of risk tolerance for public infrastructure owners, operators and their insurers
- Changing community expectations for environmental, financial and social sustainability
- A changing regulatory environment
- Constantly fluctuating levels of inflation and
- Relentless technological change.

It is generally commented that in developed countries aging infrastructure assets are entering the stage where large-scale renewal is imminent. Much of Australia's public infrastructure was built in the post war boom period that lasted from the 1950s through to the late 1970s. Since that time infrastructure development has slowed significantly and it is only in recent times that we are beginning to see an increase in infrastructure capital expenditure through innovative project funding methods. It stands to reason that if most of our infrastructure was built within a short space of time, the need for its renewal will fall due within a concentrated time span.

The peak Australian engineering body, Engineers Australia, has commissioned a series of "report cards" that rate the condition of public infrastructure both at a national level and for each of the states and territories. The summary reports provide a series of subjective grades and comments in a format similar to a school report card whilst the detailed reports discuss aspects of infrastructure condition, performance, governance and management. The American Society of Civil Engineers in the United States and the Institution of Civil Engineers in the UK compile similar reports. In general, these reports contain many references to deteriorating condition and performance of infrastructure assets and concern about the future trends.

It is common to see various forms of public infrastructure reach the point of impending failure before a renewal project commences. In fact, history provides many cases of the remedy being too late. Anecdotal evidence points to a widespread problem faced by infrastructure custodians:

It is difficult to justify a renewal project without the evidence to suggest it is needed but oftentimes by waiting for the evidence to emerge, the time available to plan, prepare and implement the optimal solution is insufficient.

The authors believe quantitative business cases are needed to support the infrastructure renewal projects necessary to build economic growth and competitiveness. This paper defines and demonstrates a new methodology and associated model for systematically building sound business cases for renewal decisions including a method for:

- determining optimal timing of asset renewal based on NPV calculations
- flagging those assets for which renewal is an unsound business proposition

- understanding the value of an option to commence front end engineering (FEE) of a renewal project
- deciding which renewal projects should commence FEE in preparation for possible implementation within the medium term.

2 RENEWAL DECISION MODELLING APPROACHES CURRENTLY AVAILABLE

Typically, the authors of asset renewal decision models have used a Total Cost of Ownership (TCO) calculation at the heart of the decision model. Few have used Net Present Value (NPV) or Internal Rate of Return (IRR) calculations perhaps because of the difficulty of assigning appropriate revenue quantities to assets. Woodhouse [2] suggests that an appropriate approach to asset renewal decision modelling is to maximize life cycle costs and minimise risk simultaneously. Our view is that revenue projections are fundamental to the asset renewal decision and assist asset custodians to understand how assets contribute to or detract from business profit targets.

Renewal decision models that use the prediction of TCO to guide the replacement decision usually include the definition and use of time dependent functions for operating costs, maintenance costs, life extending overhaul costs, replacement costs and salvage costs. Some also propose quantitative consideration of impacts on system users and/or customers and the inclusion of penalties or compensatory claims [3]. Both deterministic and stochastic approaches to decision modelling are seen in the literature. Whilst deterministic models are a useful first step in understanding the influences on a decision to renew, the authors believe that stochastic models are necessary to quantify uncertainty and that this assists the decision maker to justify feasibility studies and other preliminary steps which are necessary in building the case for asset renewal.

The effects of inflation are incorporated into many asset renewal decision models where discounted cash flow calculations are employed as part of a methodology to substantiate decision recommendations. Karsak and Tolga [4] have proposed the use of time dependent differential inflation rates, an approach that recognises some goods and services escalate much more rapidly than others. An appreciation of likely escalation rates and a methodology that enables accurate modelling of cost escalation over the long term certainly assists renewal decisions especially since time spans under consideration are often in the order of decades.

We could not locate any models that specifically incorporated the process view of renewal decisions namely feasibility analysis, front-end engineering, procurement, construction and commissioning as subsections of the asset renewal decision process. We believe that the clear identification of this process and the associated decision points for each stage of the renewal process is essential in building a realistic and flexible working model. For simplicity, we have divided the process into 2 stages – front end engineering and implementation.

We believe that the adequacy of any renewal decision model should be measured by its ability to appropriately deal with the uncertainties of:

- Cost escalation
- Equipment reliability
- Variations in revenue

and at the same time, incorporate flexibility to respond appropriately to these uncertainties at the optimum time. A decision model that considers revenue as well as costs and allows a flexible stepwise approach to renewal decisions is urgently needed.

Traditionally, asset renewal decision models have focussed on two alternatives, either completely replace an existing asset like for like or keep the asset "as is". Roll and Sachish [5] were among the first to consider a third alternative, namely to overhaul the existing asset. A sound asset renewal decision model should investigate both overhaul and replacement strategies against the decision to keep the asset "as is". In this paper, the term "renewal" is meant to encompass both replacement and overhaul possibilities.

3 THE NPV MODEL FOR ASSET RENEWAL DECISIONS

This section describes a proposed asset renewal decision model in detail. We have chosen to maximise the NPV of asset related revenues and costs over a long term period which extends past the design life of the asset. This has the advantage of aligning the decision of asset renewal timing with the financial needs of the infrastructure business.

3.1 General NPV model for use in asset renewal timing decisions

Maximum NPV is the decision objective. The decision variable is time. We have therefore developed a "renewal timing" dependent NPV function that can be used to maximise NPV. This involves calculating NPV for a range of possible renewal dates starting from one year in the future to a date well past the design life of the asset. The NPV for renewal in year R (NPV_R) is calculated as follows:

$$NPV_R = \sum_{i=1}^{R} \mathrm{Re}_i + \sum_{i=R+1}^{N} Rn_i - \sum_{i=1}^{R}(OCe_i + MCe_i) - \sum_{i=R+1}^{N}(OCn_i + MCn_i) - \sum_{i=1}^{R} pe_i CCe_i - \sum_{i=R=1}^{N} pn_i CCn_i - RC \quad (1)$$

where Re is the present value of revenue attributable to the existing asset, Rn is the present value of revenue attributable to the new asset, OCe is the present value of operating costs for the existing asset, MCe is the present value of maintenance costs for the existing asset, OCn is the present value of operating costs for the new asset, MCn is the present value of maintenance costs for the new asset, CCe represents the present value of consequential costs associated with malfunction or failure of the existing asset whilst pe is the associated probability CCn represents the present value of consequential costs associated with malfunction or failure of the existing asset whilst pn is the associated probability and RC is the present value of the renewal capital cost. The value R represents the number of years into the future that renewal takes place (the decision variable) and N represents the number of years into the future that we sum costs. As mentioned previously, this should be well past the original design life as it is often true that an asset is required in service well past its design life.

By calculating NPV_R for each year successively, we can easily determine the maximum NPV and the year R in which this occurs. For cases where no maximum is apparent, revenue may be either decreasing with time (indicating the optimum time for renewal has already passed) or increasing with time (indicating optimal renewal timing is beyond the selected value of N)

3.2 Differential Inflation

Each value in equation (2) is defined in such a way as to take into account differential inflation of goods and services over the forecast review period as proposed originally by Karsak and Tolga [4]. This approach takes into account the fact that different goods and services may escalate at different rates.

Using differential inflation modelling, it is possible to build an accurate forecasting model for each of the time dependent cost components of NPV. In each case it is advisable to separate labour and materials components and use historical data as a guide to predicting future escalation.

3.3 Revenue

The revenue calculation should use an applicable model for calculating "attributable revenue" and differential inflation modelling. "Attributable revenue" is that revenue which can be attributed to a single asset within a system of assets. Whilst it is difficult to propose a general attributable revenue calculation model for all types of public infrastructure, the following aspects should be noted:

It is common for revenue to be broken into two components:

1. An allocation charge – a charge levied for the right to use a certain portion of the service or facilities on offer. As an example, the telephone line rental charge fits into this category.
2. A usage charge – a charge levied for the actual quantity used by the customer. The charges per telephone call or per call duration is an example of a usage charge.

Attributable revenue (as a percentage of total system revenue) can be assigned according to asset usage, throughput, throughput capacity and other asset specific variables.

The attributable revenue model must take account of predicted changes to the customer base both in number and usage patterns with respect to time. The allowable escalation in charges sanctioned by the regulator is an important piece of information that will allow us to predict likely changes in revenue with respect to time. Changes in attributable revenue can also occur when the asset is renewed especially when upgrades or downgrades are being modelled.

We have not included a general model for attributable revenue in this paper since the approach used would necessarily vary between different organisations and business sectors.

3.4 Operating and Maintenance Costs

Maintenance costs should include separate estimates for equipment servicing (such as cleaning, flushing, lubricating, tightening of fasteners and replacement of filter elements), condition monitoring activities (such as the monitoring and analysis of vibration, oil samples, temperatures, thermographic and ultrasonic images, and a range of process variables), preventive maintenance activities or the planned replacement / repair of components, corrective maintenance activities including any action required to return the asset to a state in which it is able to perform its intended function. The use of Weibull functions to model individual failure modes and reliability block diagrams to model asset reliability is recommended. The calculated value for maintenance costs must take into account the different reliability predictions for both the existing asset and the new (or overhauled) asset.

Operating costs should include operating labour, power consumption and a consumables charge for each asset considered. The operating labour is likely to be shared amongst many assets rather than just one; therefore, when modelling operating costs, one should consider the method of distributing labour costs across those assets. The power consumption is directly linked to asset usage. Once again, the calculated value for operating costs must take into account the different power consumption and operating labour predictions for both the existing asset and the new (or overhauled) asset.

3.5 Cost of Consequential Impacts on Stakeholders

Asset failures or malfunctions may have significant impacts on a variety of stakeholders such as employees, customers, the community or the environment. Whilst the probability of such events may be quite small, they may be significant to the decision to renew an asset. We recommend estimating these potential costs and their associated probabilities in all cases and to consider any inherent difference between the old and new (or overhauled) asset.

3.6 Renewal Capital Costs

Estimates for renewal capital costs must include all stages of the project from feasibility and front end engineering through to decommissioning. The capital cost estimate accuracy will depend on the estimating method used. The most accurate method is generally achieved by first compiling a bill of quantities based on a fully detailed design that covers geotechnical, civil, structural, mechanical, electrical, instruments and environmental requirements as indicated by the project scope. The next step is to conduct tender enquiries for the supply of all goods and services required to complete the project. The level of accuracy achieved by following this method is usually better than ± 10%. A less accurate method is to use gross factor analysis and scaling based on similar completed projects for which accurate records are available. The accuracy of this approach is usually in the order of ± 20 to 25%.

Once the estimate has been compiled, the NPV of capital costs for different possible renewal times can be estimated by applying discounted cash flow principles over the appropriate time span. The appropriate discounting rate should be applied to each cost component separately – in line with the previously stated principle of differential inflation.

3.7 Decision criteria other than financial

Decision criteria other than financial may be influential to the decision to renew an asset. Apart from financial, the main decision criteria for infrastructure renewal usually relate to service delivery. If an asset is no longer able to provide service as specified in the Service Level Agreement (SLA) with customers, renewal of the asset must be considered. The types of performance measures used within SLAs include number of service interruptions per annum and duration of service interruptions. Any performance measures with associated targets that are included in SLAs should automatically be used as decision criteria. Whilst these criteria are important to the renewal decision, we do not consider them in detail in this paper but merely recommend that they should be considered alongside the financial decision criteria.

4 STOCHASTIC MODELLING OF THE NPV DECISION AND RENEWAL PROJECT OPTIONS

The deterministic NPV decision model shown in equation (1) is suitable for making estimations about the optimal timing of asset renewals in the short term; however, it does not take into account the volatility of costs and revenues that will occur over time. We recommend stochastic modelling to gain understanding of the magnitude of NPV volatility and real options analysis to determine the value of the front end engineering option.

4.1 Why Stochastic Modelling?

When we have flexibility in the timing and commitment level of our decisions, uncertainty can be a good thing. Stochastic modelling is used to quantify the uncertainty of the renewal project NPV. This uncertainty represents opportunity that is not taken into account with the deterministic NPV calculations.

Flexibility for asset renewal projects comes in the form of options. An option is defined as the right (but not the obligation) to acquire an asset at some future point at a known price. Options in an uncertain environment are valuable. There are methods available for assigning a value to each option. The stepwise nature of the renewal decision process gives the following options:

- Carry out renewal project feasibility study then either: (a) wait for optimal timing to do the rest or (b) abandon the renewal project
- Carry out feasibility study and front end engineering then either: (a) wait for optimal timing to do the rest or (b) abandon the renewal project
- Carry out the entire project now.

4.2 Real Options Analysis

In 1973 Black and Scholes [1] published a seminal paper on a method to price financial options. The Black-Scholes option pricing model was incorporated into a programmable Texas Instruments calculator soon afterwards and it was found that the derivative traders on the floor of the New York stock exchange with access to this pricing methodology via the TI calculator were doing better in their trades than those without.

The model uses six variables to calculate the price of an option using a closed form equation. The variables used in the calculation are:

- The stock price
- The exercise price converting an option to a share
- The dividend yield for the stock
- The volatility of the share price (measured as the standard deviation per annum)
- The time to option expiry
- The risk free interest rate

In subsequent years, a number of management consultants were responsible for applying the Black-Scholes and other financial option pricing models to decisions of many different types. The result was the birth of a new field of endeavour known as Real Options Analysis (ROA). The essence of this new field is summed up in the similarity drawn between financial and real options by Leslie and Michaels [6] shown below:

The six levers of financial and real options	
Financial Option Value Levers	**Real Option Value Levers**
Time to expiry	Time to expiry (T)
Volatility in stock price movements	Volatility in expected cash flows (σ)
Stock price	Present value of expected cash flows (NPV)
Dividends	Value lost over duration of option (nil)
Risk-free interest rate	Risk-free interest rate (rf)
Exercise price	Present value of fixed costs (X)

Figure 1: Analogy between financial and real options

4.3 Calculating the value of an option to carry out FEE

There is often value in doing the FEE of a renewal project early. The upside is that the optimal timing for the renewal project may be earlier than expected in which case the engineering is already done and the renewal can go ahead without delay. The downside risk is that the asset may no longer be needed due to changes in services demand and the engineering for renewal has been done (but this is better than fully completing the renewal and finding out it is redundant).

The value of the option to do FEE is analogous to the value of an American call option for a stock.

The steps in calculating the value of an option to do the FEE are:

1. Estimating the volatility of NPV which is done by:
    a) Collecting relevant data for determining renewal NPV
    b) Calculating revenue and cost components using data collected and then calculate NPV deterministically
    c) Determining the likely range for each variable
    d) Carrying out the sensitivity analysis
    e) For those inputs that contribute significantly to the variation of NPV, determining the distribution type and estimating the likely standard deviation
    f) Determining the likely correlation between input variables
    g) Running a Monte Carlo simulation of renewal project NPV

2 Determining the value of the option to do FEE using the following formula. Refer to figure 1 for an explanation of the variables. Note that Φ is the cumulative standard normal distribution function.

$$Call = NPV_t \Phi(d_1) - Xe^{-rfT}\Phi(d_2) \qquad (2)$$

where $d_1 = \dfrac{\ln(NPV / X) + (rf + \sigma^2 / 2)T}{\sigma\sqrt{T}}$

and $d_2 = d_1 - \sigma\sqrt{T}$

Once the FEE option value has been determined:

3 Compare the cost of FEE with the option value

4 Compare the option value / FEE cost ratio with other projects to help determine priority. Note, additional ways of determining priority may be employed – leading to a combined prioritising system.
5 Decide which projects to carry out FEE using the combined priority.
6 Carry out FEE for those projects that have the highest priority
7 Review options again at a later time and change priorities if necessary

5 APPLICATION TO A WATER DISTRIBUTION SCHEME

Application of the proposed model is briefly presented in this section. Our example is the pipelines for a water distribution scheme installed mainly in the 1960s and 1970s. The scheme consists of approximately 210 kilometers of pipelines which are mainly reinforced concrete (RC). The number of pipeline failures has been increasing in recent years and it has been found that one specific failure mode is dominant, namely joint failure. The asset custodians are currently considering their asset renewal alternatives.

Whilst preventive clamping of joints (an overhaul option) could be used as a means of life extension for the existing RC pipes, this is an expensive option. Technological advancements in pipelines since the 1960s has given rise to a new pipe material, High Density Polyethylene (HDPE) which has several advantages over the original RC pipelines. The cost of manufacture and installation of HDPE pipe is much less than RC pipe and the long-term reliability is likely to be higher than RC. This is the most cost effective renewal alternative but it requires significant engineering input.

The management is concerned at the cost of carrying out pipeline renewals too early; yet leaving renewal too late could result in high maintenance costs and too many service interruptions. There is a significant probability that some of the pipeline assets in this scheme may become redundant due to falling demand. Many farmers in the scheme are selling their land and the crop mix is changing. Some new crops have a much lower requirement for water. It could be a poor decision to renew a pipeline servicing a declining area. A better solution may be to enter into negotiations with landowners about terminating the supply of water and offering some form of compensation.

5.1 Input Data

The following important input data for the decision model was used:

Revenue related data requirements

- Water allocation charge to customers
- Water usage charge to customers
- Water allocation (for asset system)
- Water usage (for asset system)
- Attributable revenue for asset (% of total revenue for system)
- Revenue escalation rate

Operating cost related data requirements

- Operating hours
- Operating labour cost
- Power usage
- Power charge
- Operating consumables cost per annum

Maintenance cost related data requirements

- Failure prediction data of existing asset (for failure mode 1 – wearout and failure mode 2 – random)
    - Weibull shape parameter
    - Characteristic life
    - Failure free period
    - Failure mode 1 as a percentage of all failures (assumed at 100%)
    - Failure mode 2 as a percentage of all failures (assumed at 0%)
- Failure prediction data for new asset (HDPE pipe) – as listed above
- Total number of asset components subjected to potential failure – existing asset
- Total number of asset components subjected to potential failure – new asset
- Cost of corrective maintenance per instance – existing asset
- Cost of corrective maintenance per instance – new asset
- Percentage of labour cost to total cost for corrective maintenance – existing asset
- Percentage of labour cost to total cost for corrective maintenance – new asset

Consequential cost related data requirements

- Probability of consequential costs – existing asset
- Probability of consequential costs – new asset
- Consequential costs per event – existing asset

- Consequential costs per event – new asset

Renewal capital cost related data requirements

- Renewal capital costs
- Decommissioning cost for existing asset
- Percentage of labour cost to total cost for renewal capital cost and decommissioning cost

Financial data

- Consumer price index
- Materials differential inflation rate
- Labour differential inflation rate

Service level data

- Percent of failures resulting in service interruption

Note that all labour costs are inclusive of management and administrative overheads

Some assumptions made were as follows:

- Only one dominant mode of failure (failure mode 1)
- Weibull failure distribution was assumed as the best fit
- Historical failure distribution is representative of future failure distributions
- Failure mode A2 (random failures) considered to be insignificant
- All repairs are "as good as new"
- CPI data from the last 20 years is representative of future data

5.2 Results

The NPV model was used to calculate deterministic NPVs for a range of possible renewal dates each of which were one year apart. The results are shown in figure 2 below. A discussion of the results follows.

The top left hand graph of figure 2 shows zero failures until the end of the expected failure free life after which failures rise steeply. This corresponds to an increase in the peak number of service interruptions per annum (shown at bottom left and an increase in maintenance costs (shown at bottom right). The increase in maintenance costs is the main reason for decreasing NPV (shown at top right).

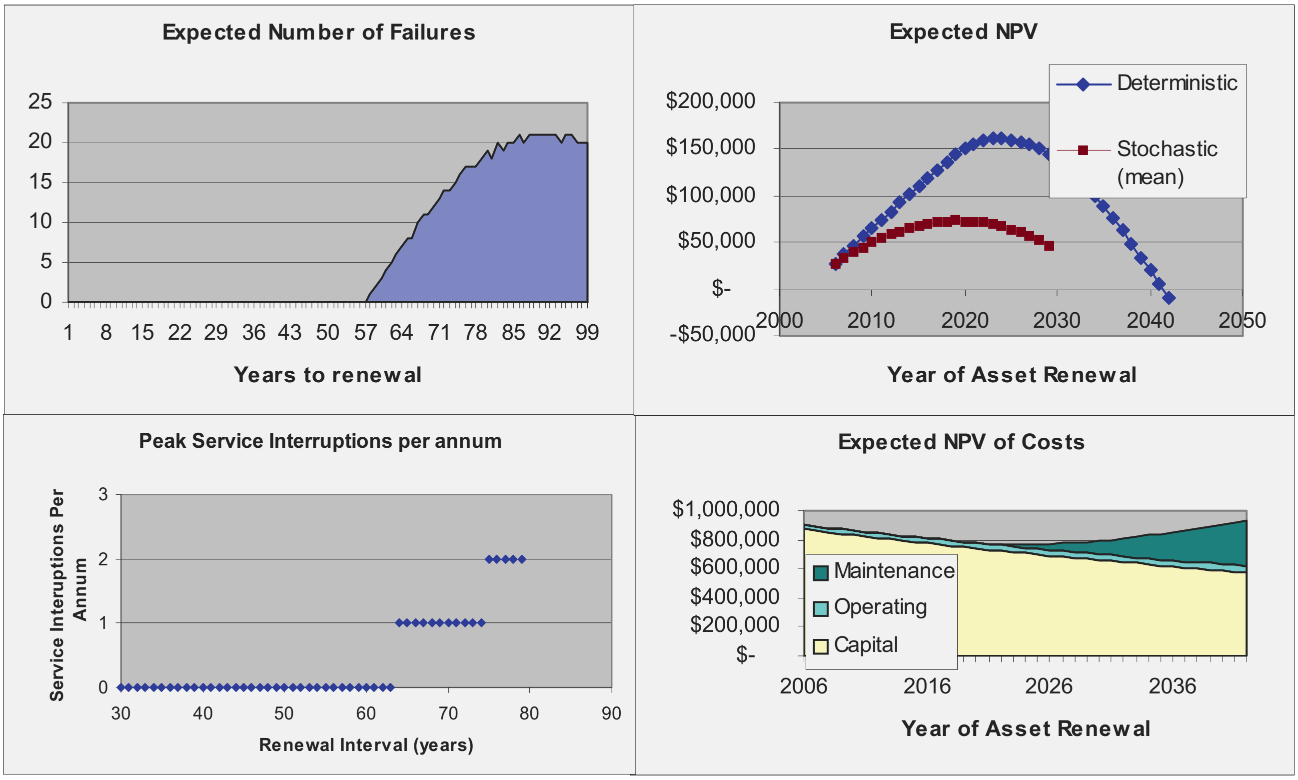

Figure 2: Graphical representation of modelling outputs

Number of service interruptions (SI) is a key measure in the SLA and, as such, is also a key criterion for renewal decisions. If the number of SIs per annum were to rise above 3 for this asset, there is a small probability that the terms of the SLA will be violated. The model predicts that the number of SIs does not rise above 2 and hence there is little likelihood that the SLA will be violated. For completeness, the expected peak number of SIs per annum as a function of the year of renewal is displayed on the bottom left quadrant of figure 2.

NPV peaks when the renewal is scheduled for 2024 (when we examine the deterministic case). When we consider the mean of the Monte Carlo simulation for NPV the optimum renewal date is 2018. This is due to the skewed NPV distribution resulting from the Monte Carlo simulation.

A sensitivity analysis was conducted next which revealed the most the most prolific contributors to variations in both optimal renewal timing and maximum NPV. Not surprisingly, the failure free period is the biggest contributor to variations in optimal renewal timing (figure 3) and it also featured reasonably high on the list of contributors to variations in maximum NPV (figure 4). Eight variables were selected as significant influencers (namely: revenue escalation, consumer price index, water allocation, renewal capital cost, failure distribution failure free period, materials differential inflation rate, labour differential inflation rate and water usage) and appropriate distributions were selected to represent their variation in each case. The correlation between consumer price index and revenue escalation was assumed to be strong positive and was set at 0.8 prior to running a Monte Carlo simulation of 10,000 trials.

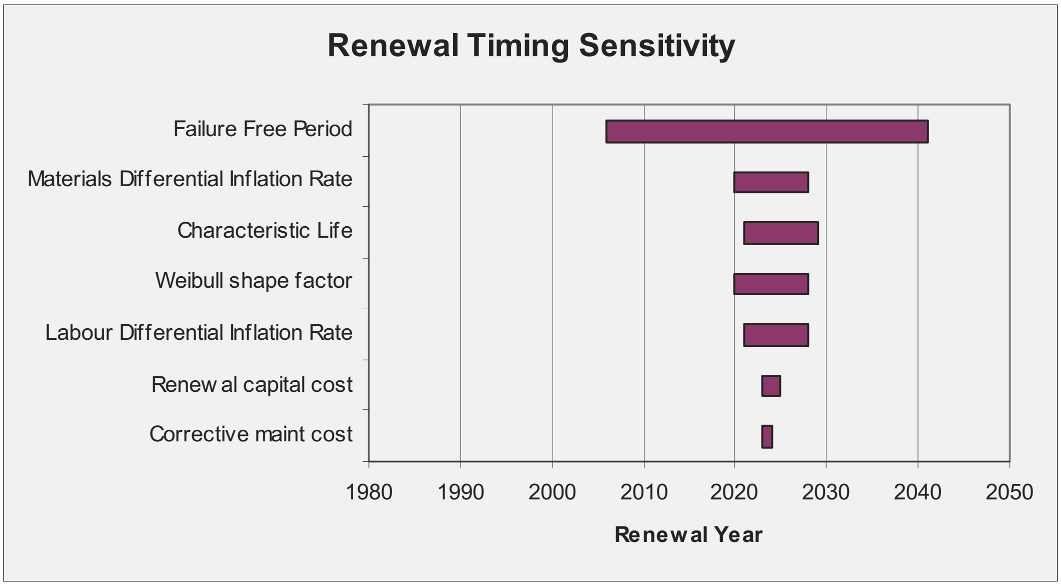

Figure 3: Optimal renewal timing sensitivity analysis results

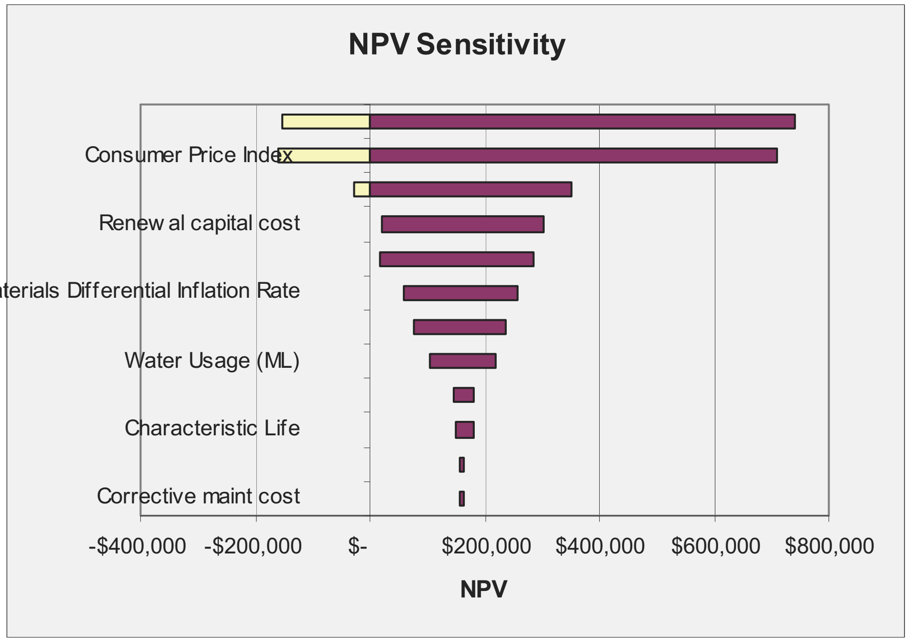

Figure 4: Maximum NPV sensitivity analysis results

The results of the Monte Carlo simulation for renewal in the optimal year (2018) are shown in figure 5. The chart shows that the probability of achieving a positive NPV result by performing the renewal in 2018 is better than 65%. However, the significant possibility of a negative NPV cannot be overlooked. Worse still is the 10% chance that the NPV will be worse than a loss of $205,000. Note that the mean value for the distribution is $74,470 which is significantly different from the deterministic base case figure of $135,629. This is a real example of the way in which a deterministic approach can be misleading.

The results of the Monte Carlo simulation can be used to calculate the NPV volatility. There are several methods. The NPV distribution can be used to calculate volatility, which, in turn, can be used to determine the value of a real option. Using the "Management Assumption" method proposed by Mun [7] the annualised volatility (σ) is given by:

$$\sigma = \frac{SD_{NPV}}{\overline{NPV}} \sqrt{T} \tag{3}$$

Where SD_{NPV} is the standard deviation of the NPV distribution $\overline{NPV}$ is the mean of the NPV distribution and T is the number of periods in one year. In this case T is 1/80 because the data has been summed over 80 years. The resultant NPV volatility is 32.9%.

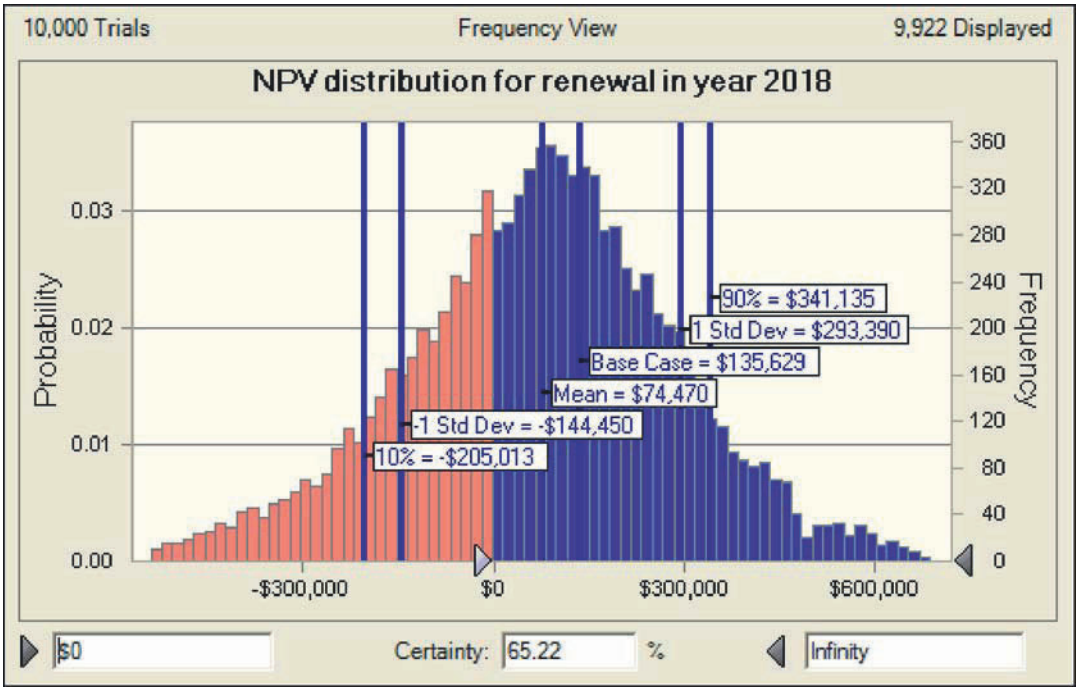

Figure 5: NPV distribution for renewal in year 2018 (optimal)

The Black Scholes equation (2) can now be used to calculate the value of the option to carry out FEE. Assuming that the life of a the engineering design (time to option expiry) is 15 years, the NPV is $74,470, the risk free interest rate is 5% and a present value of fixed costs of $826,453 which is the total renewal project cost less 5% for FEE. A FEE option value of $8,600 is derived. The cost of FEE is estimated at $43,498 hence the ratio of option value to FEE cost is 0.198.

6 ANALYSIS AND DISCUSSION

The NPV of this and other renewal projects can be used to gauge the viability of the project from a business standpoint. In our case, the NPV is likely to be positive at the optimal renewal timing. The mean NPV is a fairly small positive amount of $74,470. There is a reasonable chance that NPV could become negative with lessening demand for water, high inflation, an unexpected increase in capital costs or deteriorating reliability. The regular calculation of NPV for this and other renewal projects would enable the custodian to monitor the need to commence FEE.

Should the NPV predictions become negative, the asset manager should raise concerns with his or her colleagues and discuss the future viability of this asset and alternative approaches to renewal. One alternative could be to negotiate future revenue increases depending on the amount of leeway the regulator allows. Another approach may be to negotiate discontinuing service with the customer in exchange for some form of compensation. In any event, the custodian has a direct measure of financial viability of any proposed renewal projects and this will ultimately lead to sound financial motivation for decisions.

Should the FEE option value become higher than the cost of FEE, this would indicate that carrying out FEE is a sound proposition. There may be further gains in waiting extra time to implement renewal so it would be recommended to watch the NPV closely by monitoring the model inputs and performing regular calculations.

Considering that in our example, the option value is $8,600 as opposed to the cost of FEE being $43,498 (a ratio of 0.198). At this point, there doesn't seem to be much value in performing FEE. It would be better to wait several years when the option value is likely to be much higher. In any case, the FEE option value to cost ratio could be a useful method for prioritising FEE for renewal projects.

7 CONCLUSIONS AND FURTHER RESEARCH

The authors have argued the case for using NPV calculations for supporting asset renewal decisions as opposed to the commonly used Life Cycle Cost or Total Cost of Ownership methodology. The authors strongly believe in using a decision model that helps asset custodians to understand how assets directly contribute to or detract from business profit targets over an extended period. Using a decision model with NPV derived from attributable revenue less costs as the core calculation is one way of achieving this.

The authors have used a case study to illustrate NPV based decision models and the information that can be derived from them. Using the deterministic NPV model the case study examined shows a positive NPV of $135,629 when renewal is scheduled for optimal timing in year 2024. By using the stochastic NPV model, we see that renewal is optimal in the year 2018 and is still cash flow positive ($74,470) but is not as lucrative a proposition as the deterministic calculations would indicate.

The stochastic NPV analysis also indicates a significant probability (almost 35%) of the optimally timed renewal project resulting in a negative NPV with a 10% chance that NPV is worse than $205,000 in the red. The deterministic analysis does not reveal any information about this possible loss scenario. The case study therefore reveals one example where it could be dangerous to rely on deterministic modelling to decide the financial viability and optimal timing of asset renewal.

Noting that significant volatility in revenue and costs is a characteristic of our case study, we introduced the notion that the renewal project may be best tackled in stages. We nominated stage one as FEE (the FEE option) and noted the advantage of performing early FEE was greater surety of information and the ability to act swiftly on changes in project fundamentals. The downside was seen to be limited to the cost of FEE which is only a small proportion of the total cost of renewal. The Black Scholes equation was used to calculate a value for the FEE option ($8,600). This was compared with the estimated FEE cost of $43,498 and our conclusion was that it was not worth spending money to do FEE at this stage.

The authors therefore conclude more generally that:

- NPV renewal decision modelling is a useful approach in that it focuses asset custodians to serving the financial needs of the infrastructure management business.
- Our case study shows that whilst the deterministic NPV model can be used to obtain approximate timing for optimal renewal, it provides no information about downside risk and is therefore recommended as a guide only.
- Stochastic NPV modelling can be used to reveal the risk of a loss scenario. In our case 35% probability of loss if the asset is renewed at the optimal timing.
- The FEE option to cost ratio is one measure that could indicate those renewal projects for which FEE is justified. A ratio above 1 indicates good value for money. Note that there are other ways of justifying renewal projects, for example on the basis of likely violation of service level agreement.

The authors believe that there is scope for applying stochastic NPV and ROA methods to asset management decisions other than renewal timing.

COMMON PITFALLS WITH SAP™-BASED PLANT MAINTENANCE SYSTEMS

Leonie Gouws & Johan Gouws

Melikon Pty Ltd (www.melikon.com), Perth, Western Australia

Abstract: This paper discusses some of the most common pitfalls which had been encountered by the authors, over more than ten years, with SAP-based plant maintenance systems. The experience is drawn from maintenance engineering consulting for a variety of companies where the SAP Plant Maintenance module is used as the integrated computerised maintenance management system. The companies span the defence-, oil and gas-, mining-, and manufacturing industries in Australia and South Africa. The aims of this paper are to identify five of the most commonly encountered problem areas with the SAP Plant Maintenance system; discuss the main effects of these problems on the management of the maintenance process; propose some remedies to improve the effectiveness and efficiency of maintenance relying on the SAP PM module; and identify potential problems to look out for when implementing the proposed remedies. Although this paper is not the *silver bullet* to slay all SAP PM related problems, it will assist maintenance managers and reliability engineers to better understand how and why things can go wrong with their SAP PM systems, and where to look for solutions to alleviate these problems.

Keywords: SAP PM, Plant Maintenance, Computerised Maintenance Management System (CMMS)

1 INTRODUCTION

As part of consulting work in maintenance management optimisation, the authors had been involved in the implementation, use, review and upgrading of the SAP PM module for various companies in the defence-, oil and gas-, mining-, and manufacturing industries in Australia and South Africa, for more than 10 years. During this time, the following were identified as five of the most common areas in which problems develop which hamper effective and efficient use of the SAP PM system:

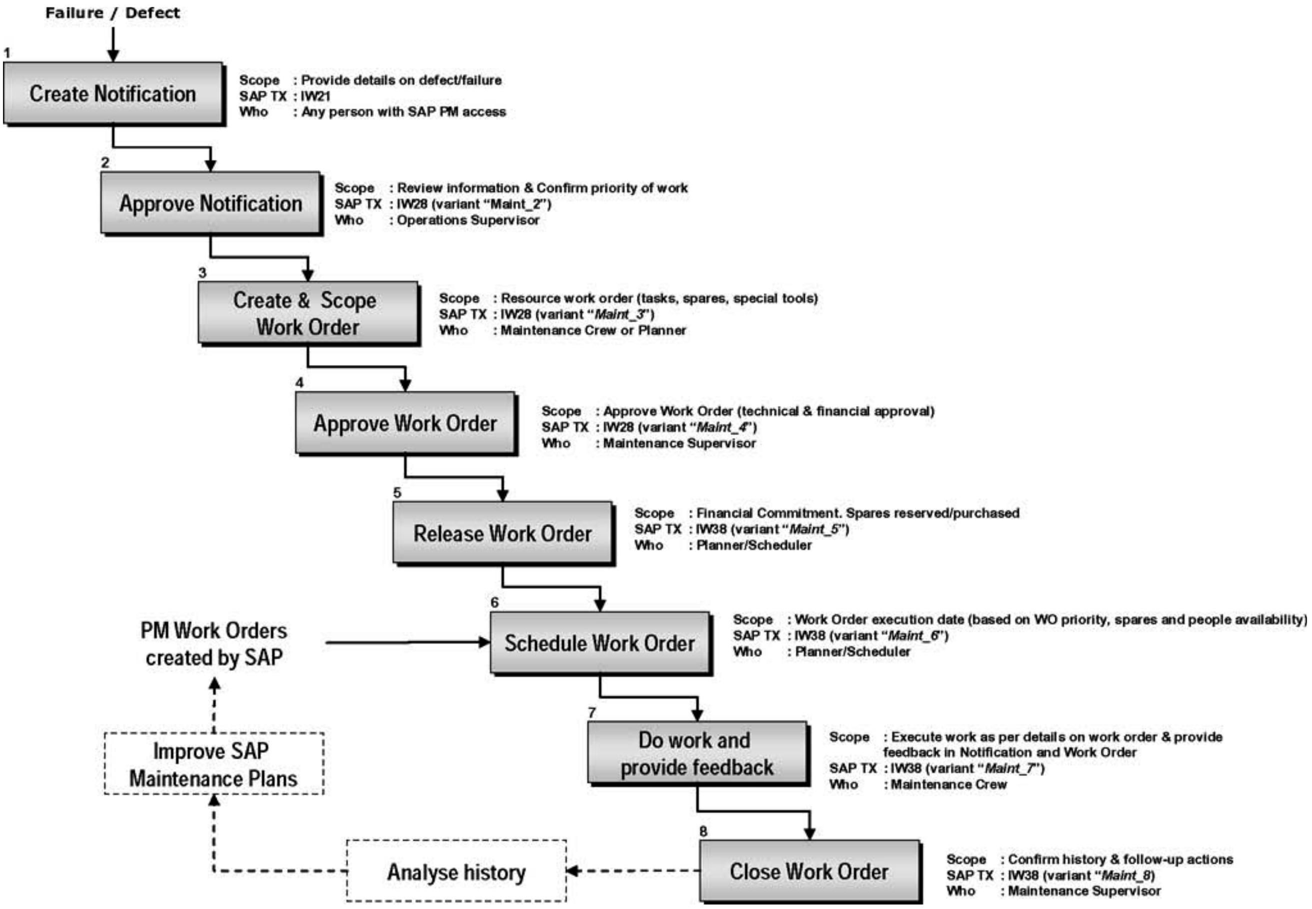
- Maintenance Work Flow Processes;
- Work Centre Structures;
- Work Prioritisation;
- Damage and Cause Codes;
- Master Data Maintenance.

The main issues to look out for in each of these areas are discussed in this paper, as well as some remedies to improve maintenance management based on the SAP PM module. Potential problems to look out for when implementing the proposed remedies are also pointed out. This paper is not intended as a *cure-all* or a *silver bullet* to slay all SAP PM related problems, but it is intended to assist maintenance managers and reliability engineers to better understand how and why things can go wrong with their SAP PM systems, and where to start looking for solutions to alleviate these problems.

2 SAP PM PROBLEM AREAS

2.1 Maintenance Work Flow Process

The Maintenance Work Flow Process (ref [1]) is normally presented as an activity-based mapping, using block diagrams to define the activities involved from identifying a requirement for maintenance to execution of the maintenance activity and close-out of the job. For the Maintenance Work Flow Process to be utilised as an effective communication tool, it should contain sufficient information to define the activities in terms of *what is required*, *who is responsible for executing the activity*, *when the activity is required*, and *how to execute the activity* in the computerised maintenance management system (CMMS). When initially developing the Maintenance Work Flow Process, it should be determined what value the activity will add, how long it should take to execute, how it will interface with other processes, and what risks will likely be associated with the activity. Figure 1 illustrates a typical Maintenance Work Flow Process containing this basic information.



(Source: Author)

The following are common mistakes made during the composition of Maintenance Work Flow Processes:

- Maintenance Work Flow Processes too complex. Many companies use the business processes developed during the implementation of SAP PM, as training tools, but these processes are normally too detailed and complex for training purposes. One case was encountered where a company used a work flow process containing 75 activities, to explain responsibilities to their new SAP PM users. With such a complex business process, the users become confused and frustrated, and invariably they then consider SAP PM as "*user-unfriendly*" and "*difficult to use*". Once such negativity has taken hold, it is very difficult to overcome. Therefore, it is important that maintenance work flow processes should be kept simple. Processes containing more than ten activities are often not well received by end-users.

- Maintenance Work Flow Processes not used during pre go-live training. Sometimes end-user training material is developed separately from the Maintenance Work Flow Processes. This can introduce a lot of confusion and resistance against the new SAP PM module, because there is no clear link between the training material and the Maintenance Work Flow Process. After go-live, users in an attempt to link their SAP PM training material with the work flow end up paging from one training exercise to another, adapting rules on the run. Also, without the Maintenance Work Flow Processes which indicate individual responsibilities, end-users find it difficult to identify what sections of the training are applicable to them. The most efficient training material is mapped to, and details individual steps in the Maintenance Work Flow Process. There is thus a clear link between the training exercises ("how") and the Maintenance Work Flow Processes ("what and who"). The relevant training exercise should also be indicated clearly on the work flow process. Many companies use the term "Quick Reference Guides" (QRGs) and use that in the numbering of the training exercises (e.g. QRG_Maint_1 "Create Notification"). By frequently referring to the relevant QRGs during training, users get familiar with how and where to find the relevant instructions again in their training manuals, later on.

- Insufficient SAP variants to support Maintenance Work Flow Processes. End-users are often expected to develop their own SAP variants (online operational reports using SAP's list editing capabilities) to identify notifications and work orders in the different parts of the work flow process. However, this practise is not advisable for the following reasons: (i) Most new SAP users find SAP's online report development feature difficult to use. (ii) New users do not have the detailed understanding of how the notification and work order system and user status codes change throughout the work flow process; and this knowledge is essential in the development of variants that will contain the correct work orders and notification in the listings. (iii) It is essential for all users to have the same layout of the report. This includes the sorting sequence of the notifications and work orders from highest importance to lowest importance, and the columns provided in the report. (iv) Any changes to the work flow process after go-live, such as the introduction of a new approval step, can be managed with ease if there are only a few generic reports to update. The users will not even be aware of the changes, which will enhance their perception that the system or processes are stable. (v) There should be a clear link between the Maintenance Work Flow Process, the QRGs and the variants, by selecting appropriate standardised names for the variants and ORGs.

It is thus unwise - and might even be a dangerous practise - to require users to develop their own reports in SAP. It is considered essential for the safe and effective management of the maintenance work to provide the users with generic SAP variants and generic layouts for each activity in the work flow process - and to provide the users with the opportunity to run these variants during training.

Insufficient decision gates. There should be a number of technical and financial decision gates in a Maintenance Work Flow Process. The technical gates provide the opportunity to ensure that the work order or notification contains the correct information; while financial gates provide the opportunity to ensure that there are sufficient funds available to do the specified maintenance. The following are gates that can be designed into the Maintenance Work Flow Process:

- Approving the notification – where a supervisor agrees that the maintenance is required, that the priority of the job is correct, that the correct functional location has been selected, and that the notification contains sufficient details to ensure that the notification can be processed further without continuous requests for information from the creator of the notification.
- Approving the work order – where a supervisor reviews the fully scoped work order to ensure that the work order contains the correct labour, spares, special tools, documentation, etc. Apart from ensuring that the scope is acceptable, there is also the opportunity to approve the financial commitment.
- Releasing the work order – this activity initiates the process of obtaining the resources as specified on the work order (i.e. spares, labour, special tools, etc.) on the right date as specified on the work order. The planner/scheduler is normally the person releasing the work order as he/she can then control when the spares are reserved or the purchasing process will start.
- Technical closure of the work order – which implies that the job had been executed as specified in the work order, that all the history had been completed and that all follow-up work had been identified. This is normally done as a final check by the maintenance supervisor.

In many organisations, the maintenance crew are the only people involved from the creation of the notification (activity 1 in Figure 1) to closure of the work order (activity 8 in Figure 1). This can be an expensive and potentially dangerous practise, because in these cases, the operations- and the maintenance supervisors are not actively involved in the maintenance work flow process to confirm the priority of the jobs or the scope of the work. Delegating the actual maintenance tasks to the maintenance crew does not mean delegating the responsibility for decision-making too. To ensure effective decision-making regarding the work flow process, it is important to limit the number of decision gates; and to clearly allocate the responsibility for each decision gate to an authorised, well-trained decision maker.

- Vague guidelines on capturing maintenance history. Activity 7 of the work flow process in Figure 1 includes capturing of the maintenance history as part of the close-out process. The following information is normally required:
  - In coded format, “what was wrong”, “what caused it”, “to what section of the object was the damage limited” and “what was done to address the damage” (i.e. damage, cause codes, object codes, and activity codes on the notification).
  - Brief description of what was done, and what follow-up work is required (normally in the *notification long text*).
  - The time spent to execute the job (part of the time confirmation).

The guidelines on where exactly to capture the maintenance history is not always clear to the SAP users. Long text in SAP’s PM module can, for example, be captured in five independent long text fields in SAP: (i) the notification long text, (ii) the work order long text, (iii) the confirmation long text, (iv) the cause code long text, and (v) the operations long text. Without proper guidelines, the maintenance crew tend to enter detailed descriptions of the work undertaken in the confirmation long text – a field often not even reviewed by maintenance data analysts.

Another problem often encountered relates to the time confirmations: Should only active tool time be confirmed, or should the time to obtain permits, spares and relevant documentation also be included? Should the time to resource the work order also be confirmed? Is there a limit to the deviations allowed between what was planned on the work order, and what was finally confirmed?

Data analysts need to understand the relevant issues and uncertainties regarding the capturing of maintenance history before attempting to analyse the data. Without compensating for these issues, conclusions will be inaccurate and corrective actions ineffective.

- Effectiveness of Maintenance Work Flow Process not monitored. In the majority of companies, there are often periods with more maintenance work than people to do the work. In such cases a backlog of work orders will result, which needs to be understood and actively managed. There are certain activities in the Maintenance Work Flow Process where a backlog is not advisable – e.g. approval of notifications (activity 2), creation of the work order (activity 3), and technical closure of work orders (activity 8). Backlog should not be allowed for activities 2 and 3, because of the risk that high priority work orders might not be executed in time. Backlog in preventive work (PM) orders in activity 8 might stop the generation of future PM work orders (depending on how the maintenance plans were set up in SAP). To ensure that backlog is understood and properly managed, online operational SAP reports for each of the activities in the Maintenance Work Flow Process must be executed on a regular basis by the maintenance supervisor or planner. Many companies fail to do this, and often only after a major failure, do they realise the value of running these reports regularly.
- Poor understanding between the Plant Maintenance (PM) Work Flow and Materials Management (MM) Work Flow. When asking maintenance crew and planners to list their biggest frustrations in terms of the Maintenance Work Flow, difficulty to find out when spare parts will be onsite often feature high on the list. Part of the problem lies in inaccurate cataloguing of the spares in SAP, but the biggest problem is a lack of knowledge of the materials management (MM) module in SAP. The following questions are often encountered:
  - How do I find out whether a material (spare) is catalogued (i.e. whether the details of the material is in SAP)?
  - Is the material attached to a Bill-of-Material somewhere?
  - How do I known how many items are in stock, and where they are?
  - What is the expected delivery time for the non-stocked item (i.e. items purchased using purchase requisitions and purchase orders)?
  - How do I know where the material is in the process (e.g. has the purchase request been turned into a “Request for Quote”, has the purchase order been created, etc.?)

  These questions are difficult to address during initial SAP PM training, since it contributes to information-overload. This is one of the reasons why follow-up training is essential; and why follow-up training for SAP PM users should also introduce them to the SAP MM module.

2.2 Work Centre Structures

In SAP Plant Maintenance, there are two different types of work centres [2]: *Main Work Centres* and *Work Centres*.

Main Work Centres generally define (on the header of the work order) the person/department responsible for ensuring that the specified maintenance task is carried out. *Work Centres* are used to specify the crafts required to perform the specified tasks. Work centres are an important means of integrating with other modules in SAP such as the Financial and Controlling modules (FI/CO), Production and Planning module (PP) and Human Resources module (HR). Refer to Figure 2 for an illustration of a typical work centre structure.

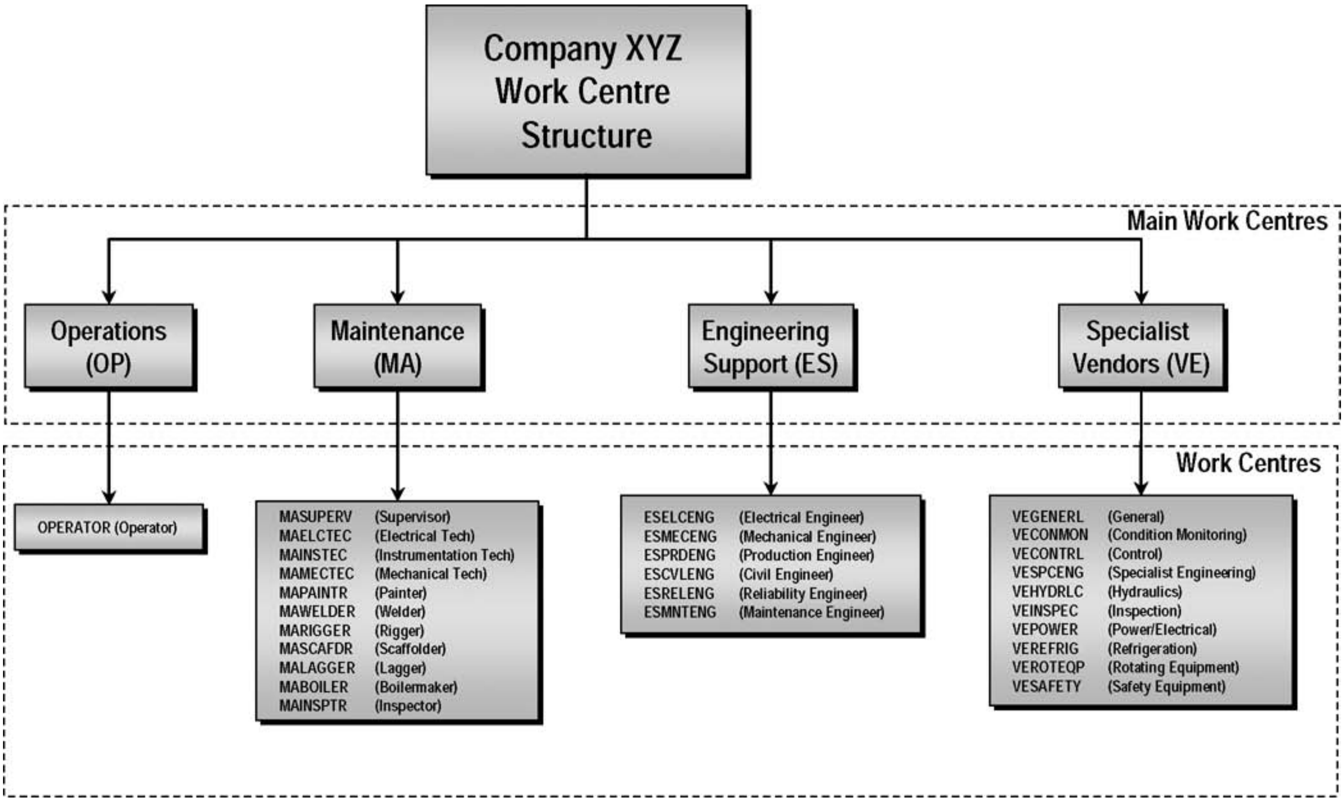


Figure 2. Typical Work Centre Structure

(Source: Author)

A major mistake made by companies is to underestimate the importance of the work centre structure during the initial configuration of SAP. Companies tend to put too little thought into the work centre structure, not realising that the highly integrated nature of work centres makes it extremely difficult (though not impossible) and risky to update the work centre structure once SAP is operational. This is especially true where there is a requirement to combine work centres at a later stage. Another common mistake is to have one person working under two or more different work centres. This complicates capacity planning, while it adds very little additional benefit. The third most common mistake is to not use the main work centre prefix (e.g. MA for *Maintenance*) in subordinate work centres (e.g. *MAMECTEC* for *Mechanical Technician*). This complicates the development of variants used to manage work orders throughout the Maintenance Work Flow Process, and in general the searching and sorting of work orders by work centre.

2.3 Work Prioritisation

Levitt **Error! Reference source not found.** has the following to say on work order priority: "Priority helps assign work where there is more work than people. It ensures that vital work is not overlooked in the rush […]. Priority systems have the habit of being abused so that users can get their work done faster." Each company must decide on the criteria to be used when determining the priority of a job, and the criteria should preferably align with the corporate risk matrix. Figure 3 illustrates a typical work order priority matrix taking into account the actual or potential effect of the defect on production, safety, environment and susceptibility to degradation. Other factors that might also be included in a priority matrix are product quality, historical failure rate, and the age of the work order. The company should agree on acceptable response times for particular work order priorities (e.g. "Complete Work Order within 14 days" for priority 2 work orders). These response times give the planner a window of opportunity in which the work order can be scheduled.

The relative ranking of work orders in each step of the Maintenance Work Flow Process will be based on the priority of the work orders, making it essential to allocate the priority correctly during the approval of the notification. The operations supervisor is normally the best person to determine the effect of a defect on safety, production, etc.; and this person should have a sound understanding of the priority matrix in order to make sensible decisions regarding work priorities.

Probability of failure

Low → High

Impact of failure	Safety	Environment	Production	Condition will not worsen over time	Condition might worsen over time	Condition will worsen over time
High	Serious injuries / fatalities	Major impact	Plant shutdown	3	2	1
	Minor injuries	Minor impact	Process shutdown	3	3	2
	Slight injuries	Slight impact	Equipment shutdown	4	3	3
Low	No injuries	No impact	No impact	4	4	3

Agreed reaction time based on Work Order Priority:

Priority 1 → Will complete WO within 24 hours
Priority 2 → Will complete WO within 14 days
Priority 3 → Will complete WO within 2 Month
Priority 4 → Will complete WO within 6 Months

Figure 3. Typical Work Prioritisation Matrix

(Source [5]: Fundamentals of Software Project Engineering)

The most common problems experienced in terms of the work prioritisation are:

- Priority based on required reaction time instead of impact on plant. In many organisations, the priority of the job is set by deciding when the job should be executed. The required schedule, instead of the consequence of the defect on the plant (as determined by criteria such production, safety and environment) thus wrongly becomes the driver of the priority. Although people instinctively include criteria such as safety in their reasoning when determining the priority of the job, this is done indirectly and will differ vastly from one user to another. As backlog increases, people also tend to increase the work order priority in an attempt to get their jobs done quicker. Therefore it is often found that the majority of the work ends up as priority 2, making it impossible to identify the really critical jobs amongst the "clutter".

- The priority of the work orders are allocated by maintenance crew or planners. Maintenance crew and planners often do not have the right exposure, experience, and "view of the bigger picture" of their plant to accurately allocate the priority of the work order. They tend to base the priority on when they think the work can or should be completed. This is based on how available the spares are, how available the resources are, and how long the job will take to complete. Smaller jobs often get the higher the priority, since these are easier to get "out of the way". The person that will be the most affected by the incorrect allocation of the priority is the operations supervisor, being ultimately responsible for maintaining production. It is therefore advisable that operations supervisor, supported by the maintenance crew, thus decide on the priority of the work order.

2.4 Damage and Cause Codes

Maintenance history is captured by selecting appropriate damage and cause codes from a list of codes provided by the SAP system. The SAP PM system can be configured to provide specific codes for specific types of functional locations / objects. The maintenance history is normally captured by the maintenance technician as part of the close-out of the job. The following two pitfalls have been the most commonly encountered, regarding the configuration of the damage and cause codes:

- List of codes to select from too elaborate. Many companies opt for elaborate and very detailed lists of damage and cause codes - sometimes even multi-tiered lists. One case was encountered where groups of codes contain an average of ten first-tier codes, with six to ten second-tier codes for each of the first-tier codes. The people who have to capture the maintenance history must therefore select the appropriate code from sometimes more that one hundred options! The intent of the detailed coding structure is to cater for all possible options in an attempt to gather comprehensive and accurate history. However, the result is the exact opposite. Maintenance technicians normally enter these codes at the end of a shift, when they are tired and hungry. When presented with a choice of up to one hundred codes for each job, they will almost always limit their selection to the same three codes – irrespective of the actual damage and cause.

When analysing the maintenance history provided of long text in work orders and notification, the data analyst must always get an understanding of the choices provided and the conditions under which this data is normally entered. The fact that details have been entered does not automatically imply that the data entered is accurate. By getting an understanding of the source of the data, the analyst might prevent incorrect conclusions based on detailed analyses using invalid data.

Levitt [3] suggest that preventive maintenance task lists should aim at preventing the *most likely*, *most expensive* and *most dangerous* types of failures. This principle can also be applied with great success to selecting the damage and cause codes to be provided in SAP for each type of object. Damage and cause codes should thus be focussed on identifying the most likely, most expensive and most dangerous failures. A good guideline to aim for when deciding how many codes should be provided per object type comes from Miller [4], who describes the capacity of short-term human memory at seven items plus or minus two, depending on the individual. Further study revealed that when presenting bulleted information in groups of the "magical number seven" the reader "sees" the information as a picture instead of words requiring reading. Limiting damage and cause codes to seven or less therefore makes it easier for the maintenance technicians to assimilate the information and to select the most appropriate code – resulting in more accurate maintenance history being captured.

- Providing generic codes that are not specific to the type of functional location/object. Some companies use generic high-level damage and cause codes instead of developing object-specific codes. Generic codes would, for example, be provided only for groups of objects classified as "mechanical components" or "electrical components". The problem with these generic codes is two-fold: (i) the list of codes to select from is generally very long to allow for all possible options (similar problem as discussed above); and (ii) the codes are not applicable to specific problems encountered, making it difficult to select "the most appropriate code".

2.5 Master Data Maintenance

Plant Maintenance "Master data" can be defined as data not changing frequently during the day-to-day operation of the plant, and form the basic building blocks of the SAP PM system. Examples of PM master data are functional locations, equipment, bill of material (BOM), work centres, measuring points, maintenance task lists, and maintenance plans. Changes to PM master data should go through a rigorous process of review and approval by the relevant custodians of the data before implementing the changes. Refer to Figure 4 for a typical Master Data Management Process.

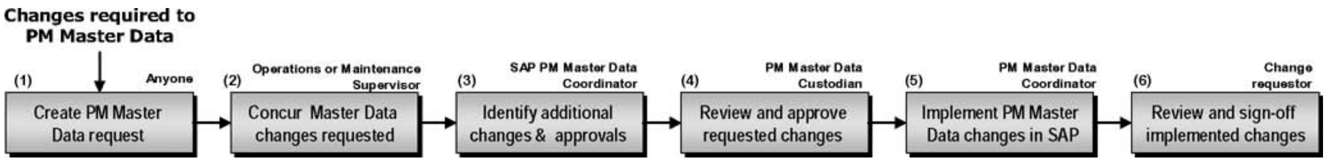

Figure 4. Typical PM Master Data Management Process

(Source: Author)

There is a need for a *SAP PM Master Data Coordinator* to facilitate the whole data update process. The SAP Data Coordinator has to be skilled in maintenance and SAP PM, and has the responsibility of ensuring that the scoping of the change is comprehensive and implementation of changes accurate. A user might for example have specified an increase in the regular inspection interval for a particular functional location by only quoting the relevant PM work order number and the required inspection interval. It is then up to the SAP Data Coordinator to determine the impact of this change on other maintenance plans, whether there are job procedures to update, whether the scheduling parameters on the maintenance plan are still applicable (e.g. is the period between creation of PM work order and required execution date of the work order still valid), etc. The SAP Data Coordinator must also identify the relevant custodian to review and approve the requested changes.

Unfortunately the importance of the correct management and updating of SAP PM master data is often underestimated. This leads to numerous problems, including:

- No SAP PM Master Data Coordinator in the Master Data Change Process. Some companies do not use a SAP PM Master Data Coordinator, but allocate this responsibility to a Master Data Administrator role (i.e. someone with SAP PM skills but with limited or no knowledge of maintenance) who might not understand the intent and full scope of the requested changes. The end-result is master data with numerous errors and inconsistencies.

- Insufficient review of requested changes by the Master Data Custodian. It is expected of the SAP Master Data Custodian (normally an engineer per discipline) to review and approve the requested changes. Unfortunately this person normally also does not have sufficient knowledge of the SAP PM system outside notification and work order management – and does not know how to interrogate SAP in order to gather various bits of information. Changes are then approved without proper review. The solution is regular follow-up training sessions or demonstrations – no longer than two hours per session as the engineers find it difficult to allocate big chunks of their day (and sometimes also big chunks of motivation!) to SAP training sessions.

3 CONCLUSION

In this article five of the most common problem areas in the use of the SAP Plant Maintenance module were identified and discussed. The list is by no means comprehensive, but provides valuable insight for other practitioners in this field. Although some of the problem areas discussed above might be easy to fix (e.g. development of a priority matrix), the difficulty does not only lie in development of the solution, but also in finding a custodian prepared to promote these changes. Implementing changes to the SAP PM system might require users to be retrained, supporting documentation to be updated, users' SAP access to be changed, additional reports to be developed, cause codes to be streamlined, data management to be upgraded, etc. In order to ensure effective and efficient plant maintenance, it is essential that SAP PM, as one of the tools used in this process, is configured and used as well as possible. This requires continuous attention to how SAP PM can be better utilised, instead of an "implement and forget strategy".

Team Leader Operational Performance - Asset Capability Management P/L - www.assetcapability.com.au

Abstract: The maintenance function performs a range of activities to deliver reliable equipment performance and meet business goals. This activity is described by a series of independent, yet integrated, processes that form a maintenance work management system (MWMS).

All processing systems are in some way constrained by bottlenecks. The Theory of Constraints (TOC) is a philosophy effective in optimising the performance of processing systems by working on bottlenecks.

The concept of lead and lag measures evolved from use of the Balanced Score Card. Lead measures can be levers to achieve lag measures (targets). Lead measures can be used to define bottlenecks and manage the work flow in the WMS and thereby ensure maintenance performance is improved and eventually optimised.

Direct application of TOC to managing maintenance WMS performance, using integrated lead and lag measures, derived from data captured within a CMMS, will enable an organisation to realise performance far beyond that possible by traditional approaches.

Key Words: Maintenance work management, process, system, Theory of Constraints, improved reliability.

1 DEFINING THE CHALLENGE

Maintenance has been on a journey to understand and demonstrate its' purpose in the value chain of manufacturing businesses for some time. More recently manufacturing business has come to recognise maintenance and production as two interdependent processes linked through the functional performance of the equipment. The most significance aspect of this change is that maintenance, like production, is now expected to demonstrate how it adds value to the output of the operation not be treated just as a cost centre.

Whilst maintenance personnel have always known they contributed to the plant output, being able to demonstrate how they do has been a challenge. The maintenance function has been treated as purely a cost for so long that all its management systems are a reflection of this cost driven paradigm. The new paradigm must be able to balance the cost of maintenance against the plant output it supports. Maintenance must get a new map to navigate. It must develop and manage its systems to navigate towards an optimum balance between cost and benefit and thereby achieve 'optimum maintenance performance'.

For maintenance to find this new map it need look no further than the philosophies adopted to optimise production performance. One such philosophy is the Theory of Constraints (TOC). When applied to the maintenance WMS this philosophy not only facilitates the change in paradigm required, it delivers immediate and significant benefits. These benefits include significant increases in equipment reliability, more effective work completed, reduced cost, improved morale, a common language with production and an solid foundation for equipment strategy development. Most significantly the application of TOC to the WMS delivers a systems model which facilitates the ongoing optimisation of maintenance performance.

2 UNDERSTANDING THE THEORY OF CONSTRAINTS (TOC)

All real-world systems have at least one constraint; otherwise they would be capable of infinite throughput, which is clearly impossible. TOC purports that a real-world system with more than three constraints is extremely unlikely. A major implication of this is that managing a complex system or organisation can be made both simpler and more effective by providing managers with a few specific areas on which to focus; maximising performance in the areas of key constraints, or "elevating" the constraint (making it less constraining) [1].

2.1 Five Focusing Steps

How can any generic solution have such broad applicability? It turns out that no matter what an organisation's offering is; products and/or services, the methods for most effectively and efficiently managing processes and resources are basically the same. To use another powerful analogy: just as the strength of a chain is dictated by its weakest link, the performance of any value-chain is dictated by its constraint. Recognizing this, the resulting steps to maximise the performance of a value-chain are [2]:

1. Identify the constraint.
2. Decide how to exploit the constraint.
3. Subordinate and synchronize everything else to the above decisions.
4. Elevate the performance of the constraint.
5. If in any of the above steps the constraint has shifted, go back to Step 1.

WARNING DO NOT LET INERTIA BECOME THE SYSTEM'S CONSTRAINT

Steps 1-5 can result in significant changes to the operation of the business. If this change is not carefully managed the chaos that ensues may result in the process delivering less than the potential throughput. In effect the process of changing would then be the constraint. Slowly changing, elevating constraints / subordinating non-constraints would make the system less likely to become chaotic.

3 ESTABLISHING THE FUNDAMENTALS OF THE MAINTENANCE WMS

Maintenance is viewed as a set of interdependent processes that create value by reducing operational, safety and environmental risk introduced by equipment defects. Risk is reduced by either minimising the likelihood of occurrence or by reducing the subsequent effects. Ideally the risk is eliminated through the removal of the defect all together.

Before TOC can be applied across the maintenance WMS several fundamentals need to be clarified.

1. The first is to draw a distinction between the two management systems within maintenance that form the maintenance value chain.
    a. One system deals with the application of existing equipment strategy (existing knowledge). Its processes include identification, approval, prioritisation, planning, scheduling and execution of maintenance work. (Work Orders)
    b. The other system deals with the development of new equipment strategy (new knowledge); the continuous improvement of equipment strategy, delivering new knowledge to reduce equipment defect risk. Its processes include identification, approval, prioritisation, planning, scheduling and execution improvement projects.

For the purpose of this paper only the former system is considered, the more traditional system for managing day to day maintenance work. However TOC can be applied just as effectively to the latter system but that is a story for another day.

To draw a comparison to a manufacturing process; focus on the products you need to make today not the products you are developing.

2. The second is to draw a distinction between processes and system. The maintenance processes describe how one work order would be progressed from identification to completion. The maintenance system describes how all work is managed within the constraints (Cost, Resources, Skill etc) of the system. TOC is applied at the system level.

To draw a comparison to a manufacturing process; focus on how you can achieve the desired throughput of all products instead of how you make one product.

4 BUILDING AN OPERATIONAL MODEL

To apply the TOC philosophy to the Maintenance WMS we must first define the model of the production process. The process of manufacturing completed maintenance work.

In this production process the product is maintenance jobs, referred to as "Work". There are several points of entry for "Work" into the production process and generally the later the "Work" enters the process, the more likely it is to be completed.

For this reason it is more effective to build the model by starting at the end of the production line and working backwards. The completed model is shown in figure 1.

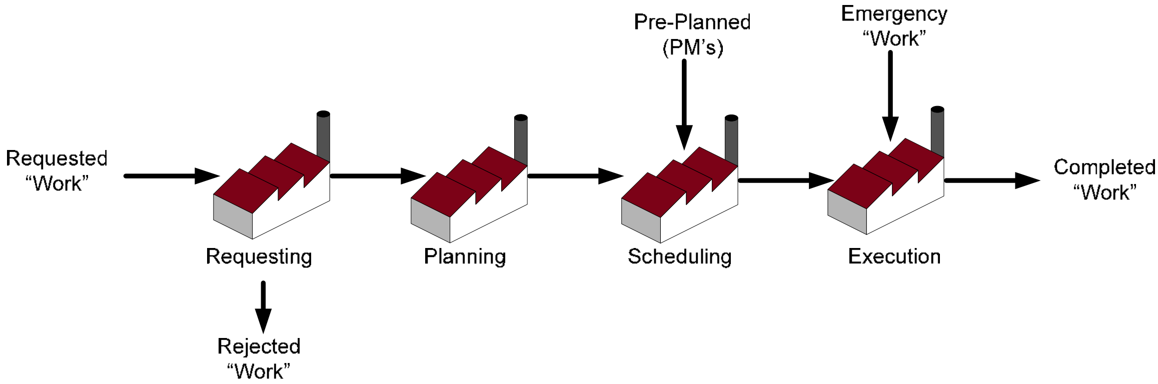

Figure 1 - Maintenance WMS Model

Remembering the product being produced is "Work", then stepping backwards from completed "Work";

- The first processing area encountered is "Execution". In this processing area "work" is done that was delivered to it from either the scheduling process or directly as unscheduled activity (breakdowns). Execution also includes the recording that "Work" was done and any identification of follow-up "Work", i.e. *History Collection*.
    - Unscheduled work should only consist of work that is so urgent that it must by-pass the planning and scheduling processes. For example if the "Work" was to be planned and scheduled then by the time it was completed the consequences it was intended to prevent would have already effected business performance.
- The second processing area is "Scheduling". In this processing area "Work" is confirmed as ready for "Execution" and then assigned within various constraints. These constraints include availability of plant, internal / external resources and budget. In some cases the "Work" is not able to be processed as parts or specific equipment / tools that are assumed to be available are not. The "Work" typically enters the "Scheduling" processing area from either the "Planning" process or as *pre-planned* work (typically PM's).
    - Pre-planned work typically comes from equipment strategies where the "Work" has been predicted and is automatically generated on a calendar basis or potentially by some event or usage based monitoring. The key difference of pre-planned from planned "work" is the assumption the specifications of the "Work" are the same each time it is processed.
- The third processing area is "Planning". In this processing area "Work" is given detailed specifications so that it can be Scheduled and Executed efficiently and effectively according to relevant company policies e.g. Safety Policy. In addition any orders for resources not available within the business are placed, such as parts or contract labour. The "Work" enters the "Planning" processing area from the "Requesting" processing area.
- The fourth and last processing area is "Requesting". In this processing area "Work" is reviewed to ensure that it is real, of a type that can be manufactured using the maintenance WMS and that an order for the same "Work" is not already in process. In addition the "Work" is tagged with a priority that effects how it is handled at the other processing areas. When this priority is determined as *emergency* the "Work" is immediately directed to "Execution" processing area. All other work enters through the Requesting" processing area. The "Work" enters the "Requesting" processing area from several sources. These sources are:
    - The need for work is recognised and a request is raised.
    - The nature of executing emergency "work" sometimes results in the quality being compromised and a need for further "Work" is requested to ensure the equipment is returned to original specifications.
    - Whilst executing Preventive Maintenance type "Work" a need for further follow-up "Work" is identified and a request is raised.

Now the WMS model is defined we can apply TOC to increase the throughput of the system and reduce the inventory or work in progress. Considering the maintenance WMS model the throughput is the amount of completed "Work" that comes out of the "Execution" processing area. The inventory is the "Work" still to be completed, stored at various processing areas.

5 APPLYING TOC TO THE MAINTENANCE WMS

Table 1 illustrates how the TOC can be applied to the Maintenance WMS by drawing on two specific examples of potential constraints (bottlenecks).

TOC step	Example 1	Example 2
Identify the constraint (bottleneck)	Planning capacity. The rate of planning "Work" cannot meet the rate of Requesting "Work". The rate of planning also cannot supply sufficient planned work to scheduling or execution.	Internal Electrical Resources Availability. In this case the "Work" requires specialised in-house skills. Currently there are not enough resources available to do all of the "Work" of this type.
Exploit the Constraint (bottleneck)	Ensure that the planner is planning as efficiently as possible. Consider reasons why planning cannot have greater throughput of planned work. Ensure that all of the information systems that support planning are effective, eg Parts Listings.	Ensure that the personnel with the specific electrical skills required are primarily focused on this "Work". Consider actions such as remove all other work from the specific electricians or allow overtime for this "Work".
Subordinate all other processes	Do not schedule or execute more "Work" than the planning rate (allowing for emergency "Work" throughput). Unfortunately it is too risky to not review incoming "Work" so the requesting process cannot be subordinated and work will build up at planning.	Subordinate the Planning and Scheduling of this type of "Work" to meet the capacity for Execution. Ensure that the preventive "Work" can still be managed as a priority over all other types.
Elevate Constraint (bottleneck)	Increase the planning capacity, either by allowing the planner more time to plan, or by providing assistance to the planners.	Increase the Execution capacity around the specific electrical skills required. There may be several ways to do this such as work overtime, remove all other work from the specific electricians or potentially recruit / contract more of this skill. Note there may be a time lag for new resources to become effective.
Check the constraint (bottleneck) has not moved	Potentially the rate of planning has now increased such that more "Work" can be planned than can be executed. Hence the bottleneck has moved to execution.	As the "Work" completed by the electricians starts to increase ensure that Planning and Scheduling can match the rate of Execution, especially in the case where the electricians' non critical skill "Work" is reallocated to others.
Manage Inertia	Slowly increase planning rate. If the amount of work planned immediately doubles then other parts of the system may be shocked, such as scheduling or supply of parts.	Steadily increase the flow of "Work" to Execution by increasing Planning and Scheduling". Continue to watch the levels of "Work" of this type as it may only be necessary to elevate this constraint for a short period.

Table 1 – Application of TOC to maintenance WMS

5.1 Introducing a Prioritisation Policy

In order to manage the flow of "Work" through the processing areas a prioritisation policy is introduced to ensure the highest risk (operational / safety / environment) "Work" is completed first and the lowest risk "Work", completed last. The prioritisation policy must also allocate priority to the types of maintenance work; Reactive, Preventive, Corrective. e.g assign emergency Reactive work as highest priority, followed by Preventive then Corrective.

If the total Work throughput goes up but low risk work is placed ahead of high or medium risk work, the impact on operational performance will not be maximised. Adherence to this prioritisation process must be achieved to maximise the effectiveness of reducing the risk due to equipment defects. The prioritisation policy will have the effect of:

1. Ensuring only emergency "Work" by-passes the Planning & Scheduling process
2. Ensuring that "Work" is processed in order of priority at each processing area.

6 MANAGING FROM LEAD MEASURES TO LAG MEASURES

For the managers of the maintenance WMS it is the lag measures, or system outputs, that are important for assessing operational performance and managing the manufacturing value chain. Lag measures for the maintenance WMS model must be defined and clearly linked to operational performance. These measures would typically be:

- Equipment Availability and Reliability to measure manufacturing plant performance.
- Cost / Unit to measure compliance to budgeted R&M cost.

These measures are known as "Lag" due to the difficult in directly influencing them. For example you cannot simply change your reliability by being more reliable. You must change the activities that you do or don't do that result in your reliability. The measures of this type of activity are the lead measures. For the maintenance WMS these lead measures are:

- Work throughput. For the whole system this is measured as completed "Work" volume. For each processing area it is the volume of work passed to the next processing area.
- Work Inventory. For the whole system this is measured as the total number of open "Work" orders. For each processing area this is the volume of "Work" waiting to be processed.
- Time to process work. For the whole system this is measured as "Cycle Time" defined as the time for work to progress through the system. For each process area this the time from receiving the work, processing it and then passing it on to the next process area.

From the two examples shown in Table 1 it can be seen that from just a single pass using the TOC process all processing areas within the maintenance WMS and consequently all of the lead measures will be affected. As the changes in lead measures occur a subsequent effect on lag measures will be observed, usually with some time delay (lag). In the examples an increase in the total throughput of completed "Work" was achieved and within a month or two the reliability increased.

Taking a systems approach of adjusting the maintenance processes, observing the system and process lead measures and the consequential effect of lagging business performance is an enormously powerful learning experience. Using this systems approach managers are able to quickly and sustainable increase the value generated by the maintenance function.

7 REAPING THE REWARDS

Significant benefits are achieved very quickly through the application of the constraining management process as well as the adherence to the risk based prioritisation of work. "Work" throughput steadily increases, reliability improves and in addition a shared understanding of the maintenance system emerges. The focus shifts from being on individual jobs to the whole system.

However to maintain the benefits the improvement must be sustained. This requires taking a holistic or systems approach across all aspects of the maintenance function e.g. Process, System, Management, and Communication. Influencing the whole function is key to the sustainability of all benefits. Like a bucket of water with a small hole, a partial dysfunction could result in all of the benefits being drained away over time.

The following provides greater detail of how these benefits are manifested.

7.1 Process Benefits

For personnel with responsibility within individual maintenance processes the benefits come in the form of more work completed through better organisation, alignment of individual activity to the system and clear goals for each process. These benefits are demonstrated by the following examples taken from the application of TOC to the maintenance WMS of several steel manufacturing plants;

a) The prioritisation of work ensures the minimum emergency "Work" occurs, hence allowing those responsible for completing emergency "Work" to be more effective. In one example a lot of breakdown work was done on standing work orders with no strategy and no planning control. As this work was reviewed for strategic purpose it allowed more work to be systematically fed to the Execution process. Typically the work on Standing orders is not well defined and allows for a wide variety of activity making it a source of inefficiency and making it difficult to assign priority.

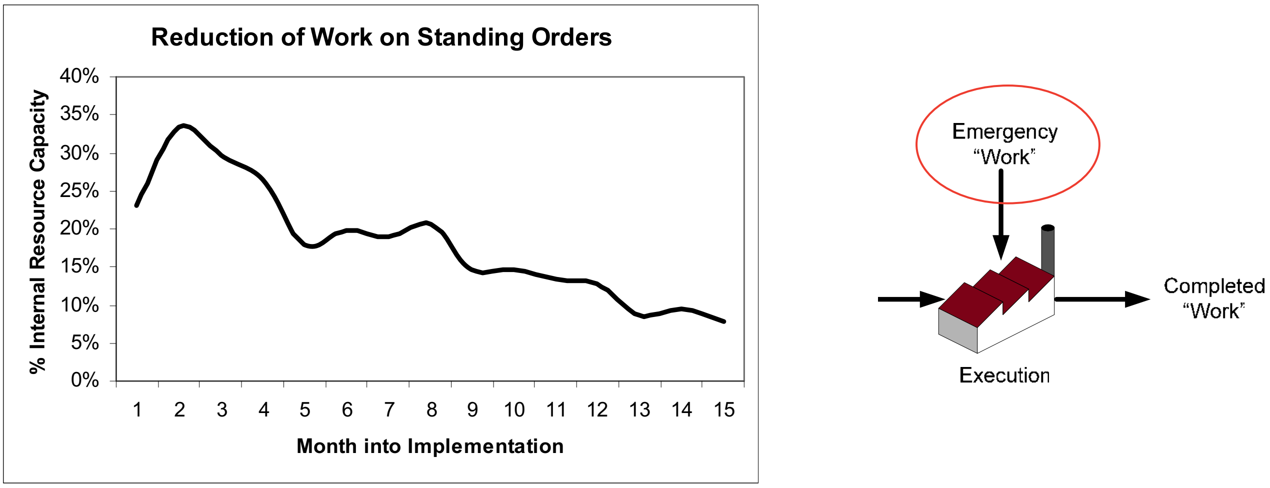

Figure 2 – Reduction of Work on Standing Orders

When the "Work" inventory at the Scheduling process is examined it typically contains a lot of duplication and redundant "Work". In two cases scheduling backlog was halved virtually over night as it contained many instances of the same preventive maintenance (PM) work order that had not been completed.

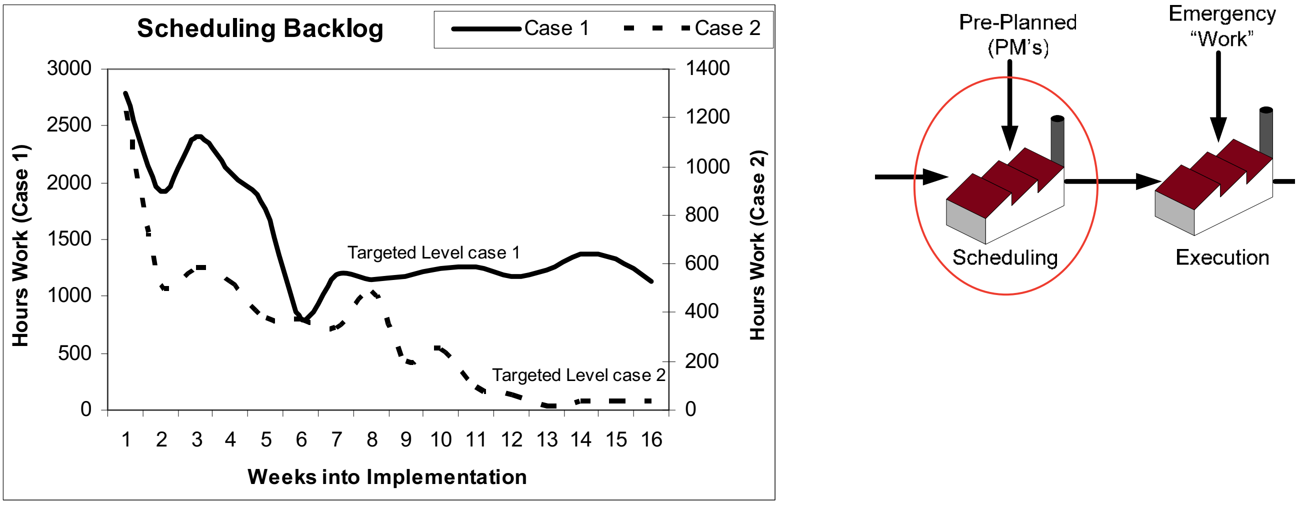

Figure 3 – Reduction of Scheduling backlog

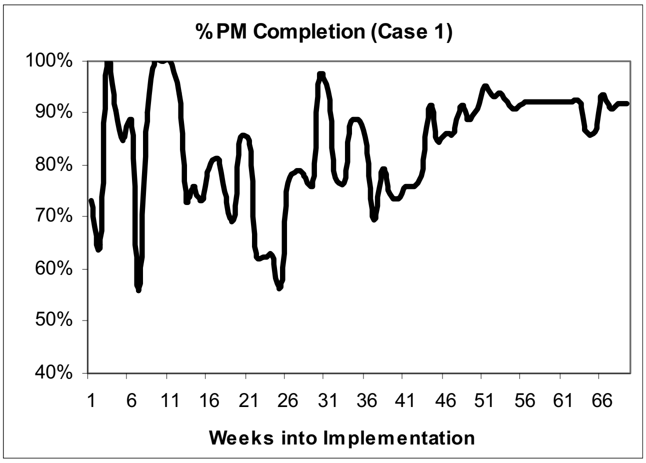
As the scheduling backlog is work that could be done immediately this means the parts required for the "Work" are in stock. The cash tied up in the parts is only of benefit to the business when the "Work" is done. Reducing this scheduling backlog means reducing the cash tied up not working for the business. In Figure 3 the original value of the scheduling backlog was in the order of $300K.

b) Preventive Maintenance (PM) work orders are generated from an equipment strategy that is designed to minimise the risk to the manufacturing operation. Success of the equipment strategy depends not just on the completion of the PM work order but completion on time. PM work orders should be prioritised as high risk "Work" ensuring they are processed first. This will lead to a significant increase in compliance to PM due date. In the following two cases where TOC was applied, PM compliance went from an average 70% to almost 100% and the consistency (reduced variability) of performance also increased.



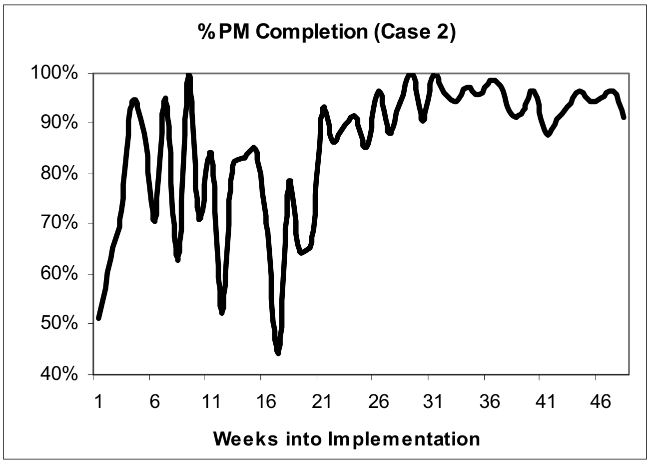


Figure 4 – Increase of PM Completion on time

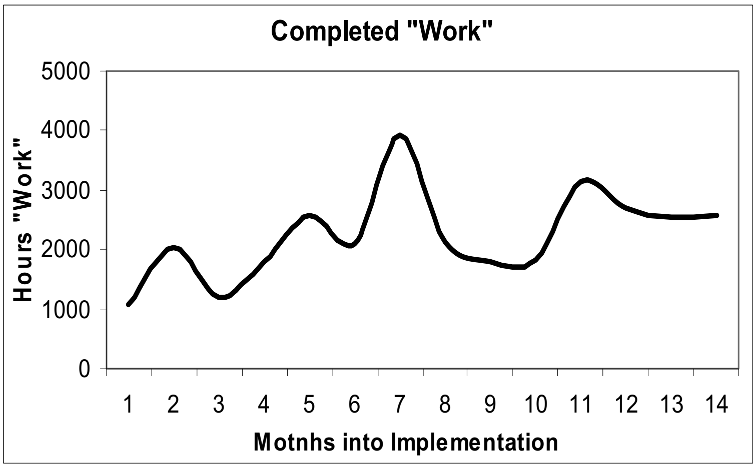
c) Using TOC the effort to manage the WMS can be more effectively distributed as subordinated processes require less effort. This effort can then be better redirected to the constrained processes or to managing the system.

- For example in one manufacturing plant the mechanical planner had no planning backlog yet the electrical planner had a significant planning backlog and was the constraint for electrical "Work". The mechanical planner started working 1 day / week on helping the electrical planner with data entry, hence allowing the electrical planner more time to plan. This effectively elevated the constraint.
- In another example the planner and supervisor were both planning and distributing all ready jobs to the tradesman. Consequently too much work was being handed out for execution each week. Matching the planning rate to the scheduling and execution rates meant only one person needed to plan. The resulting benefits were that the supervisor was able to spend more time on managing the scheduling process and the tradesmen were less frustrated as they were able to complete every job given to them.

7.2 System Benefits

As mentioned previously, for the managers of the maintenance WMS it is the lag measures, or system outputs, that are important for demonstrating their effect on operational performance. The impact of TOC on the system outputs is substantial. These benefits are demonstrated in the following examples taken from the application of TOC to maintenance WMS of several steel manufacturing plants;

d) As the constraint is exploited and the system elevated, throughput of completed "Work" increases. In one example throughput increased by approximately 60% with the same resources. Maintenance personnel also received encouraging feedback from operations who noticed a substantial increase in jobs getting done.



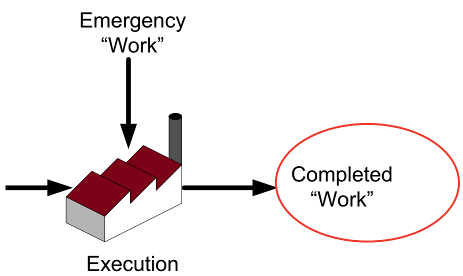


Figure 5 – Increase in completed "Work"

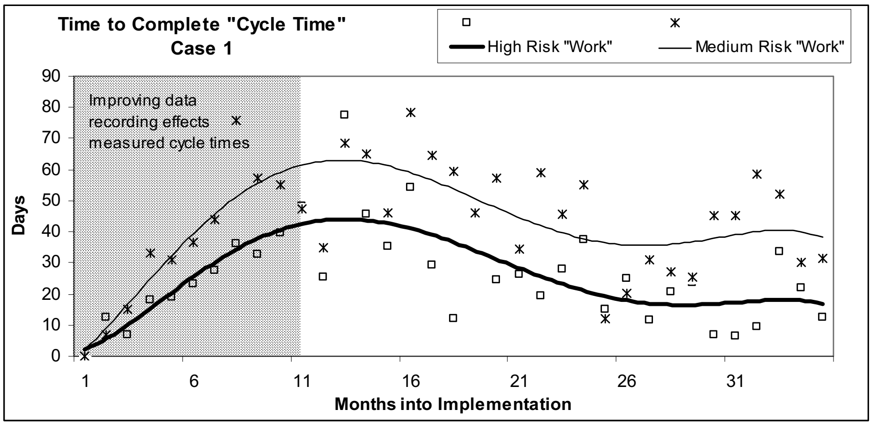
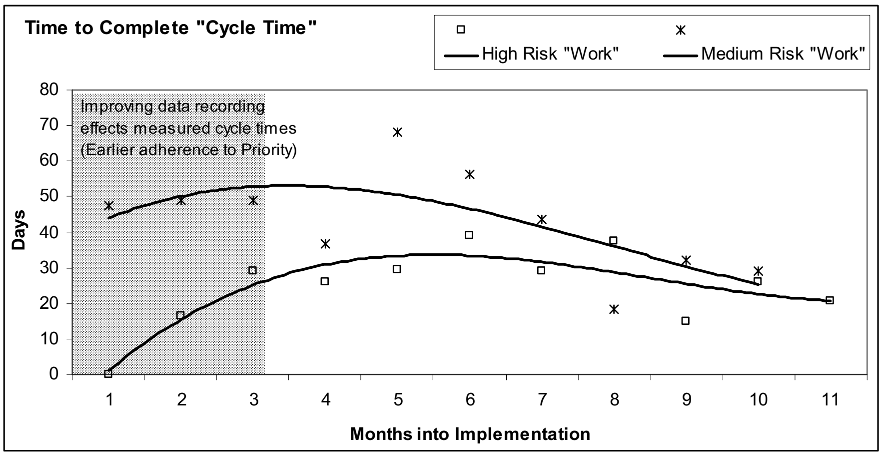
e) As throughput increases and the prioritisation policy is adhered to the time taken for planned "Work" to go through the maintenance WMS, known as Cycle Time, decreases. This is most significant for high and medium risk "Work". In two separate cases the cycle time appears to increase as the prioritisation policy is adhered to. Once all "Work" is completed with a recorded priority the trends show a steadily declining time to complete "Work". This effectively means the risk posed by equipment defects is removed from the system more quickly.





Figures 6a & 6b – Reduction of "Work" cycle times

f) There is an increase in the Reliability of the equipment. In two separate cases the reliability increased more than 4% over a 12 month period and then was sustained at this new level of performance.

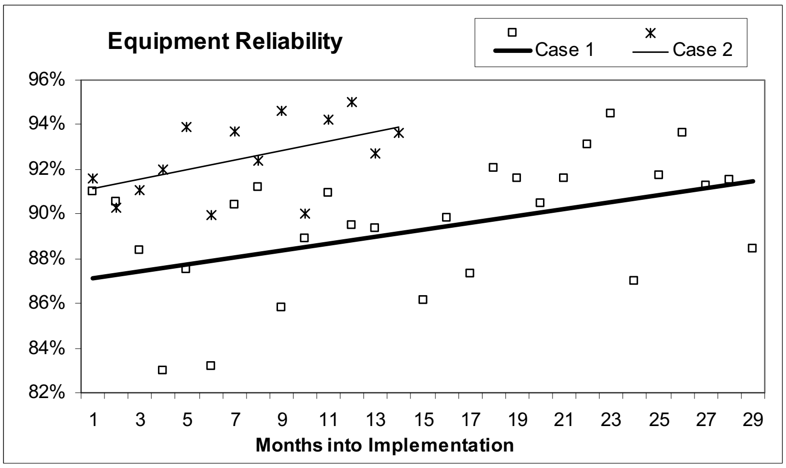


Figure 7 – Increase in equipment Reliability

7.3 Management Benefits

The old adage, "If you can't measure it you can not manage it", is just as true for maintenance. Applying TOC across the WMS and monitoring lead and lag measures is a great tool for managers to systematically link process to systems to business performance.

True commitment to measurement means that you are prepared to question every activity for its validity in relation to business performance. A key benefit of the application of TOC to the maintenance WMS is that it aligns all activity, through performance measurement, to the throughput of completed "Work". Put simply the measurement system answers the question "What is the point to doing this?" This line of thinking sparks a chain of events that ultimately reshape the culture;

1) What is our key output? What must we influence?
2) Now allow every single activity to be driven by this measure, this is performance management.
3) Now what gets done is done to serve the key output.
4) As culture is "what gets done" now the culture is aligning to the key output

Additional benefits to management are;

g) Management can determine budgets based on level of risk to the operation held in the maintenance WMS. Effectively the business is able to determine a desired cost / unit for production and convert this into an equipment reliability / availability and R&M budget. This is further explained in section 4 - ACHIEVING OPTIMUM PERFORMANCE.

h) Management benefits from the formation of teams and the alignment of performance around the whole maintenance WMS. This allows departmental division created through technical barriers such as Mechanical and Electrical knowledge to be broken down.

7.4 Communication

i) Individuals performance is aligned to a shared understanding of maintenance. For example one maintenance manager said " *I can have very quick and direct conversations with my team as to where we should focus our efforts to improve. We can stop arguing about what each measure means and start looking at the whole picture*".

j) Maintenance can explain their processes to production personnel using a picture that production are used to thinking about. Parallels between the actual plant process and the maintenance model can easily be drawn.

8 CHALLENGES TO ACHIEVING OPTIMUM PERFORMANCE

The production process, the maintenance WMS, is now much more effective at turning out complete "Work". As the constraints (Bottlenecks) are elevated the throughput of "Work" continues to increase. High risk work is completed in shorter time periods and the equipment reliability improves. This improving equipment performance feeds back to the maintenance WMS as less emergency work, allowing greater volumes of planned and scheduled work to be processed.

Effectively a self perpetuating system; improve the way you do work means less work. However after a time the increase in "Work" throughput comes at a higher incremental cost. The improvement costs more and more each time.

This concept is illustrated in Figure 8, taken from [5], where a relationship between cost of lost output and the direct maintenance cost to sustain the output is shown.

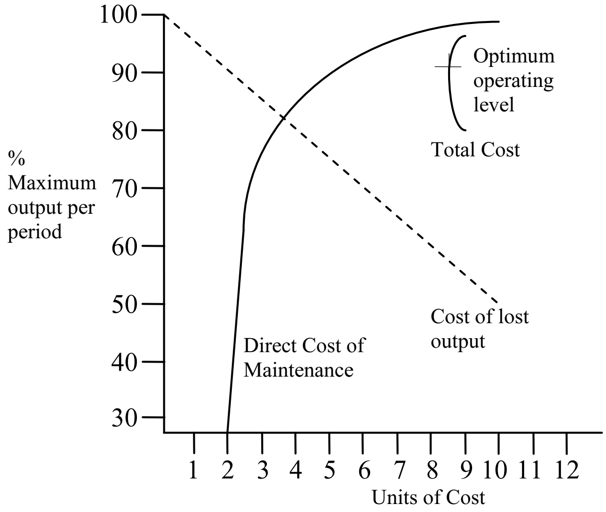

Figure 8 – Optimum Operating Performance

As the output drops from 100% the cost of lost output linearly increases as well. Similarly as output increases the direct maintenance cost to support the level of performance at first changes very little and then as 100% output is approached the direct maintenance cost rapidly increases, potentially asymptote to 100%. Hence 100% output may not be financially feasible. The resulting combination of these two effects suggests that for each manufacturing business an optimum level would exist somewhere less than 100% output.

Clearly the challenge for the maintenance manager is to achieve this optimum maintenance performance balance by monitoring plant output (Cost / Unit) together with "Work" throughput .

The maintenance WMS model is used to achieve this goal as it creates linkage between plant output (Cost / Unit) and "Work" throughput. The systems map shown in Figure 9 demonstrates how this occurs.

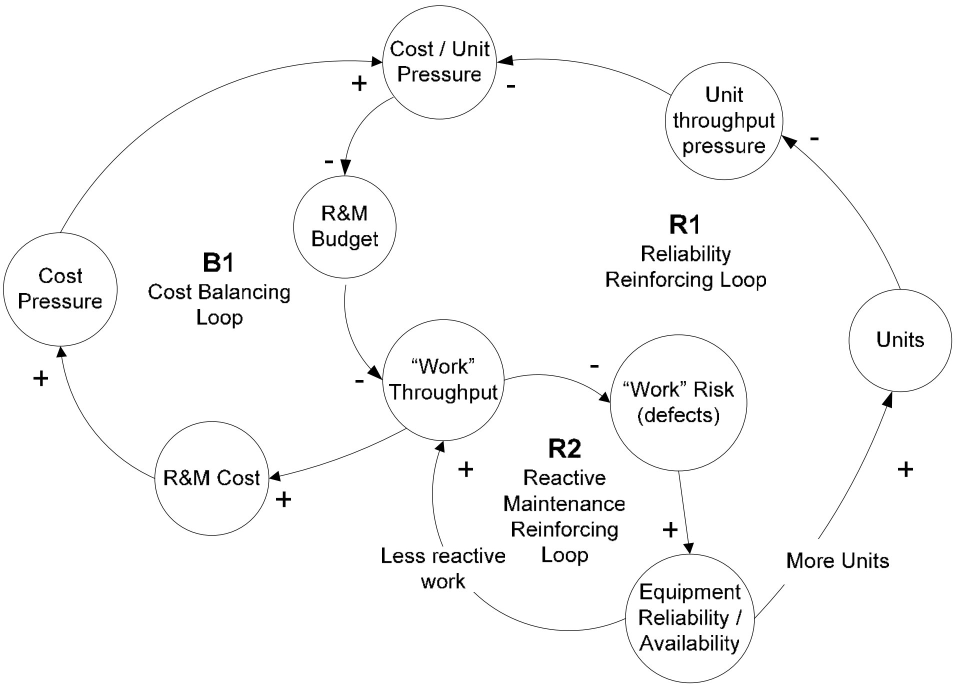

Figure 9 – Systems Map of relationship between Plant Output and Work Throughput

Starting with reliability loop R1 at "Work" throughput; as more "Work" is complete, less Risk exists which turns into improved reliability producing more units and eventually leading to less pressure on plant throughput. As the plant throughput pressure is lowered so is the cost / unit pressure lowered. This eventually leads to less pressure on budget allowing even greater "Work" throughput. This relationship tends to drive improving plant performance.

Coming to the balancing loop B1; as more "Work" is done the cost of R&M goes up and consequently puts more pressure on operating cost. This increase pressure on operating cost increases the pressure on cost / unit, which in time can lead to decreased maintenance budgets. Declining maintenance budgets means less "Work" throughput. This relationship tends to push the "Work" throughput back towards previous levels.

Finally R2, shows that a reinforcing loop feeds back from Equipment Reliability into "Work" throughput due to the level of emergency, or reactive, work. As reliability increases less breakdowns occur this allows more preventive "Work" to be completed. This relationship does not necessarily affect the amount of work done but does effect the type and the associated risk to the operation. As the type of work shifts from reactive to preventive the equipment reliability increases without associated increase in the costs of performing the work. This relationship can be used to very quickly drive increases in plant performance without substantial increases in operating cost. This is commonly referred to as "Breaking the Reactive Cycle".

In addition, in meeting the challenge of finding the optimum performance balance, it should be remembered that the WMS was defined as the application of existing equipment strategy (Section 3). This balance will be a function of the knowledge contained in the existing equipment strategies. Generating more effective strategies will elevate optimum performance.

The importance of the maintenance WMS in elevating the point of optimum maintenance performance is two fold;

a) When questioning the effectiveness of existing equipment strategy it is essential the strategy has been adhered to. If this cannot be guaranteed the root cause of the strategies ineffectiveness may be that the PM was not done on time. The maintenance WMS removes this root cause by ensuring PM compliance and reducing the time to complete high risk follow-up work.

b) When implementing new strategy the benefits are only realised when the resulting work is complete. The maintenance WMS guarantees immediate adherence to the new strategy.

9 CHANGING PARADIGMS

"A paradigm is a way of thinking; a paradigm is like a mental model. A good way of thinking about a paradigm is like it is a map. If you had an inaccurate map of the city you are in and you are trying to find a certain location what success would you have?" [4].

The plight of Australian manufacturing competing in a global market place is all too obvious. Daily media proclaims the need for numerous panaceas; innovation, improvement in managing skills, government support. [5]

For Australian manufacturing to survive it requires a change in paradigms. Maintenance can contribute to this change but it must get a new map. It must develop and manage its systems to navigate towards an optimum balance between cost and benefit and achieve 'optimum maintenance performance' and thereby show true purpose in the value chain of manufacturing businesses.

At the heart of it this is the application of TOC to the maintenance WMS. This is the map that maintenance needs to navigate its way to optimum maintenance performance where the ideal balance between maintenance cost and plant output are achieved.

The beauty of this journey is that significant benefits start to flow immediately. The immediate benefits come from the identification and exploitation of the constraints within the WMS. These include reduced risk as high priority work takes precedence, removal of obsolete and improvement work from the system, reallocation of the management effort to the constraining process and more work complete for the same cost and effort. These early wins for the maintenance personnel are crucial to sustain the motivation to change paradigms.

Within months the improvements at the work processing level start to show benefits in plant performance. This early impact on plant performance is crucial for sustaining the commitment from the whole business to change paradigms. With the commitment from the business, maintenance can then move to elevating the constraints within the WMS and start its journey towards optimal maintenance performance.

There are also many less tangible benefits for maintenance personnel. Confidence to modify failing equipment strategies knowing the root cause is not "Preventive Maintenance not done on time". The ability to explain maintenance to production using a production model removes many of the communication barriers. Setting maintenance budgets can become a question of the business managing levels of risk instead of trying to cut costs. Within maintenance barriers created by technical knowledge are broken down as everybody's focus shifts to increasing the total work throughput.

As the new paradigm solidifies it results in a changed maintenance culture. This in turn brings benefits as people are less frustrated and enjoy work more. They feel they are successfully contributing to improved business performance.

However nothing worth having comes easily. The changes that occur to the maintenance processes are essentially not that large but the changes in how the whole system is managed are. It is a big challenge to reshape the management systems and practices of the old cost focused paradigm.

OPTIMISING THE MAINTENANCE FUNCTION - IT'S JUST AS MUCH ABOUT THE PEOPLE AS THE TECHNICAL SOLUTION

Dr. Brendan J Smith

Team Leader Organisational Performance Asset Capability Management P/L www.assetcapability.com.au

Abstract: It is relatively easy for engineers to think about improvement in terms of a technical solution. Typically improvements will involve the replacement of equipment or the application of a specific technique. However often the improvement, particularly large scale improvement, will not meet expectations and you will hear excuses like "…we forgot the culture" or "… we just couldn't get the people to adopt the change". Typically these words describe what most people realise; improvement or change requires consideration of both the technical and the social aspects of the system. Realising the technical side of systems change and improvement is where engineers and maintenance managers traditionally are most comfortable. This paper will deal more with the social aspects. Offering Maintenance leaders a framework and system to design and implement sustained improvement. Considering "where we are now" in order to be able to effectively plan and navigate the path to "where we need to get to".

Key Words: Leadership, Change, Systems, Assets, Maintenance, Culture

1 CHALLENGES FACING MAINTENANCE AND ASSET MANAGERS

In most developed countries, gross national product continues to increase markedly faster than population growth; this is largely the result of replacing manual operations by technological innovation [1]. Modern industrial societies are thus more and more dependent on technology to produce goods and services. The increasing complexity of technology, our increasing reliance on it, and the growing potential for businesses to incur heavy losses when their equipment is not fully operational, signals challenges ahead for manufacturing and asset managers[2].

The industrial mode that describes a stable business environment where firms compete in national markets, have long product life cycles and competitive advantages that rely on low production costs and economies-of-scale, is changing. Now markets are global and varied, competitors can access diverse labour, capital, and supply conditions and product life cycles are relatively short as new products are introduced with increasing speed [4].

The businesses that form and implement the best responses to these challenges will be those that survive to tell the story and the way that return on equipment assets is optimised, will be key to competing in the fiercely competitive global economy.

Within this market context, given that maintenance plays a major role in business success, there are a series of questions asset and maintenance managers need to be asking: (i) How will the business respond to these competitive and technological challenges? (ii) How can we manage our equipment assets in line with the business strategy and add more value? (iii) What knowledge, skills and attitudes do we need to promote and engender within our people to help us face these challenges head on?

Maintenance and asset managers have never had a better opportunity to lead, to work with the rest of the business to collectively formulate how the future should be shaped and then to marshal the resources and support to make a difference. Leadership however is a choice that individuals make to take a step forward, to show the way and to positively influence their organisation. Whilst leadership can occur in any position and at any level within an organisation, what do Asset and Maintenance managers need to consider to be better leaders and to make a difference?

2 A LEADERSHIP FRAMEWORK

The increasing need for organisations to be responsive and competitive requires maintenance leaders to harness systems and practices at the functional level that are designed to add maximum value at the business level. Dealing with both systems and practices requires a new approach to leadership, one that considers both the hard (plant) and soft (people) assets.

Crucial to this new approach is developing a shared vision or understanding of where the organisation or department is headed and what it needs to achieve. This vision is then translated through strategy, structure and culture to create behaviours and results in individuals that lead to successful functional and company performance.

Leaders can define what needs to be achieved and can set in place strategies and a structure to achieve the required outcomes but unless they motivate employees to want to achieve, then performance will always be less than what it could be. Employees are most motivated in a work environment that provides increasing challenges and support; that encourages recognition and participation and develops all employees' sense of worth and belief that they can positively impact on the performance of the company.

This work environment or culture is achieved by fostering learning, change, open communication, continual improvement and problem solving. A culture in which leaders demonstrate a commitment towards improvement initiatives and ensure that stakeholders are given the awareness, feedback and support that they need to continually learn and improve.

The framework that enables maintenance leaders to make a difference must provide a clear understanding of strategic direction, establish appropriate structure and provide for a culture that relies on employee involvement for performance success.

2.1 Think Strategically

The interaction between any organisation and its environment can be viewed as an open system where inputs, resources and assets (both tangible and intangible) are converted into outputs (finished products and services, dividends, salaries). The capabilities of the organisation describe what it can consistently do to create value for stakeholders [5] and stakeholders will include customers, employees, shareholders and regulatory bodies.

Organisations compete for customers either by offering and delivering: (1) comparable value (to competitors) at lower prices, or (2) by providing more value (than competitors) at the same or a higher price (differentiation). Competitive advantage is the ability to outperform competitors and it is usually measured by above normal profits or return on investment.

The point of strategy is to identify and exploit sources of competitive advantage. Strategy seeks to answer the question "how do we capitalise on existing resources and capabilities and build new resources and capabilities to be more competitive in the future?" Competitive advantages arise when a strategy is implemented that results in enhanced value for customers. The more difficult it is for competitors to copy and sustain this offering and the more scarce the substitutes then the more sustainable this competitive advantage will be [5,6,7].

The competitive environment requires that senior business managers think about the organisations competitive strategy. They should be asking strategic questions like: "What are our core capabilities?", "How can we use these and build new capabilities to ensure long term success?", "What are our rare and costly to imitate resources and capabilities and how can we exploit these throughout the organisation to create sustainable value for customers in our targeted market segments?" And more specifically for Maintenance and Asset managers: "how can our maintenance systems and practices be configured to enable the business to create more value for our stakeholders?"

The four generic building blocks of competitive advantage are described briefly below in Table 1 together with examples of how maintenance can be integrated into the broader business strategy and contribute to the development of competitive advantage. This contextualised or situational approach to maintenance optimisation demonstrates how Asset and Maintenance managers can provide leadership and add value in the broader business context. In short, "Plant-specific and environment specific issues should be considered when developing or improving the maintenance system." [8, pp 139].

In support of this, research has found that companies that have implemented strong quality programs (Total Quality Management or TQM); also have strong autonomous and planned maintenance systems (Total Productive Maintenance or TPM). This may be evidence of more integrated strategies being implemented as companies that continue to improve their quality (through TQM), may also need to improve their maintenance delivery system and the overall equipment performance (through TPM) [8].

This integrative approach also recognizes that the maintenance subsystem operates alongside and interacts with a myriad of other business systems. The impact of a change within one part of a maintenance system (e.g. a planned maintenance initiative) will have far reaching effects throughout the business that are not always easy to estimate (e.g. rising inventory costs, decreased staff satisfaction or improved safety performance). It is thus important for maintenance leaders to invite other stakeholders within the business to understand and participate in initiatives that may previously have been considered "maintenance only".

A prime opportunity thus exits for maintenance leaders to work with other stakeholders to explore how the maintenance function can work collaboratively to deliver better value to the business. But having convinced the business that maintenance deserves a place at the strategy table, where to from here?

2.2 Structure and Culture: Key Elements of Maintenance Design

Strategy answers the questions "what do we need to do to compete? and, what are our goals?", the organisation or department then needs to implement this strategy by designing and putting in place the appropriate structures and culture to influence the activities of people in line with the achievement of these goals.

Structure describes the formal system of task and authority relationships that influence how people coordinate their actions and use resources to achieve company goals [6]. Structure typically follows strategy meaning that the role that the maintenance department plays in the overall business strategy should influence how it is structured. Following from Table 1, if the strategy is to be quality focused then the maintenance organisation may be structured so that specific equipment strategies can be meticulously carried out by specialised trades-people, in this case the structure would include detailed formalised procedures for execution and recording of maintenance activities. If the business strategy however is to be first to market in response to customer needs, then developing rigorous equipment strategies or formalised procedures may not be warranted. The ideal structure in this case may be decentralized, lack specific planned maintenance policies, procedures and information systems and be focused on ensuring that all trades-people are highly adept at fixing any type of problem, the so called "jack of all trades". Organisational structure can be configured or designed to suit the business strategy. However structure on its' own means little, unless the culture supports it.

Table 1. Application of the generic building blocks of competitive advantage to maintenance

Building Blocks	**Features**	**Maintenance role in developing competitive advantage**
Efficiency	Efficiency is a function of inputs/outputs. Using the same level of inputs or resources to produce more output; or alternatively, producing a given level of output with less inputs is a factor that can lead to an increased ability to compete.	More efficient maintenance leads to lower costs and improved availability Planned Maintenance initiatives give management the tools to better control the maintenance spend versus equipment reliability relationship.
Quality	A product or service contains a set of attributes such as form, features, reliability, functionality, support and performance. A product is said to have superior quality when it has attributes that customers perceive to be superior to the competition	Better designed and commissioned equipment leads to increased ability to deliver quality products Better equipment maintenance systems lead to increased ability to reliably deliver superior quality products Equipment maintenance strategies developed to sustain functional performance where the defined function includes product quality as well as plant operation.
Innovation	Innovation includes advances in the types, product, production processes, management systems, organisational structure and strategy developed by a company. The ability to innovate is crucial as it is a source of uniqueness, the ability to offer something different to competitors	Maintenance people have equipment and control system expertise and intimate knowledge of the equipment; they also talk to equipment suppliers and could participate in determining what technical innovations could add the most value. Maintenance need to be structured to align equipment strategies and life cycles with the innovation strategy.
Responsiveness to Customers	Responsiveness is the ability of an organisation to identify and respond to customers needs. This leads to customers placing more value on its' products than the competition. Customer Response Time is an important aspect of responsiveness as is the ability to customise an offering to respond to the particular needs of customers or customer groups.	Maintenance need to be structured to support the responsiveness strategy e.g. if being the quickest to respond to a request for a new feature is crucial then the maintenance system must be able to respond to this need for flexibility If the key value driver is being flexible in terms of meeting a customers' "just-in-time" requirements then the maintenance system must support this.

* See [5]

The second aspect of organisational design that needs to be considered to ensure alignment with the business strategy is the culture. Culture is a more abstract but an equally important component of design; it describes the shared values and norms that influence members' behaviours and interactions with each other. The strategy is meant to clearly outline "what we need to do to compete", the structure to formalise "how we should operate to carry out the strategy to achieve our goals". The final piece of the puzzle is the culture which is "what we have learnt to do and what actually gets done". Culture is a key influence on behavior. Behavior is what gets done and people need to do the right things, otherwise the structure and strategy won't work and the goals won't be achieved. Unless the culture promotes those behaviors necessary for achieving success in the organisations' competitive environment (i.e. the strategy); the culture will become a liability for the organisation [10].

So in systems that rely on the coordination and performance of people, such as the maintenance function, improvement implies change. Change implies shared learning and sustained shared learning means a change in the culture. This sounds pretty simple, surely we just have to work out the strategy and structure and communicate this with some training and the culture will sort itself out. Well unfortunately it is not that simple and it is the lack of understanding of the complexities of culture and how to change it that often brings improvement efforts undone. Culture is actually quite complex, it operates across many levels and it is largely intangible. Figure 1 illustrates the often used onion model of organisational culture.

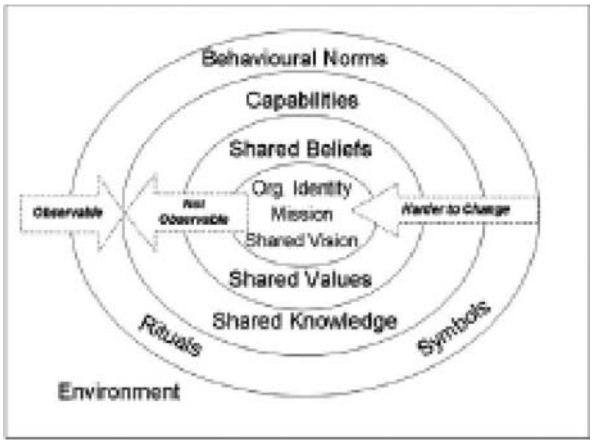

Figure 1. The Onion Model of Organisational Culture

Understanding the complexities of culture requires an appreciation that the systems that people work in are not solely technical systems. The mechanical systems that engineers design and use to manage performance are purposive; their purpose is to perform according to their design requirements. A maintenance function however contains people as well as equipment. Within this technical and social system people generate their own purposes and these do not necessarily correspond to those of the managers so these systems can have many purposes or they are purposeful. What determines an individuals' purpose in any context is their mental models or unique mixtures of beliefs and values [9]. Behaviour, which is what gets done, is the result of the purposes or intentions of employees played out in a specific environmental context.

If the culture is not considered as a part of design and all of the levels in Figure 1 are not aligned across a function or business then the individuals within the system will largely operate according to their own unique beliefs, values and motives. Typically in a maintenance function the culture and structure could reinforce a reactive work environment and the function will add little more value than just fixing breakdowns. Table 2 outlines a typical reactive maintenance culture across the levels of culture and contrasts this with a preventative maintenance culture. It can be seen that there is a significant shift required to move from reactive to preventative. It also becomes obvious why an improvement strategy like "let's just send all the planners to some training and then they can put in place the preventative maintenance system" is almost certain to fail.

Successful cultural change involves aligning all the stakeholders impacted by the system; their identity (what is my role), values (what is important), beliefs (what is the best way to maintain our equipment), knowledge and skills (know-what and know-how) and ultimately their behaviours to be consistent with the formal structure of the organisation. This type of change does not happen through individuals (even managers) working in isolation to design the ideal solution and then impose the change on others. Every key stakeholder has to want to change for the change to work, and every stakeholder has their own purposes, perspectives, and levels of understanding, that they bring to the table. Change occurs in an environment where individuals can share their concerns as stakeholders in the system and then mutually agree on courses of action to obtain the levels of performance that are required. The challenge for leaders is to be able to create the environment that encourages shared understanding and an exploration of the real issues that need to be resolved for a system to work effectively.

This implies an expanded skill set for the maintenance leader; knowledge of maintenance structures and systems needs to be matched with the skills to develop effective relationships between stakeholders and to create meaning and negotiate win-win solutions out of confusing and complex scenarios.

Many prescriptions exist to align the workforce culture with the strategy and the structure. An important ingredient in these prescriptions is 'employee involvement'.

Table 2. Clash of Cultures between Reactive and Preventative Maintenance Departments

Levels	Reactive Cultural Features	Preventative Cultural Features
Environment	Fluctuation between crisis and calmness	In control
Rituals, Symbols	The panicked reaction of the breakdown The status afforded to the most technically astute breakdown expert	Graphs on the wall The morning meeting between supervisor and tradespeople
Behavioural Norms	We play cards until we get the call Everyone drops everything and we together in a crisis Work overtime to get breakdowns fixed work	PM's are done on time and given priority Clear lines of escalation are followed for a breakdown Everyone works to Work Orders
Shared Knowledge	Everyone needs to be able to fix any problem and know all equipment systems / failure modes Short cuts to get the job done	Different types of maintenance activities and performance criteria Understand the concept of planned maintenance Understand different roles we all carry out to make the system work
Capabilities	Crisis management Able to make at least a temporary fix to all but the most serious breakdowns	Detailed and accurate planning, scheduling and execution of planned maintenance activities Able to control maintenance budget in line with optimal equipment availability and reliability
Shared Values	What is important is teamwork in a crisis Quick decision making is important in a crisis We value the time between breakdowns	Data and Measures are important Repair equipment before it breaks Process control is important Everyone understanding the preventative maintenance system is important
Shared Beliefs	Shift-men add the most value and are promoted into higher management The best way to maintain is to wait for the equipment to break, If it isn't broken, don't fix it We don't need systems and measures	Planners and schedulers add significant value and are promoted into higher management The best way to maintain is to work out and then systematically apply individual equipment strategies. We manage by systems and measures
Maintainer Identity Mission and Vision	We fix breakdowns our, mission is to do this as quickly as possible	We work together to systematically eliminate defects from an equipment system

2.3 Employee Involvement

Kearney states that employee involvement (EI) is one of the dominant elements of world-class manufacturing that can make both small and large companies competitive in the global market [11]. EI also "pervades all the other World Class Manufacturing components; TPM (Total Productive Maintenance), JIT (Just in Time), and TQM (Total Quality Management)" [12, pg 42 (parentheses added)]. Recent research also suggests a positive correlation between high levels of employee involvement and both company productivity and long-term financial performance. Manufacturers have also stated that the benefits of EI practices are employee satisfaction, quality improvement and productivity enhancement [11].

EI practices involve structuring the work environment to value employees' participation in processes such as quality improvement groups, problem solving groups, roundtable discussions, or suggestion systems. Employees are given independence in making day to day decisions and may also participate in the design of their own job, planning and scheduling of their own work and in business planning. EI relies on the manager(s) maintaining open communications with employees.

It is important to realise however that EI has its own risks and leadership challenges. A sure and well trodden path to failure comes from granting power to individuals without replacing the command and control (or reactive) structure and culture of the past with a design that provides individuals with the support to develop the knowledge, skills and confidence that they require to exercise the self judgment, discipline and leadership to succeed in their roles [13].

Despite the illusion that managers control employees and "make" them perform; employees make choices as to how diligent they are in working towards achieving their goals and the goals of the organisation. Empowered employees, the ones who make you think "if all my employees were like this, then my job would be easy", choose to do their best everyday and they frequently go above and beyond expectations. These employees are nurtured from a long term and committed effort from senior and local managers to involve employees, to provide them with the appropriate training, feedback and rewards; and by management doing what they say they will. This leadership style promotes trust and commitment amongst employees and results in psychologically empowering (or motivating) thoughts. Four primary thoughts or cognitions have been identified: meaning, competence, self-determination, and impact. In effect, to be their best, employees must believe that what they are doing is worthwhile (meaning). They must believe that they are competent to do what is expected from them (competence). They must perceive that they have choices (self-determination) and they must believe that their behavior will have some influence on what happens in their work environment (impact) [14].

Navigating the path towards an involved and empowered workforce requires the ability to lead individuals, departments and organisations through change; it could in fact be argued that this ability to foster change is the essence of leadership [15].

Both employees and managers need support to become empowered leaders in their workplace so that they in turn can assist others to change in line with the needs of the business. To achieve this effective people management practices are needed to effectively align strategy, structure and culture [16].

3 A SYSTEM TO MANAGE PEOPLE PERFORMANCE

Similar to the journey of Asset Management, People Performance Management (PPM) practices have also undergone a search for strategic relevance over the last 30 years. Whilst maintenance and engineering functions attempt to manage equipment across its' lifecycle in the best strategic interests of the business, PPM practices have focused on implementing and supporting business processes that do exactly the same thing for the people, i.e. recruitment and selection, training and development, workforce planning, performance management, career and succession planning and remuneration and reward. [16]. The analogy continues when one considers that an equipment breakdown is equivalent to a people management breakdown (a workforce strike) and preventative or proactive maintenance is akin to high levels of employee involvement and empowerment [17].

PPM practices are described by an integrated set of processes (system) that define, support, assess and reinforce employees' behaviors and results that are required for business success. The system enables maintenance leaders to implement and manage the framework described in the previous section.

PPM provides the means to set clear expectations of; the outcomes needed to meet stakeholder expectations, the activities (roles) required to make the structure work and the behaviours and values consistent with the culture and the optimal performance of roles. Individuals are appraised and given feedback, training and support so that all activity is directed towards business goal achievement. People are motivated by receiving positive feedback, training and by having personal interests, career plans and rewards aligned with business needs.

The result is a motivated, focused, competent and committed workforce, that can use work processes more effectively and efficiently to deliver better value to business stakeholders.

4 A HOLISTIC APPROACH: WHERE IS THE EVIDENCE?

It is relatively simple to measure the performance of tangible assets like equipment, using such measures as Overall Equipment Effectiveness (OEE). Measuring the performance of intangibles like people performance is far more difficult.

On a business scale there is a significant amount of research purporting the benefits from utilising the leadership framework and PPM. One research study collected data across nearly 1000 organisations on the link between their High Performance Work Practices (HPWPs) and hard measures of company performance such as employee turnover, sales revenue and profit. Companies were thus assessed on their adoption of HPWPs, which were divided into two major factors (i) employee skills and organizational structures and (ii) employee motivation. Employee skills and organizational structures describe mechanisms where employees could enhance and use their knowledge, skills, and abilities to perform their roles. More specifically job design programs, improved selection processes, formal training, quality of work life programs, quality circles, and labour-management teams were all assessed. Information-sharing programs, formal grievance procedures and profit- and gain-sharing plans help to increase the probability that employee participation were also a part of this factor. The employee motivation factor was composed of a more narrowly focused set of High Performance Work Practices designed to recognize and reinforce desired employee behaviours. These practices include using formal performance appraisals, linking those appraisals tightly with employee compensation, and focusing on employee merit in promotion decisions. It was found that the magnitude of the returns for investments in HPWPs is substantial. A one-standard-deviation increase in HPWP's yielded a relative 7.05 percent decrease in employee turnover, $27,044 increase in sales, $3,814 increase in profits and $18,641 increase in (company) market value annually on a per employee basis [19].

Further evidence comes from a case study in an Australian steel manufacturer (Australian Maintenance and Engineering Excellence Award - 2005) where the mechanical maintenance department was functioning in a well controlled preventative manner. Yet the electrical maintenance section was still deeply entrenched in a reactive culture and structure that reinforced breakdown management as the predominant mode of operation and did not believe that preventative maintenance principles could apply to electrical equipment. Electrical equipment performance was limiting the overall equipment performance of the maintenance department.

To promote a change within the electrical section sponsorship was provided from operations, production and maintenance management and other stakeholders included the electrical tradesman, a union representative and the production shift managers were engaged. Together an electrical design was formulated that outlined the ideal culture and structure required for the electrical section to function effectively alongside the mechanical section and meet the goals of all stakeholders. This shared vision that was developed through involvement of key stakeholders was then successfully implemented through consideration of both the soft (e.g. open and regular communication to teams and individuals, wide involvement, employee satisfaction) and hard (e.g. CMMS and process training, documented roles and procedures, targets were agreed around the break up of maintenance activities, openly displayed hard performance measures) aspects of change.

The result was that electrical maintenance equipment reliability improved to the point where it was no longer the bottleneck on the overall maintenance performance. In addition the new understanding and level of trust that emerged between electrical and maintenance personnel lead to the cooperative resolution of many issues that had previously been explained as the electrical sections issues. Perhaps the best evidence of cultural change comes from the electrical shift workers, who traditionally are dedicated to reactive maintenance; in the electrical section they are now spending over 30% of their time on planned and scheduled preventative maintenance activities and are key supporters of the new system

The evidence is thus starting to mount that this holistic approach works, people who recognize and respond to this will be the leaders of the future.

5 "WHERE ARE WE NOW - WHERE DO WE NEED TO GET TO"

The rapid development of technology, the ever increasing focus on customers and the ever expanding globalisation of markets are leading to the increasing need for organisations to be more responsive and competitive. Only those organisations able to respond to these challenges will succeed. The challenge for maintenance and asset managers is to collaborate with other business leaders to define, implement and nurture the structures and cultures that will enable the business to succeed. Doing this will require a new set of leadership skills; they will behave in a way that demonstrates that the people who operate and maintain the equipment assets are a key component of their success. Typically this will involve designs that encourage and support a flexible and empowering work environment.

Not to forget the importance of the technical side of improvement. Along with the need for involvement and empowerment and effective people management practices, there is also a need for a well understood system and for processes (e.g. equipment strategy) and tools (e.g. a CMMS) that operate and interact with other business systems in alignment with the business strategy. So it is a holistic approach; leadership plus systems, tools and technologies (to automate systems and manage data) plus competent, empowered, satisfied, performance focused people that will deliver plant performance to meet business goals.

It is difficult to fully understand, to bring everything together and consider all the relevant aspects of a holistic approach, particularly if you extend this to thoughts like; "where are we now" and "where do we need to get to". Organisational audit or assessment methodologies that consider such a holistic approach to improvement do exist. Models are available from The European Foundation for Quality Management, Maintenance bodies - MESA (Aust), SMRP (USA), IFRIM (EU) and The Australian Business Excellence Framework to name a few.

Maintenance and asset managers are thus encouraged to engage the support they require either from within their business or from the wider business community, and to go on a journey to become leaders and to further foster leadership throughout their organisation.

“THE END OF THE BEGINNING”

Ross Francis

Ross Francis Consulting Pty Ltd

Abstract: Plant commissioning is possibly the shortest process in the asset life cycle of major assets. It is a critical time in the life cycle and a phase that frequently gets little attention. Never before this period and never again is there such a frenzy of activity and an accumulation of excited people with differing expectations and influences.

- **What is involved in the process?**
- **When does commissioning start and when does it end?**
- **How do we manage this process it to the best advantage?**
- **Is it too late to have any significant positive impact on asset life?**
- **Can poor commissioning have an adverse impact on reliability, integrity and life?**
- **How do differing expectations, influences and constraints affect the outcomes?**

Commissioning is the time when you first see the conceptual plant in its physical form and realise what you have got, what you haven’t got and the gap between what you wanted and what you will live with. It’s a time of good news and bad news but also a time when good management can still have an influence on the ongoing asset life cycle.

Keywords: Commissioning, asset life cycle, commissioning process, reliability, asset integrity, expectations, constraints, project, construction, operations, commissioning management, operate & maintain, operability, maintainability, strategic approach, start-up curve, handover, documentation, training, schedule goals, sub-systems, commissioning phases, alignment, change management.

1 INTRODUCTION

Plant commissioning and project handover is possibly the shortest process in the asset life cycle of our assets. It is, however, a critical time and a period that can be quite confusing and difficult to manage. Never before this period and never again throughout the long life span of an asset is there such an frenzy of activity and an accumulation of excited people with differing expectations and influences.

- What is involved in the process?
- When does commissioning start and when does it end?
- How do we manage this process to the best advantage?

- Is it too late to have any significant positive impact on asset life?
- Can poor commissioning have an adverse impact on reliability, integrity and life?
- How do differing expectations, influences and constraints affect the outcomes?
- Do sound commissioning principles apply to ongoing minor projects, modifications and scheduled plant shutdowns?

Commissioning is the time when you first see the conceptual plant in its physical form and when you realise what you have got, what you haven't got and understand the gap between what you wanted and what you will live with. It is the moment of truth, a time of good news and bad news but also a time when through good management we can still have an influence on the ongoing asset life cycle.

2 COMMISSIONING & ASSET LIFE CYCLE

On a time scale Commissioning occupies a very small part of the Asset Life Cycle as shown in Figure 1 below. Depending on the industry and types of equipment, the commissioning period is often days or weeks in a total life cycle for the assets of several decades.

Generally the Asset Life Cycle is shown with the four main phases of Plan / Design, Construct / Acquire, Operate & Maintain and Dispose / Divest. Commissioning is usually regraded as part of the pre-operations phase but in fact it fills a very small fissure between the Construct / Acquire and the Operate & Maintain phases. This often means that it falls between two quite different groups (Construction & operations) even if it is managed and resourced internally in the operating organisation. Because of the short time available and its place in the big picture it is a process that is frequently under managed, under resourced, poorly planned, and given a low priority often leading to ongoing operational difficulties. Efficient and effective commissioning requires a strategic approach, clear thinking, a sound process as well as committed and dedicated management.

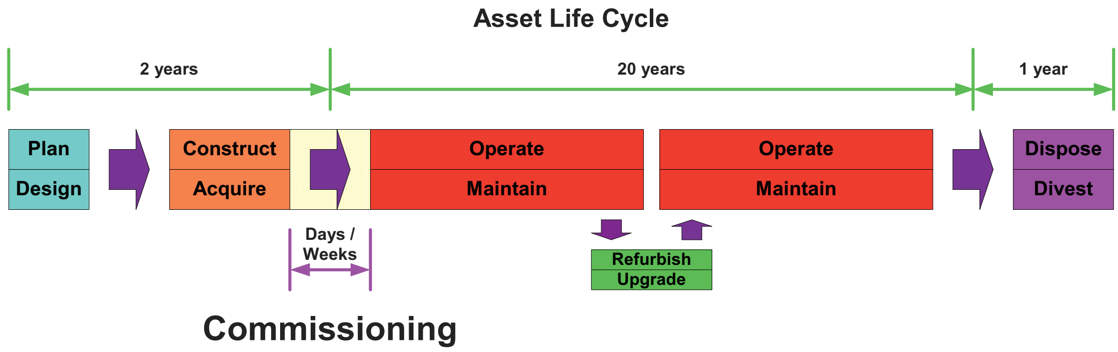

Figure 1

3 THE GOALS

- A strategic approach begins by establishing Commissioning Goals. These may include:
- Secure an efficient and quick start-up of production facility (start-up curve)
- Validate that the project construction team has installed according to the design requirements
- Ensure 100% mechanical, electrical and automation tests done before production start-up
- Clarify management processes and responsibilities before handover

- Demonstrate and document that all plant and process systems are operational
- Identify deficiencies and make corrections
- Adjust or modify equipment for best operability and maintainability
- Maintain cost, time, quality and OHS&E control to defined standards
- Phase out of construction and phase in of operations
- Complete handover documentation
- Ensure operations receive the appropriate hands on training and exposure during this time
- Progress commissioning in accordance with project requirements and long-term asset goals

4 COMMISSIONING PROCESS

Activities performed on a construction site after installation and before start-up are called ***Commissioning***. The objective of the commissioning process is to bring the plant into production with a minimum of problems. During the commissioning there is a finishing of construction, and a concentrated focus of machine vendors and a phasing in of maintenance and production activities. This complex operation in the life cycle of a facility, when it changes from the Construction / Acquire Phase to the Operate / Maintain phase, is shown in Figure 2 below.

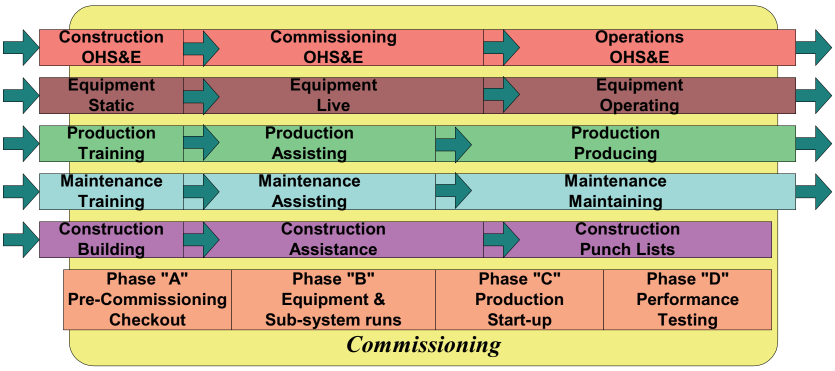

Figure 2

This picture illustrates that the roles of people involved in construction and plant operations change in nature during commissioning along with many key activities such as construction, maintenance, OHS&E. The installed equipment too changes from dormant to live, dirty to clean and untidy to orderly.

It is this phasing effect that makes it difficult to place the commissioning process in either of the main Asset Life Cycle phases on either side (Construct / Acquire and Operate / Maintain).

The commissioning process is depicted in simple terms in Figure 3 below. Although the process flow here is really concerned with the short term of the commissioning activity it can be seen from the list of inputs that the complete process of commissioning commences very early in design and is re-visited at critical stages during the Plan / Design and Construct / Acquire asset life phases.

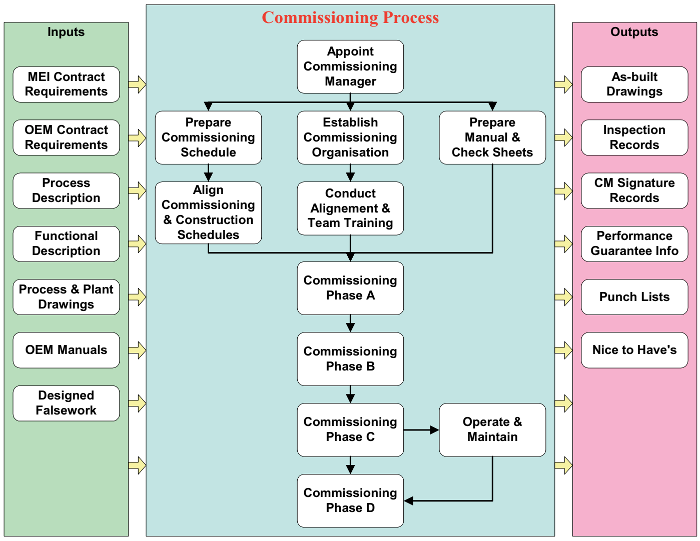

Figure 3

5 THE FOUR PHASES OF COMMISSIONING

Early planning during the construction phase and the preparation of an appropriate strategy for the plant commissioning is important to later success. This must be purpose generated to suite the circumstances and will obviously vary from project to project dependant on the plant configuration, contractual responsibilities of the parties and the requirements of the end user. A strategy for a large project for example may have, as it's key premises: -

- Divide the plant into manageable sub-systems
- Arrange the sub-systems into a logical sequence
- Assign target dates for the construction completion of each sub-systems
- Progress commissioning in pre-determined phased sequence
- Commissioned support systems (services) first followed by process systems

Having determined the overall strategy and established procedures for all parties to follow, the physical commissioning work can then proceed on a phased basis. Major phases for a process plant may include: -

- Phase A – **Installed Testing -** Normally the direct responsibility of the construction management company and / or the MEI contractors. This includes installation checks, point-to-point checks, system flushing and equipment rotation.
- Phase B **- System Checks** – The responsibility of commissioning team. Involves running equipment and conducting inspections and tests and checking operation to design. This critical phase would also be used as an opportunity for training of operators and maintenance personnel in the practical aspects of the new plant operation.
- Phase C **- Production** Dry and Wet Running. Still the responsibility of the commissioning team but a key time in the handover to operations
- Phase D **- Performance Guarantee** Testing. Carried out at appropriate times during the final stages of production runs or final operations.

A good method of illustrating and managing commissioning is to view it in four phases A, B, C & D as indicated in the Figure 4 below for a process plant (Pulp & Paper) commissioning:

5.1.1.1.1.1 5.1.1.1.1.2 PHASE	A **Completion of Construction**	A **Installed Testing**	B **Water Runs**	B **Stock Runs**	C & D **Production & Start-up**
RESPONSIBILITY	Construction Suppliers	Construction Suppliers	Commissioning Construction Suppliers Operations	Commissioning Construction Suppliers Operations	Operations Suppliers
MEDIUM	None	None	Water	Stock	Stock
MECHANICAL, PIPING & CIVIL	Complete erection Grouting Cleaning Supports Painting Punch lists	Vendor checks Safety, guards Visual Internal inspections Drive belts Alignment Lubrication Hydrostatic	System flushing Isolations on Supplier tests Service tests Functional tests	Operation Supplier tests	Acceptance Handover Optimisation Performance & Guarantee tests Full system start-up
ELECTRICAL	Installation complete Control circuits Power ready Point to point	Emergency stops MCC activated Rotational tests Dry interlocks Group starts	Interlocks Groups starts Motor loads Validate process description	Motor loads Interlocks Groups starts	Automatic ops

Figure 4

6 ORGANISATION

All stakeholders must feel ownership, take responsibility and facilitate the transition of ownership. This requires a sound, fluid, composite structure and the appointment of a suitably experienced "independent" Commissioning Manager. The manager should be a person experienced in project work as well as operations and have sufficient status to be able to manage all of the parties involved. A generic organisation chart is shown in Figure 5 below.

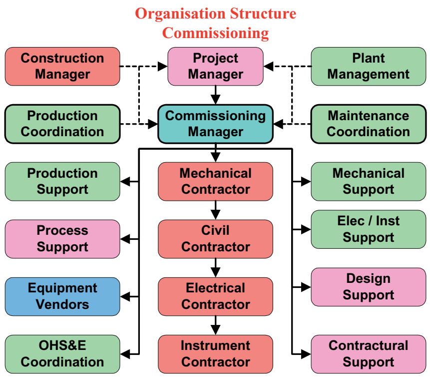

Figure 5

The commissioning manager key responsibilities include:

- Alignment of all parties involved in Commissioning of each major plant section
- Coordinate contractor commissioning assistance
- Manage changes required to process and equipment and as necessary call for revised HAZOP
- Manage the affixing of "Ready For Testing" tags and the issue of "Notice of Energisation" and all applicable OH&S requirements
- Conduct commissioning progress review forums
- Preparation of commissioning action lists
- Problem resolution directly or via appropriate referral
- Manage the handover from construction to operations
- Manage handover package (documentation) delivery
- Ensure environmental requirements are covered
- Ensure all parties work together for the same agreed goals

An early involvement is required for the commissioning manager so he can:

- Development of a comprehensive procedures manual incorporating all relevant existing operational and safety procedures
- Determine plant boundaries covered by the commissioning procedures
- Define and communicate the commissioning manager's responsibilities
- Coordinate the development of commissioning check sheets and books
- Define live equipment tagging procedures for those areas of plant not covered by the existing danger tag procedure.
- Clear determination of all relevant contracts clauses covering any aspect of commissioning
- Ensure new confined space and other procedures
- Determine required sequencing of runs, flushing, start-up etc
- Coordinate commissioning responsibilities
- Determine shift requirements
- Determine communication requirements (e.g. radios)
- Coordinate the preparation of a commissioning schedule

There are many players in the commissioning melting pot including:

- Contractors - mechanical
- Contractors - civil

- Contractors - electrical
- Contractors – instrument
- Project management & staff
- Design team representatives
- Equipment OEM & vendor representatives
- Government authorities
- Production personnel
- Maintenance personnel
- Training staff
- Auditors
- Senior management
- Public relations
- Visitors & spectators

The Commissioning Manager will coordinate and manage these individuals and groups who all come to the scene with widely differing priorities and backgrounds.

An early involvement of maintenance and production personnel, preferable those involved in design. This is important from a training perspective and also to get the early hands on experience necessary to continue into operations

6.1 COMMISSIONING ARRANGEMENTS

There is a range of normal project and operational management activities that continue through commissioning, however a few need emphasis during commissioning and a concentrated effort from the Commissioning Manager:

6.1.1 Alignment

Even if an alignment was conducted for the project at commencement it is important to have a specific alignment for the commissioning phase. This is an excellent way for the Commissioning Manager to kick off the process. It is important for all to understand how this time is seen through the eyes of others and to align the team to one set of goals and a common schedule

6.1.2 Communication

Extra effort on person-to-person communication and information circulation are essential to maintain a clear focus and to maintain efficiency across all work groups. Schedules are important as are punch list etc but time is too short to miss a daily all-in communication where issues and priorities can be raised

Daily stand up communication meetings to keep all stakeholders informed, decide on the daily priorities in accordance with the schedule and to allocate small teams or individuals to resolve issues that arise

6.1.3 OHS&E

A critical topic for the commissioning phase and as a minimum must be discussed at the daily meetings. Apart from the work complexity, housekeeping challenges this is a time of significant change from project to operational conditions.

Tagging of equipment to ensure that visually all site personnel are aware that equipment is changing from dormant to active. The concept is to have site equipment tags to inform all parties of the condition and inspection stage of every piece of equipment and to have an overall picture recorded progressively in a master folder.

6.1.4 Training

Production and maintenance training would have commenced well prior to this time. It is important however to capitalise on the unique opportunity to understand the new equipment from personal learning and technical aspects, data collection, instrument settings performance measurement and vibration signatures etc.

A wide range of personnel can get experience and learning by being involved with equipment activities such as equipment numbering and tagging, pipeline identification, checking installation and equipment to drawing and inspecting for operability and maintainability. Allocating appropriate technicians and operators to OEM's is critical.

6.1.5 Procedures Manual

Although each project is unique a procedures manual should include the following key sections: - introduction / purpose / structure, safety, isolations (testing & operations), confined space, environment, commissioning procedures, commissioning schedule, organisation, responsibilities & relationships, communication channels, handover, regulatory requirements, general procedures, vendor requirements, contacts etc.

The procedures manual can be combined with the master handover records file required to capture all inspection, test and defect information.

6.1.6 Schedule

It is important to have a schedule for all commissioning activities specifically construction, commissioning and production. The schedule will allow for inspections of the installed equipment, actioning of high priority punch list items and dovetail in with the completion of construction schedules that may continue on into the commencement of commissioning

The Commissioning Manager will manage the process to ensure that the work is carried out systematically and in the correct sequence. The sequence is important to keep personnel focussed and also to allow for system operational constraints that require some equipment and systems to be functional before others. Generally services need to be commissioned first

6.1.7 Change Management

Commissioning is the most comprehensive change management exercise that will be undertaken by a manufacturing organisation. Changes will impact on, or be influenced by, all areas of business including:

- People - recruitment, training, technical and operational safety knowledge, and communication.
- Process - design, regulatory, process descriptions, safe operating limits, and abnormal operations.
- Assets - physical changes, design standards, regulatory requirements, CMMS, accounts, procedures, records, maintenance regimes.
- OH&S - legislative (e.g. MHF) requirements, Safe working environment, dangerous goods
- Environment- approvals are gained and records modified
- Business - objectives, economic or on non-economic justification
- Procedural - codes, standards (internal and external)
- External - quality of feedstock, delivery arrangements, transfer equipment, upstream process changes, services supply, land use change, addition of plant or changes to nearby facilities.

It is important to have change management processes in place. Clearly some of the change process commences very early in the project, however it is during commissioning that it all becomes critical.

It is important to have a review and approval / rejection process for plant changes (modifications) that are raised. As a minimum they should be categorised into must do, do at some time and "nice to have's" to be listed for review and justification. Whilst not forgetting the project imperatives of cost, time, quality and scope any defects or unsatisfactory operability and maintainability aspects will most likely remain with the assets for many years.

7 WHERE DO WE GO WRONG?

7.1 People & Processes

Many of the problems in commissioning emanate from operations and project management not giving the commissioning processes and the commissioning team sufficient importance, authority and attention. This results in organisational and people aspects not being effectively controlled. Some of the key aspects are:

7.1.1 Alignment & Involvement

Not having an alignment or not have a complete (all stakeholders) effective alignment severely impacts on the success of the commissioning process.

7.1.2 Involvement

Not having the right people available or dedicated to the project at the right time. It is important to involve production and maintenance people from very early design. Unfortunately this involvement is not always seen as a priority at that time. This extends to not making a commitment in design phase or then again at commissioning to dedicate operations maintenance and production personnel to the project. Commissioning is a time where a large number of tasks must be completed. It is also the best time for training. Operations people involved at this stage get an unparalleled learning through experience opportunity that cannot be equalled late in the asset life. There is also the opportunity to influence the equipment and process that is finally handed over.

7.1.3 Communication

Commissioning is not a controlled ongoing situation that most are used to in industry and neither is it a controlled steady change as in a project, rather it is a constantly changing environment with errors, omissions, oversights, defects and physical changes coming to the forefront. There can never be enough communication, particularly face-to-face and particularly between combatants that may normally communicate only infrequently. Special effort is required to achieve an integrated effort from all of the participants and this area requires alert commissioning management.

7.1.4 Training & Understanding

The introduction of bad practices through low involvement from the early project conception and poor training prior to and during commissioning. Irreparable damage can be caused to machinery by operators and maintainers not running the plant the way it was designed to be operated. This leads to frustration, breakdown, and incorrect operations leading to very early requests for plant modifications. "Read the instructions first" still applies.

Formal training is essential there is no substitute for a wide range of plant people developing an in-depth understanding of the equipment and production process design and how it is meant to operate.

7.1.5 Process & Procedures

Operations management often assume that commissioning will occur as a natural part of the construction project, and what they miss will be picked up once it is operational. They frequently fail to realise that there are some very specific processes that must be put in place and managed. An organisation is only as effective as its processes. The process is best presented to the complete team in the form of a Procedures manual.

7.1.6 Schedule

Most participants enter the commissioning phase with their own departmental schedules that they have been working to, particularly project schedules, or the schedules that are in front of them, notably the forward production forecasts and associated budget promises.

7.1.7 Change Management

Regrettably most plants commence operations with inadequately prepared work teams, particularly from the aspect of understanding the changes and the differences to the old plant they are so familiar with. Engineering and maintenance documentations and technical data frequently is slow in being delivered and inadequate. This is compounded by the operations people not being mobilised in sufficient time before operation commences.

Inadequate data and documentation emanates from not tying down the documentation requirements at the design phase and not specifying documentation and schedule requirements at negotiation and purchase time.

7.2 Engineering & Equipment

Failure to set up the commissioning team adequately will result in short cuts being taken often resulting in damage to machinery occurring, often unnoticed at the time. Below are a few examples of minor problems that can have lasting deleterious effects on the plant, subject operations people to unnecessary personal risk and increase the ongoing cost base:

7.2.1 Design

- Valves that need to be operated frequently being place above floor access level and no fixed means of access.
- Poor lighting in dark corners
- Pumps positioned so that piping prevents crane access for maintenance
- Long equipment aligned incorrectly for 2 hoist crane lifts
- Poor access to key pieces of equipment resulting in excessive manual efforts for maintenance and operations

7.2.2 Construction

- Grouting installed to ensure water is trapped and diverted in under sole plates – unfinished work
- Hurried appearance painting in place of protective coating
- Improper line flushing and screening with foreign material remaining in the systems
- Pipe supports not in place
- Forgetting to grease, not recognising that some remaining orifices are in fact grease points or over greasing

7.2.3 Inspection & testing

- Sealing water systems forgotten and not operational
- Plastic, wood, oil dry in the wrong places so that it can enter the process system

- Leaving an oil filler cap of the hydraulic system and undoing all the pre-commissioning filtration and reducing the equipment life.
- Making assumptions on equipment condition before inspection and testing is complete
- Failure to run in equipment such as seals

Significant design problems that do not have an immediate effect on the plant operation is unlikely to be corrected at commissioning and will have a detrimental effect on life cycle operations thereafter. Other items, such as valve access, can be corrected during construction and during the frenzy of project completion at commissioning. This can only occur by having some budget provision and people with appropriate experience "on the spot" to pick up these items and initiate the corrective actions.

8 WHAT CAN WE DO

Is commissioning the end of the beginning or the beginning of the end? It could be the start of premature asset degradation if errors occur and are not noticed during commissioning, or if poor start-up practices are adopted, even if unwittingly.

Good start-up and long asset life can be assured by having experienced maintenance and production people involved in a project from a very early design stage. This needs to be seen as a priority from an asset life cycle perspective. Although the vast majority of asset life cycle costs occur during the long (20+ years) operate and maintain phase the opportunity to influence this in terms of maintainability, reliability, operability, integrity and life is at critical times during the design phase. There is a further very small but important window of opportunity to further this cause during the phase of commissioning. Regardless of how many drawings we study, even three dimensional walk throughs, there is no substitute for seeing the new plant in real life and making final corrections within the project constraints.

Sound commissioning principles certainly apply to ongoing minor projects, modifications and scheduled plant shutdowns. In many industries shutdowns are infrequent and of relatively long durations (weeks) resulting in a natural tendency to employ project management techniques and sound commissioning and handover processes. Other industries, however, have more frequent and smaller duration shuts (hours / days) and the pressure to produce often results in the sound commissioning principles being bypassed. Unfortunately this has the same effects as project commissioning in that it will affect the performance and life of the assets. The same sound principles need to be applied to these operational aspects including the appointment of a Shutdown Manager (cf. Commissioning Manager) for all shuts. Even the smallest of "projects" require the same change management and commissioning principles and practices.

The most important thing we can do is to educate all stakeholders, particularly senior management, in the importance of life cycle considerations and the importance of each phase. Project specialists are notoriously poor at developing any understanding of the life cycle. Their focus is different for obvious reasons and centres on the project time and cost budget. It is often said that quality is a given but this is only so if the correct input is applied. In all aspects it is important to take a long-term strategic asset view to achieve best benefit from the commissioning process.

VALUE DRIVEN PREVENTIVE MAINTENANCE ACTIVITIES USING QUADRANT ANALYSIS

Deryk Anderson

Oniqua Enterprise Analytics, Brisbane, Queensland, Australia

Abstract: An organization's maintenance strategy may consist of many thousands, even tens or hundreds of thousands of preventive maintenance activities. These activities, properly executed, determine the success of the preventive maintenance program. The management of large volumes of preventive maintenance activities is a challenge for maintenance practitioners. Maintenance activities do not exist as a single entity within the work management system, and it is often difficult to associate performance indicators with individual activities. Additionally the lack of a methodology for segregating and managing activities as a whole has not been well documented. Quadrant Analysis can be used to visualize and segregate maintenance activities based on simple measures of business risk, cost and performance. This paper explores the application of quadrant analysis to the management of preventive maintenance activities. Actual data is demonstrated and shows how quadrant analysis can be used to drive strategies for data collection, determine causal analysis strategies, and apply risk based maintenance analysis. Examples and case studies from Australian and overseas organisations are presented in this paper.

Key Words: Maintenance, Strategy, ERP, EAM, CMMS, PM, Quadrant, Boston, Matrix, Analysis, Activities, Risk, Cost, Analytics

1 INTRODUCTION

Asset intensive organisations in the private and public sectors rely on assets to provide products and services. The ability of these organisations to provide desired service levels, function safely (with regard to personnel, public and the environment), and economically or profitably is dependent on the effective maintenance of these assets. The assurance of asset capability [1] to meet these business objectives is the role of the maintenance function.

Preventive Maintenance designed to avoid unplanned component failure [2] is an essential part of a maintenance program. The preventive maintenance program consists of a multitude of time based activities that are directed at assets and their components. The development and continuous improvement, or management, of these activities should require a significant proportion of the maintenance management effort.

The challenge for maintenance is to effectively manage large volumes of Preventive Maintenance activities. This paper explores the application of quadrant analysis to the segregation and development of policies for the ongoing management of preventive maintenance activities.

2 PREVENTIVE MAINTENANCE

In this paper the term Preventive Maintenance [3] refers to any activity that is designed to:

- Predict the onset of component failure,
- Detect a failure before it has an impact on the asset function,
- Repair or replace asset before failure occurs.

Based on available literature, it is most likely that the development of failure prevention and management policies for most facilities will be based on a combination of:

- Operational research;
- Risk based maintenance analysis;
- Quality approach;
- Non-Risk Based Approach.
- Event and situation analysis.

These categories are described in the following sections.

Operational Research

Operational research is concerned with defining quantitative solutions to problems of Maintenance Management. The approach is to define a maintenance problem in logical terms and then express the problem as a mathematical relationship. The solution to the maintenance problem is then derived from the solution to the mathematical relationship. Operational research in maintenance is typified by work by Jardine [4], which describes models for maintenance strategy decision making based on the analysis of historical data

Risk Based Maintenance Analysis

Risk based analysis refers to the development of failure prevention and management policies based on an understanding of the consequence and probability (hence risk) and modes of failure of an item. Methodologies that describe the development of failure prevention and management policies are numerous and often amount to variations of a similar fundamental approach.

This type of approach is typified by inductive techniques such as Reliability Centred Maintenance [5]. Other examples of these techniques are Failure Modes, Effects and Criticality Analysis (FMECA) [6].

Quality Approach

The Quality Approach refers to methodologies for developing maintenance strategy influenced by Quality Management approaches, which emerged from Japan in the 1940's. These systems provided the foundation for the evolution of quality maintenance systems which were initially aimed at the application of quality tools to maintenance related problems. The quality school of maintenance includes Total Productive Maintenance (TPM) described by Nakajima [7], "Total Productive Maintenance (TPM) is productive maintenance carried out by all employees through small group activity. In TPM the machine operator is responsible for the maintenance of the machine, as well as its operation.

Non-Risk Based Maintenance Analysis

Non-Risk based maintenance analysis refers to the development of failure prevention and management policies without understanding the consequence and probability of failure of an item. These methodologies are classified as:

- Manufacturer's recommendations
- Personal Experience
- Past practice

Event and situation analysis

Failure prevention and management policies are developed to produce certain outcomes described by the objectives of maintenance. These objectives make specific assumptions about organisational and operational requirements and conditions. The development of maintenance strategy is also carried out with the use of the best available knowledge about item reliability, local work practices, and external (e.g. legal and regulatory) requirements. With time, these elements may change, and the maintenance strategy must change to remain relevant to the original maintenance objective (i.e. it must be a dynamic and evolving strategy).

A facility can be made up of thousands of individual assets, tens or hundreds of thousands of individual components [8] and tens or hundreds of thousands of individual maintenance activities. The development and management of maintenance activities for facilities of this magnitude is an enormous undertaking in terms of effort and data management. If a maintenance analyst was to do nothing else but review the performance of 10,000 maintenance activities over the course of one year – the application of simple mathematics shows that they would have just over nine minutes per activity to devote to the task. There is a need to be able to segregate maintenance activities for control purposes.

2.1 Control of Maintenance Activities

In many businesses, Preventive Maintenance activities have been established over time with little technical discipline supporting the decision process. This has resulted in Preventive Maintenance activities that:

- Are ineffective in detecting the onset of failure,
- Duplicate the effort of other preventive activities,
- Are missing for critical failures.

Control of the maintenance activities involves modifying the description or timing of the activity as changes are detected in the performance of assets or the organisational environment in which the activity is applied. This control can be required for the following reasons:

- The original assumption on which the maintenance strategy was developed is now wrong (e.g. incorrect assumption about failure rates or failure consequences)
- Changes to equipment design or parts supply

- Changes to the organisational or operational environment or requirements
- Changes to external environment or requirements.

The effective control of maintenance activities is challenged by the volume of activity data as well as a lack of classification of maintenance activities and a framework for their segregation and management.

3 THE NATURE OF PREVENTIVE MAINTENANCE ACTIVITIES

A preventive maintenance activity is a specific instruction to perform a maintenance action to address a specific failure mode or range of failure modes for a particular component. Simple examples (additional information would be required to represent a quality instruction) of preventive maintenance activities are:

- Check Gearbox Oil Level every 3 Months;
- Replace Oil Filter every 1000 Hours;
- Measure brake pad thickness every 5,000 kilometres.

Preventive Maintenance has a few apparent features or attributes: An activity to be performed, a frequency or interval (the timing) at which the activity is performed and material and labour resources required to perform the activity. The maintenance planning process generally assumes that all maintenance activities are equally important, and it is difficult to discriminate between activities just by the attributes stored in work management systems. In reality there are many other attributes of a maintenance activity. For the purpose of this paper, examples of these attributes are limited to:

- Criticality – The impact of the particular failure mode of a component that the maintenance activity is designed to prevent;
- Cost – The labour, material, services, overhead cost of the maintenance activity;
- Frequency – The frequency or interval of the maintenance activity;
- Repair Time – The average repair time of the failure mode of a component that the maintenance activity is designed to prevent;

These attributes are explored in the following sections.

3.1 Criticality

Criticality describes the impact of a failure in terms of its effect on the safety and profitability of the business. An example of a means of classifying equipment is demonstrated in Table 1.

Table 1 – Assets Criticality Rating [3]

Code	Criticality	Business Impact
S	Safety / Environmental Critical	Safety / Environmental
10	Major impact on output of all machines/lines, contributing to long factory outages. Orders lost on all products.	Total Loss of Production
9	Major impact on output of one or more machines/lines, contributing to long machine/line outages. Orders on specific products are lost.	Total Loss of Production
8	Significant impact on output of all machines/lines. Inability to meet customer order quantities by delivery dates.	Partial Loss of Production
7	Significant impact on output of one or more machines/lines. Unable to meet specific product order quantities by delivery dates.	Partial Loss of Production
6	Minor impact on output of one machine/line. Production can be rescheduled. Unable to meet some customer orders for a specific product by delivery dates.	Partial Loss of Production
5	Loss of assets with 100% capacity backup. Failure of backup assets will affect ability to meet customer order quantities by delivery dates.	Negligible Impact
4	Loss of assets with some contingency or buffer storage. Significant impact on output of single machine/line (with no affect on ability to meet orders).	Negligible Impact
3	Loss of assets with significant contingency or buffer storage. Significant impact on output of single machine/line (with no affect on ability to meet orders).	Negligible Impact
2	Minor impact on output of single machine/line (with no affect on ability to meet orders) e.g. short reduction in production capacity.	Negligible Impact
1	No affect on output of any machine or process line within repair time.	Negligible Impact

The application of criticality ratings to individual maintenance activities in a case study from [3] is shown in Figure 1. This chart shows that a high proportion of activities, by cost, were directed at the prevention of "Negligible Impact" failures or failures with low levels of "Loss of Production".

The application of the criticality attribute provides one way to discriminate between maintenance activities. There may be an opportunity to reduce maintenance effort on equipment failure modes with negligible impact.

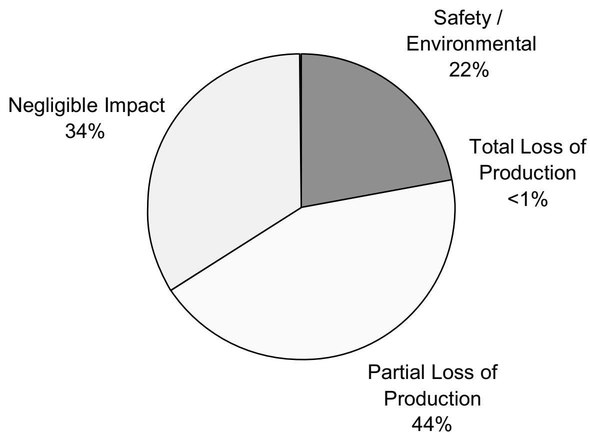

Figure 1 - Preventive Maintenance Activity against Business Impact

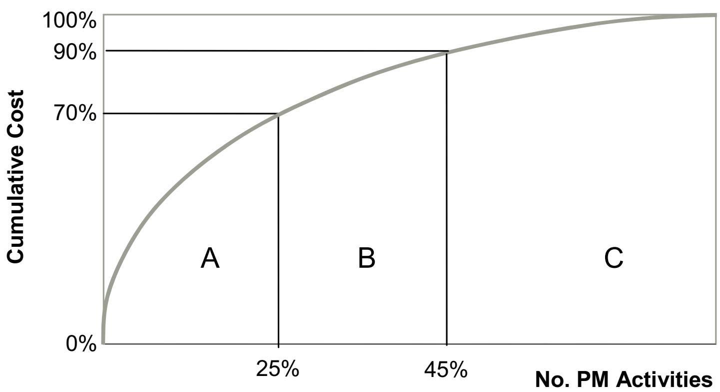

Figure 2 – ABC Analysis [3]

3.2 Cost

The total cost of performing a maintenance activity is the summation of labour, materials and services costs. One means of discriminating maintenance activities by cost is to use an ABC analysis - a common method for classifying inventories aimed at identifying critical inventory items. ABC classification is based on the Pareto Principal (Vilfredo Pareto (1848 – 1923)), that a relatively few items account for the majority of any given result. ABC classification argues that a relatively small number of inventory items account for the major part of the total inventory value. When applied to Preventive Maintenance activities a similar pattern is seen.

Figure 2 shows the results of applying ABC analysis to the Preventive Maintenance activities in the case study. The graph of Figure 2 shows that:

- 70% of Preventive Maintenance Costs were incurred by 25% of the Preventive Maintenance activities
- Just under half of the Preventive Maintenance activities accounted for 90% of Preventive Maintenance costs

ABC Analysis is another way of discriminating between maintenance activities. Combined with the previous measure of criticality further categorisations are possible – e.g. High Cost (A Category) activities on Negligible Impact failure modes etc.

3.3 Other Attributes

There are many other attributes available to categorise maintenance activities. Examples of these are frequency and repair time.

An example of the allocation of activities by cost to frequency is shown in Figure 3. The visibility of activities in this way identifies a challenge or opportunity – that of potential over maintaining. Particularly when combined with the information from the previous attributes.

The combination of information provides a point for managing maintenance activities. How do I manage my activities that are directed at negligible impact modes of failure that have a high cost and a high frequency?

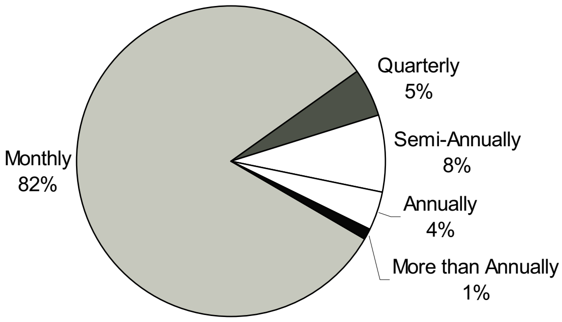

Figure 3 - Preventive Maintenance Activity Costs by Frequency [3]

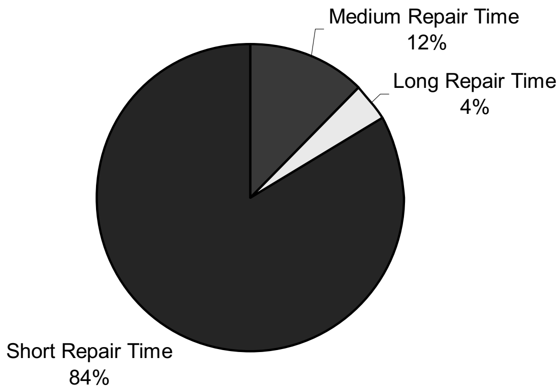

Figure 4 - Preventive Maintenance Activity Costs by Frequency (Source – Author)

A further and final example of an attribute is Repair Time for the failure mode shown in Figure 4. A repair time category can be applied to a component or failure on the basis of historical experience. For example, a Short Repair Time category may be 0 to 2 hours, while a medium repair time is 2 to 6 hours and a Long Repair Time greater than 6 hours.

A combination of attributes can create a profile for a maintenance activity that can be used to identify the activity for a specific course of management action. In this way there are no longer tens or hundreds of thousands of activities to be managed, but clusters of maintenance activities to be managed in a specific way.

There is potential for multiple attributes to become unwieldy if used to profile activities. The attributes described above give 180 different combinations or potential profiles for maintenance activities. The remainder of this paper considers the use of two attributes and four combinations to explain the features and benefits of the profiling approach. Quadrant Analysis is used for visualisation purposes.

4 QUADRANT ANALYSIS

Quadrant Analysis is a methodology of graphical representation and visualisation of any number of entities by two attributes. Quadrant analysis is viewed as a scatter plot of two variables on a set of axes to understand relationships between these variables.

An example of such an application of quadrant analysis is the Boston matrix [11] or Boston square analysis developed by the Boston Consulting Group during the 1970's [12] to plan market strategies. In the model of Figure 5, an organization's products and services were analysed in terms of Market Growth (percentage change in sales in a product or service category) and Market Share (ratio of an organization's sales in a product or service category to the total value of sales in that category).

An organization's products and services are positioned according to their perceived values and ranked within the various quadrants. These products and services are then categorised and managed accordingly. Cash Cows are used to finance other initiatives; problem children are monitored – hoping that they will eventually become stars. Dogs may be dumped.

Quadrant analysis has been extended to general problem analysis including risk assessment [9, 10]. The quadrant analysis approach is applied to the problem of maintenance activity management.

The Quadrant Analysis can be applied to the problem of maintenance activity analysis. Two possible attributes are identified in the content of Section 3, namely Criticality and Cost. A matrix with these attributes is shown in Figure 6.

4.1 Application of Quadrant Analysis to Maintenance Activities

The quadrants are described as:

Trivial – Maintenance Activities in this category have a low cost (Category B or C from Figure 2) and a low criticality (a score of 5 or lower in Table 1).

Excessive – Maintenance Activities in this category have a high cost (Category A from Figure 2) and a low criticality (a score of 5 or lower in Table 1).

Critical – Maintenance Activities in this category have a low cost (Category B or C from Figure 2) and a high criticality (a score of 6 or higher in Table 1).

Strategic - Maintenance Activities in this category have a high cost (Category A from Figure 2) and a high criticality (a score of 6 or higher in Table 1).

The naming of the quadrants is somewhat arbitrary. It is the management strategies for the Maintenance Activities in the quadrants that is the key point of the segregation. Management strategies for maintenance activities are argued on the basis of achieving the objectives of maintenance and opportunities to reduce direct maintenance costs.

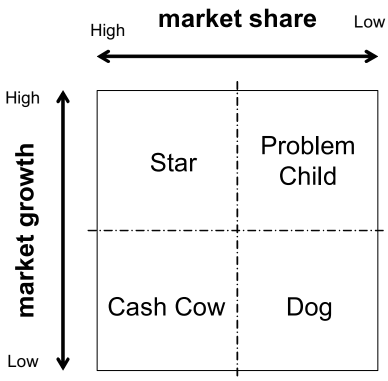

Figure 5 – Boston Matrix

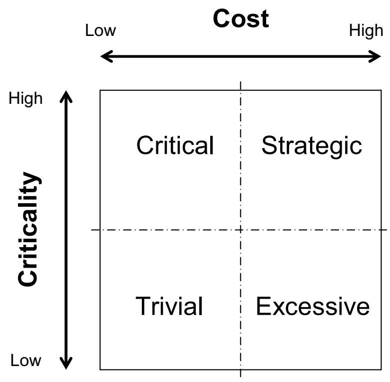

Figure 6 – Quadrant Analysis Applied to Maintenance Activities

4.2 Management Policies for Maintenance Activities

Management policies for the various segment of maintenance activities are influenced by observations on the features of these segments. These are discussed below.

Trivial maintenance activities have a low cost and a low criticality. Typically these activities take little effort to execute. The impact on the organization of not performing these activities, or working with less than optimal activities or timing is low. The effort required to make changes to these maintenance activities may be significant.

Excessive maintenance activities have a high cost and a low criticality. These activities may cost more to execute over the life cycle of a component than the opportunity cost associated with component or asset failure.

Critical maintenance activities have a low cost and a high criticality. These activities are significant because of the impact of failure. There is little opportunity to reduce maintenance costs by analysing these failures.

Strategic maintenance activities have a high cost and a high criticality. These activities are significant because of the impact of failure and the cost and effort associated with their execution.

Management policies for the various categories of maintenance activities are proposed in Table 2.

The management policies of Table 2 are considered to be a work in progress. While the content of the management policy for each segment is arguable, the diversity of the management policy is demonstrated.

5 APPLICATION OF QUADRANT ANALYSIS

To demonstrate the application of quadrant analysis to maintenance activity segregation, over 7,000 activities for a manufacturing facility were analysed. This facility was unusually appropriate for such an analysis because:

1. Recent work had been conducted to isolate individual maintenance activities from the Computerised Maintenance Management System;
2. A criticality assessment of assets and components was available to associate with individual maintenance activities.

Equipment criticality was allocated to the maintenance activities as shown in the scale of Table 1. A random factor was applied to provide a spread of points within the score band for visualisation purposes. The cost of the maintenance activity was converted to an equivalent annual cost based on the cost of the single activity annualised by its frequency. An A, B, C analysis of maintenance activity costs was conducted as indicated in Figure 2. Costs were adjusted with the A, B and C bands for visualisation purposes.

A scatter plot of the cost and criticality data was created. The number of maintenance activities in each of the four quadrants was counted. The results of this analysis are shown in Figure 7.

These results analysed by numbers show that relatively few maintenance activities were assessed as Strategic or Critical for the facility studied. Figure 7 shows that in terms of numbers (a count of maintenance activities in each segment):

Table 2 – Activity Segment Management Policies

TRIVIAL	- Perform activities as they arise (they do not take much time or effort); - Manage by exception (monitor metrics or KPIs by exception); - Delegate execution of these maintenance activities to other resources (e.g. contract or operations); - Consider activity redesign or elimination in the case of off-line maintenance activities (i.e. where downtime is required to perform the activity – or the maintenance activity is intrusive); - Pay a low level of attention to these maintenance activities (there are more important activities to be managed).
EXCESSIVE	- Consider task elimination based on economics; - Consider increasing maintenance intervals
CRITICAL	- Monitor compliance of these maintenance activities; - Monitor measures relating to cost of the activities on an exception basis; - Analyse unplanned failures related to these activities using causal analysis techniques; - Review the effectiveness of the maintenance activity on a periodic (say annual) basis; - Ensure that accurate maintenance records are kept; - Consider the use of risk based methodologies such as FMEA or RCM to improve task effectiveness, particularly on highly critical activities.
STRATEGIC	- Monitor compliance of these maintenance activities; - Actively apply risk based methodologies such as FMEA or RCM to improve task effectiveness and reduce costs; - Revisit the risk assessment associated with the maintenance activity on a periodic (say annual) basis; - Analyse unplanned failures related to these activities using causal analysis techniques; - Ensure that accurate maintenance records are kept.

- 5% of maintenance activities fall into the Strategic segment.
- 18% of maintenance activities fall into the Critical segment
- 23% of activities fall into the Excessive segment
- 54% of activities fall into the Trivial segment

The analysis of segment numbers show that relatively few maintenance activities are indicated as strategic and critical to the organisation.

If this is analysed by cost (sum the cost of the maintenance activities within each segment, the results show:

- 14% of total cost of maintenance activities falls into the Strategic segment.
- 7% of total cost of maintenance activities fall into the Critical segment
- 56% of total cost of maintenance activities fall into the Excessive segment
- 22 % of activities fall into the Trivial segment

The analysis of segment costs indicates the opportunity to challenge excessive maintenance activities.

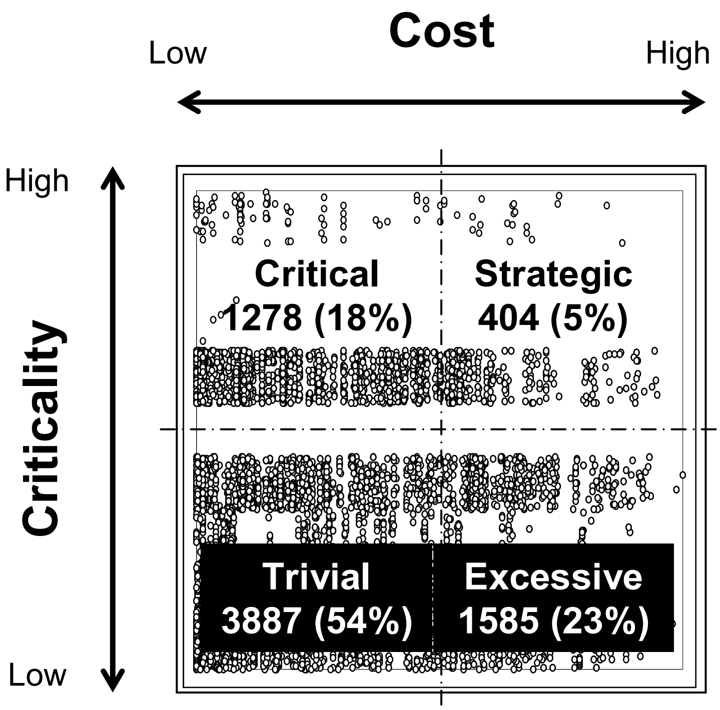

Figure 7 – Scatter Plot for Quadrant Analysis Application

The immediate benefit of maintenance activity segregation lies in the reduction of excessive activity. A study by Anderson [3] reports a reduction in the direct cost of Preventive Maintenance Activities by frequency reduction. This reduction was reported to be 40% of the total cost of Preventive Maintenance for the facility studied. Significant benefits are evident in maintenance activity segregation.

The results of the single application of quadrant analysis are not conclusive. There is insufficient analysis across sites to conclude a pattern of population of segments as a general rule. The following is indicated by these results:

1. There is variability in the criticality of maintenance activities within a facility;
2. There is variability in the cost of maintenance activities within a facility;
3. There is variability in the distribution of maintenance activities by cost and criticality;
4. Segmentation of maintenance activities indicates that different management strategies are justified for the various segments identified.

Additional work at different sites is warranted to further explore the application of quadrant analysis to the management of maintenance activities.

Technical analysis is challenged by:

- Lack of facilities with a complete set of maintenance activities identified as individual entities;
- Lack of facilities where a rigorous and dependable criticality analysis has been performed across the entire site

It s hoped that this paper will challenge organisations to consider the applicability and benefits of segmentation analysis of maintenance activities to facilitate access to additional data for analysis purposes.

6 CONCLUSION

There is a challenge for organisations to effectively manage large volumes of Preventive Maintenance activities. Quadrant analysis indicates that valid maintenance activity management strategies could be determined on the basis of the attributes of the maintenance activities.

Variability has been demonstrated in the application of quadrant analysis to a single facility. While this study is not conclusive, applicability of Quadrant Analysis to the segmentation of maintenance activities is indicated. It has been further demonstrated that management policies based on segmentation could be valid.

Additional application of quadrant analysis to the problem of maintenance activity analysis is warranted.

DEVELOPMENT OF A STRATEGIC ASSET MANAGEMENT FRAMEWORK

Ankur Maheshwari

Senior Consultant – Engineering and Asset Management
Norman, Disney & Young, Level 10, 200 St. Georges Terrace, Perth, Western Australia 6000, Australia

Abstract: Success of an asset intensive organisation is based on adoption of high quality asset management practices and systems. A strategic asset management framework (SAMF), ties an asset management organisation from end to end, and is targeted at improving efficiencies, effectiveness and overall performance whilst meeting the business objectives. A SAMF relies on three critical components – People, Process and Technology (Tools and Systems). Appropriate level of maturity is required in all the three aspects to ensure consistency and sustainability of the asset management outcomes. The development and maintenance of a SAMF is a continuous process and needs to be executed over the entire life cycle of an organisation. A sound approach has to be followed to ensure that an appropriate framework on asset management exists and is practiced and maintained by the organisation. Apart from a thorough understanding of the business objectives, a SAMF ensures harmonious operation of an organisation (consistency) and continual improvement (sustainability). This ultimately leads an organisation a step closer to achieving business excellence. The paper defines a strategic asset management framework and discusses steps involved in the development and implementation of such a framework. The approach presented in this paper can be applied to any asset management organisation.

Key Words: Asset, Strategy, Asset Management, Framework

1 STRATEGIC ASSET MANAGEMENT

The term asset management has differing meanings to different organisations. The definition of asset management may vary even within the same organisation. To some, asset management is just a means to an end, whilst to others it is the core mission. Asset management exists in one form or other in all aspects of life – be it managing one's real estate assets or industrial assets. The term 'strategic asset management' is proposed instead of the more loosely used term – 'asset management'.

There are various definitions to the strategic asset management. These can be found in numerous strategic asset management plans developed by building, university, utility, industrial and other infrastructure organisations. Each of these plans has defined the strategic asset management based on their organisations drivers and the needs. One of these definitions [1] is – "Strategic Asset Management can be defined as the planned alignment of physical assets with service demand. It is achieved by the systematic management of all decision-making processes taken throughout the life of the asset." Most of the other definitions closely align with this definition. These definitions assume a certain maturity level of the organisation, whilst may not ideally provide an environment of a complete assessment of the framework, process maturity and integration systems. This does not mean to say that there is any deficiency in this definition or associated management plans.

For the purpose of this paper we define strategic asset management as – "A process of developing, creating, maintaining and disposing assets through a complex series of interlinked well-defined processes that are continually improved, over the life cycle of an organisation, with an aim of achieving the objectives of the organisation." This definition takes asset management beyond mere operation and maintenance, and incorporates the creation of new assets as well. Traditionally asset management is only related to managing here and now assets – but this is not adequate in terms of ensuring long-term viability of the organisation. Strategic asset management is therefore beyond what is being done or how it is being done.

Just like parts of a body need honing and ongoing management to ensure sustainability, asset management processes also require continual development. Strategic asset management also involves this continual improvement of the processes, by monitoring and measurement. In a nutshell, strategic asset management matches the organisations assets (physical, human and resource) to its strategic directions. It develops the relationship between the strategic directions and the operational works.

2 STRATEGIC ASSET MANAGEMENT FRAMEWORK (SAMF)

One of the definitions on Strategic Asset Management Framework (SAMF) [2] "Strategic Asset Management Framework (SAMF) is an integrated policy strategy developed to improve asset management and capital investment across the State public sector. The SAMF is designed to ensure that the Government can continue to successfully manage its capital program while meeting its financial targets."

The Strategic Asset Management Framework as discussed in this paper is considered a more enhanced version of this definition. For the purpose of this paper we define "Strategic asset management framework (SAMF) as a tool that ties an asset management organisation's entire business operations from end to end. The framework forms the foundation on which the entire organisation operates." The key objectives of the framework are to ensure that –

- The objectives of the organisations stakeholders (shareholders, customers, regulators, employees, contractors and the community) are met.
- The performance of the organisation is continually improved.
- Long-term viability and sustainability of the organisation is ensured.
- The organisation is advancing towards a business excellence framework.

The discussion below presents a very fundamental view of the SAMF.

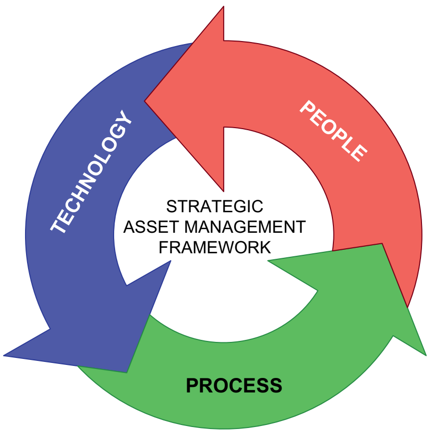

Figure 1 - SAMF Concept

The SAMF ties the three key links of the organisation namely – people, process and technology (see figure 1) and on this integration resides the delivery systems of the entire organisation.

The balance between the people, process and technology is achieved through an adequate understanding of the three links, and ensuring that an appropriate framework exists to retain the bond between these links.

People – The people aspect of the asset management framework is one of the most critical. From this comes the power of an organisation to 'think' and 'act'. It is the people of an organisation that conduct the process formulation and improvement, by applying the technology (tools and systems). Having said this, it is vital to recognise that, an organisation should render its processes and systems matured enough so that it could sustain itself even when the people turn-around is high.

Process – This is the second link of the SAMF. An organisation should endeavour to formalise all its key processes. This should be undertaken to drive value and ensure long-term sustainability. The formalisation of processes does not tend to limit the continual improvement of the organisation or enforce any form of bureaucracy. It provides a common meaning and direction to its internal and external customers, whilst presenting an orderly and matured image of the organisation. Formalisation of process also enables a framework for formal measurement of the performance of these processes and evaluation as to when the time is opportune enough to modify the processes or retain the good performing ones.

Technology – The third link of the SAMF is 'technology'. This can also be called as 'tools' and/or 'systems'. This link is made up of the tools and systems that enable the processes of the organisation. The technology arm binds the people and process links and is vital to consistency and sustainability while ensuring governance and control. The various systems deployed by an organisation need to be thoroughly integrated to ensure a smooth transition between the individual processes and deliver maximum efficiencies and effectiveness. The systems link is also the source of the critical information on which people of an organisation rely to make their decisions. Asset Management Information System (AMIS) is the key system within this link. Growing importance of the AMIS around the globe and its increasing application and maturity levels are example of the criticality of this link.

3 THE NEED AND BENEFITS

SAMF is a best practice approach to management that is utilised by high performing asset management organisations. The framework exists in one form or the other in varying degrees of maturity in each organisation, however its formal development and enhancement is what distinguishes high performing organisations from the rest. It is important to acknowledge that:

- an organisation with a SAMF does not guarantee success; and
- an organisation that is succeeding does not necessarily have a formal SAMF.

Whilst the above holds true, development and implementation of the SAMF provides a foundation for success, consistency, sustainability and credibility within an organisation. Depending on the operating environment of an organisation, the drivers for a SAMF may vary from organisation to organisation. Typically, the drivers include one or more of the following:

- consistency of application of business processes, including business sustainability;

- direction and guidance to staff (and contractors/ service providers);
- development of a culture of continual improvement;
- greater immunity from staff turn-around;
- efficient utilisation of scarce resources and appropriate allocation of resources (by prioritisation);
- minimisation of waste;
- enhanced productivity (by identification of poor performing processes);
- increased efficiency and effectiveness;
- greater returns from investment;
- critical input into strategic business planning processes;
- transparency in business operations;
- greater customer and community satisfaction;
- tool for regulatory compliance and demonstrating effectiveness of business operations.

Whilst the above are some of the many drivers for adopting a SAMF, there could be other factors that could act as catalysts to this process. These could include – scarcity of skilled resources, customer and regulator assurances and company image as a sound operating business etc.

3.1 The Benefits

As discussed above, the drivers and related benefits from a SAMF vary and it is up to an organisation's staff and management to harness the potential of this framework. Some benefits that a SAMF is known to deliver include –

- Cohesiveness of the processes (that may be operating in isolation) resulting in a transparent, integrated and commercially focused end-to-end management process.
- Consistency in application of processes and systems.
- Enhanced business image.
- Increased staff morale.
- Enhanced customer, regulatory and community confidence.
- Strengthening of inputs to the strategic planning process.
- Clear directions and objectives to management of assets.
- Sharpening the focus on organisation's risk appetite.
- Better management of organisations risk portfolio.
- More streamlined business functions and processes, leads to a more profitable commercial outcome.
- Greater efficiencies from within the business and enhanced effectiveness.
- Better positioning of the business to change and its adaptability to adjust to changes in the operating environment.
- Increased business sustainability and viability.

4 DEVELOPMENT OF A STRATEGIC ASSET MANAGEMENT FRAMEWORK (SAMF)

The complexity of the process of development of SAMF should not be underestimated. It may appear to be a simple concept, but in practice it requires careful planning, management and adequate steering to enable its success. There is no rules book to the development of the SAMF. The International Infrastructure Management Manual (IIMM) [3] is an accepted industry 'best practice' guide to asset management and has been known to be a reference document adopted by regulators and many other industry participants. This manual develops some basic concepts upon which an organisation can develop sound asset management fundamentals. Whilst these principles can be adopted in development of SAMF, it is to be acknowledged, that an organisation over the time develops its own useful and practical approach to asset management. Various factors need to be considered and analysed in this process.

This paper presents a methodology that could be applied by organisations. The most appropriate methodology has to be decided based on a critical assessment of the present state of operations. Whilst presenting the various options (where they are known to exist), it is assumed that the organisations do not have an existing formal SAMF.

An organisation could embark on the development of the SAMF, regardless of its age. However, the younger organisations (with some years of operational experience) are more ideally placed to development of a SAMF. This is assuming that the organisation has had a holistic experience of all aspects of its internal and external operating environment. As [4] puts it "In the early stages of evolution, companies that have adopted the strategic asset management business model see it first as a catalyst for organisational change and cost reduction." For other organisations, the case will more be of development with continual refinement until the most appropriate framework is developed. Nevertheless, it is important to realise that the framework is not static and needs continual review and refinement as operating environment changes and organisations performance/ performance driver changes. An organisation that has undergone a major structural review, a change of ownership, a major merger, change in regulatory environment, change in supplier/ resource environment, can also be treated as a "young" organisation and has a greater chance of seamless introduction of a SAMF. For older organisations, (with minimal recent changes), the road to introduction of the framework may be more complex and will require deployment of more complex 'change management' techniques than those that may be required for younger organisations. This is based on an assumption that older organisations have established traditional processes that will be hard to break or change. However, this may not hold true for all older organisations.

4.1 Methodology

The methodology proposed for the development of SAMF is based on the following key steps –

- Knowledge of the business.
- Clear definition of the business and associated processes.
- Development of an 'end-to-end' process model of the business.
- Definition of each process – including necessary dissection of the process into elements.
- Defining the process maturity levels and scoring system.
- Establishing the measurement framework.
- Assessment of maturity levels of existing process (and elements).
- Agreement to the targeted maturity levels for each process (and its elements).
- Development of action plans (to bridge the identified gap between targeted maturity levels and existing maturity levels) including associated expenditure budgets – for implementation.
- Prioritisation of the identified actions.
- Development of processes to ensure sustainability of performance of each process.
- Formal delivery of the entire framework.

5 STEPS IN DEVELOPMENT OF THE SAMF

The various steps for development and implementation of the framework are shown in figure 2. Each step is discussed in turn below.

5.1 Preparation

The preparatory phase in the development of the framework requires the following key steps –

- Appointment of a champion to lead the development of the framework – this should ideally be a senior management who has the overall accountability for process improvement, and a thorough understanding of the entire business process.
- Formation of a team of professionals (including process owners) who will be in charge of developing and implementing the framework. The team could be split between – the resources that participate in development (strategic and tactical management) of the framework and the resources that participate in implementation (tactical and operational management). A good overview of the 'total asset management process' is presented in [3].

- An understanding of the organisations objectives and targets (including its obligations and commitments to staff, customers, regulators and community).
- A process view of the organisation (input – output cycle).
- Organisation chart (present and foreseeable future) – this should include a critical evaluation of the enablers and blockers to the asset management framework.
- An understanding of the organisation's suppliers, service providers and contractors – this should include high-level information on the objectives of these service providers. More emphasis should be placed in understanding how the supplier's objectives relate to the organisations own objectives.

The above information needs to be collected and critically analysed. The analysis of this information will result into formation of a strategic plan for development and delivery of the SAMF. This analysis will identify any likely pit falls (blockers) to the framework and the enablers to the framework. The strategy should be to utilise the enablers while ensuring that the blockers do not have negative influence. This can be achieved by adopting appropriate change management techniques involving education, controls and (if necessary) removal of the blockers. It is important to note that the framework development and its implementation will need to be established as a 'non-negotiable' agenda within the organisation. *Observation – Whilst an organisation will have existing inherent strengths, it needs to en-cash on these strengths to improve in the areas where it may not be performing to its best. An organisation that has a culture of continual improvement presents an ideal environment for implementation of such a strategic framework.*

5.2 Identification of key processes

The process view of the organisation (as collected in preparatory phase) is to be analysed and detailed processes need to be identified and analysed as a first step. The second step is to produce an ideal process map that must exist for the organisation. This can be developed based on information on better processes deployed within other groups of the same organisation or other better performing organisations. Where an organisation considers its process model matured enough, such that it cannot identify any better process model/ its elements, it can rely on its own internal process model.

The processes that form the SAMF of an organisation are complex but interlinked. In order to ensure overall effectiveness within the organisation, each process in itself needs to be matured, well understood and applied. At the same time, it is the interplay between these processes that provide the overall strength to the organisation and improves its effectiveness and efficiencies. For e.g. even if each part of the body were performing at their best, if they are not synchronised to each other, the end result will not be as productive as it could / should be.

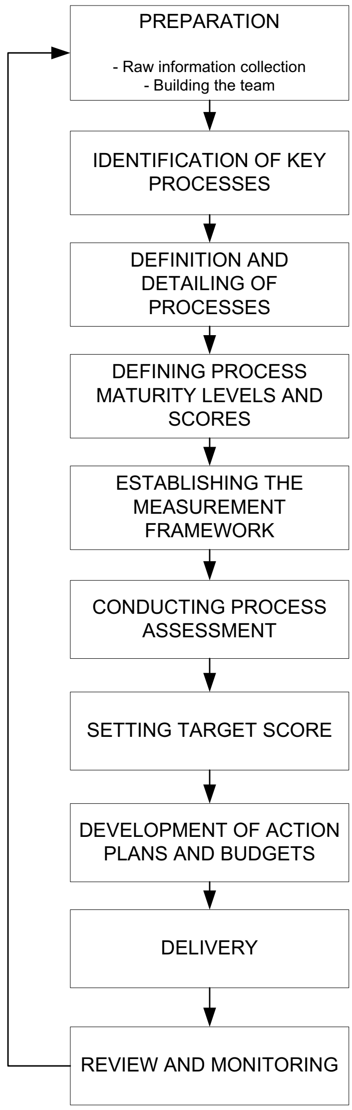

Figure 2 - Steps for Development and Implementation of SAMF

Once the information on the individual processes have been received, an overall process chart should be formed to show how individual processes link to each other to get the final outcome. This process chart needs to display all the inputs and outputs including the manner in which these interact.

A typical process model for an asset intensive organisation is shown in the figure 3. Processes must be identified for all aspects of the business from inputs down to the delivery/ outputs.

5.3 Definition and detailing of processes

The processes being identified in the last step need to be defined and detailed. This will result in a –

- Definition of each process.
- Dissection of the processes into individual process elements.
- Detailed mapping of the input – output cycle for individual processes and process elements.
- Detailing what the desired outcomes of each process will be and how will they be monitored. This must include setting appropriate performance targets that can be utilised to measure the performance of individual process.

- Process / process element owners must be identified for each process. Ideally these must be the lowest level staff responsible for the overall process within the organisation. This will ensure higher degree of acceptance.

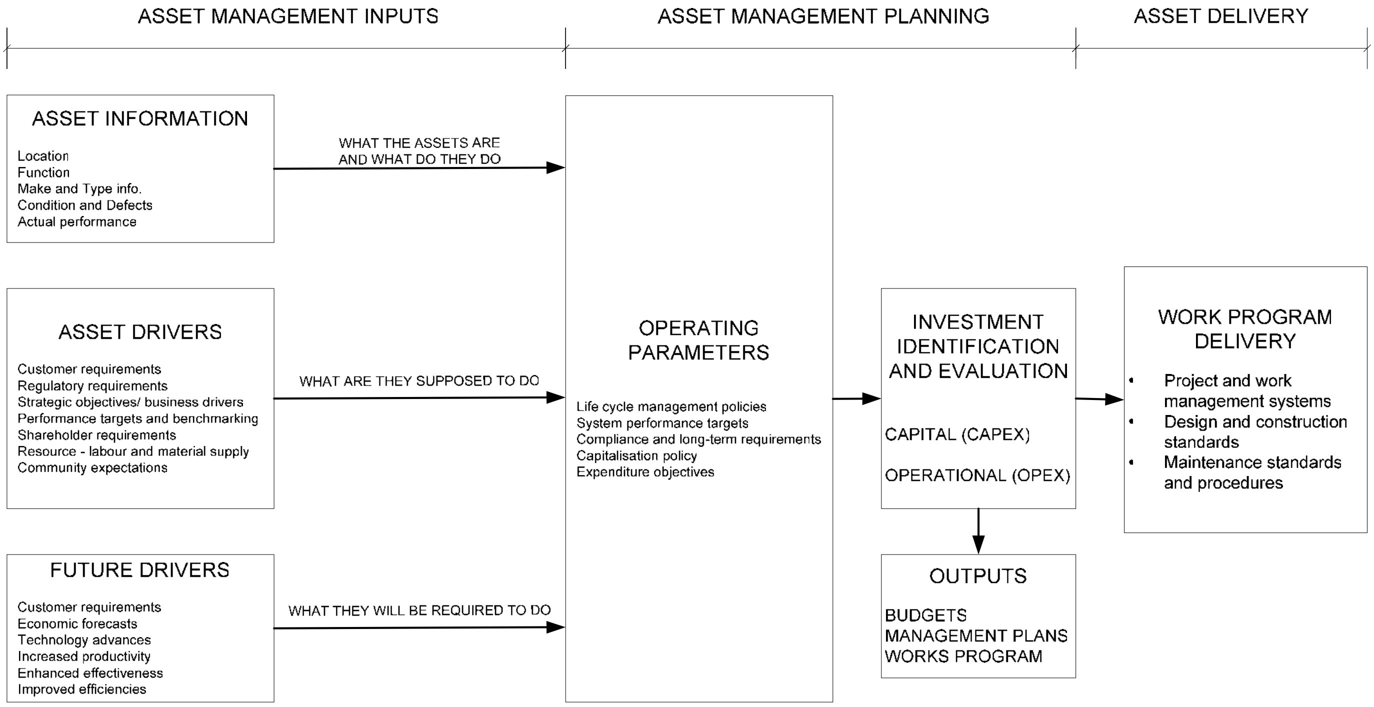

Figure 3 - Typical asset process model for an asset intensive organisation

An example of the elements to individual process is –

Process Asset Information

Process element Asset register, Asset attributes, Asset data, Systems integration

The process of splitting of the processes to elements provides a more robust platform to develop the asset management framework and subsequent delivery. The processes should be split to as many manageable process elements as possible.

5.4 Defining maturity levels and scores

This step involves defining the terminology that will be used to assess the maturity level of individual processes / elements and the related scores that will be used to mark the maturity of individual processes. A suggested terminology and score range that can be used for measurement are discussed below. These are represented in the figure 4. The terminology and scoring methodology include this measurement concept is discussed in [3] (section 2.4.3, Current Asset Management Status and Gap Analysis).

Unaware A rating that shows that the organisation and its staff are not aware of a particular process or a process element.

Score 0 - 10

Aware A rating that shows that the organisation and its staff have a reasonable awareness of the process, but do not practice (apply) it widely.

Score 11 - 30

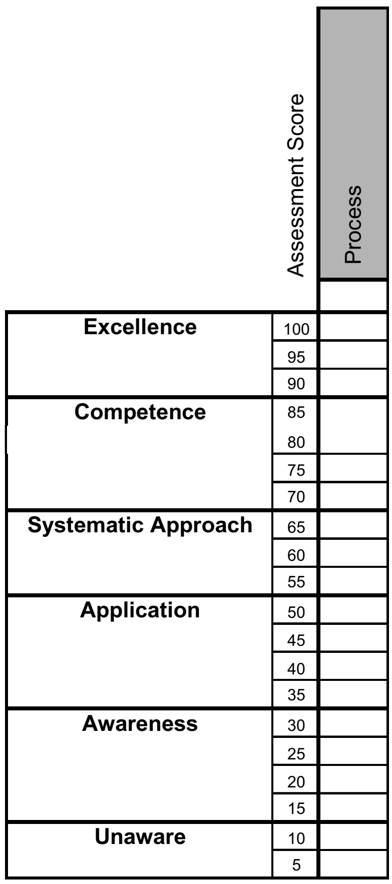

Figure 4 – Maturity Level

Application	A rating that shows that awareness of the process exists and is being applied in some cases. **Score 31 - 50**
Systematic Approach	A rating that shows that the organisations awareness of the process is very high and it is being applied consistently in almost all the cases. **Score 51 - 70**
Competence	A rating that shows that the organisation is well aware of the process, applies it systematically throughout the organisation (high compliance) and its process is matured to an extent that it can be classified as one of the best processes (when benchmarked against other similar organisations). **Score 71 - 85**
Excellence	A rating that shows that the process is applied systematically within the organisation and the process that is followed can be rated as the best in the industry. **Score 86 – 100**

5.5 Setting the measurement framework

This step involves formalising the measurement framework on which the existing maturity levels of individual processes will be gauged. The measurement framework prescribes how an individual process could be scored – for e.g. an asset register process may be considered as "unaware" if less than 80% relevant staff of organisation understand the concept, the organisation does not have a formal asset register or associated policy. At the same time, this process could be provided "systematic approach" rating if there is a formal asset register, formal asset data policy; more than 90% relevant staff understand the concept and complies with the same. This measurement framework will also assist in preparation of action plans to improve organisational process performance to improved levels.

This is a very critical step and one on which the success of the SAMF resides. This step involves establishing the benchmarks that will be utilised to score the existing maturity levels of the various processes and individual elements. This is a subjective exercise and can be very time consuming. The objective of SAMF must not be lost in this process – the objective being 'creating an environment of continual improvement and business excellence'.

The measurement framework could be set up using:

- 'absolute benchmarking' technique – that involves comparing one process of the organisation with another process within the same group or other groups within the same organisation; or
- 'relative benchmarking' technique – that involves comparing the processes of the organisation with those of another organisation with a similar or comparable operating environment.

The overall measurement framework could be a mixture of the above two techniques. The measurement framework should be formally established and endorsed by the key management staff. This will avoid conflicts and disagreements to the outcomes of the SAMF.

5.6 Conducting process assessment

This step involves formal assessment of maturity levels of each process. This requires information to be gathered on individual processes including – available formal documentation on processes and series of interviews with relevant staff (responsible for implementation of these processes). As many information sources as possible should be consulted to conduct an informed process assessment. This is a vital step as it sets the foundation to the robust framework. An inappropriate or loose assessment can lead to an inadequate framework.

The process assessment is conducted in two steps:

- The first step involves maturity assessment of individual elements of each process.
- The second step involves compilation of the individual element maturity assessment to generate an overall process maturity assessment.

The results of these assessments are then compiled to form a process assessment report. A sample of how this could be undertaken is shown in figure 5.

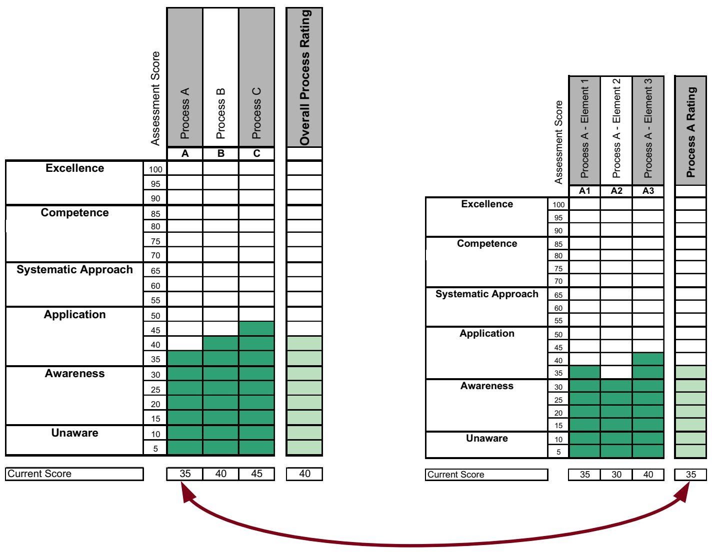

Figure 5 - Process and process element maturity assessment

5.7 Setting target score

As discussed earlier the objective of SAMF is to identify the avenues of improvement by enhancing current processes (where they exist) or developing new processes (as required) to meet the strategic objectives of the organisation.

This step in the development of SAMF involves setting the target score for each process and its process elements. Suggested time frame for implementation of the improvements is two years. The target score should be set based on an assessment of the practicality of implementing the improvements over a two-year period. The target scores are set in the context of –

- The processes that deliver the most benefit to the organisation in short-term and long-term.
- The processes that have maximum influence over the risk levels of the organisation (i.e. have more influence on reducing the risk levels).
- The processes that address the immediate business priorities of the organisation.

This step process is iterative in nature and requires recurring assessments to ensure that the target scores and associated initiatives can be delivered. Organisations need to be conscious of how much appetite they have for change. Such improvement initiatives could bring around a significant amount of change and the initiatives should be in 'bite size chunks'.

Once the target scores are set, a road map needs to be developed for incremental movements over two year period, i.e. the improvement targets for 12 months and for 24 months should be set. Figure 6 provides an illustration of the possible target score setting.

5.8 Development of action plan and associated budgets

Action plans need to be developed in order to bridge the gap between existing maturity levels of each process and the targeted maturity levels. These action plans need to be sufficiently clear and associated deliverables need to be clearly identified. The action plans should prescribe in details, the assessment criteria that will be applied to evaluate if the action has been completed or not. These criteria should be robust enough to ensure that the end result of implementation of the action is an enhanced maturity score of the individual process/ process element. The action plans should also be supported by budgets to undertake these actions. This is a substantial process improvement exercise and is adding to the value of intangible assets (process) of an organisation. The effort in this exercise should therefore be seen as an investment rather than expenditure. This will however depend on the capitalisation policy of the individual organisation.

5.9 The overall framework

The result of the above actions is a completed SAMF that enlists the organisations core business processes and the individual elements, their existing maturity levels, targeted maturity levels and the actions to be undertaken to bridge the gap. This framework is supposed to be managed as a living document and provides a key input into the overall strategic plan of an organisation.

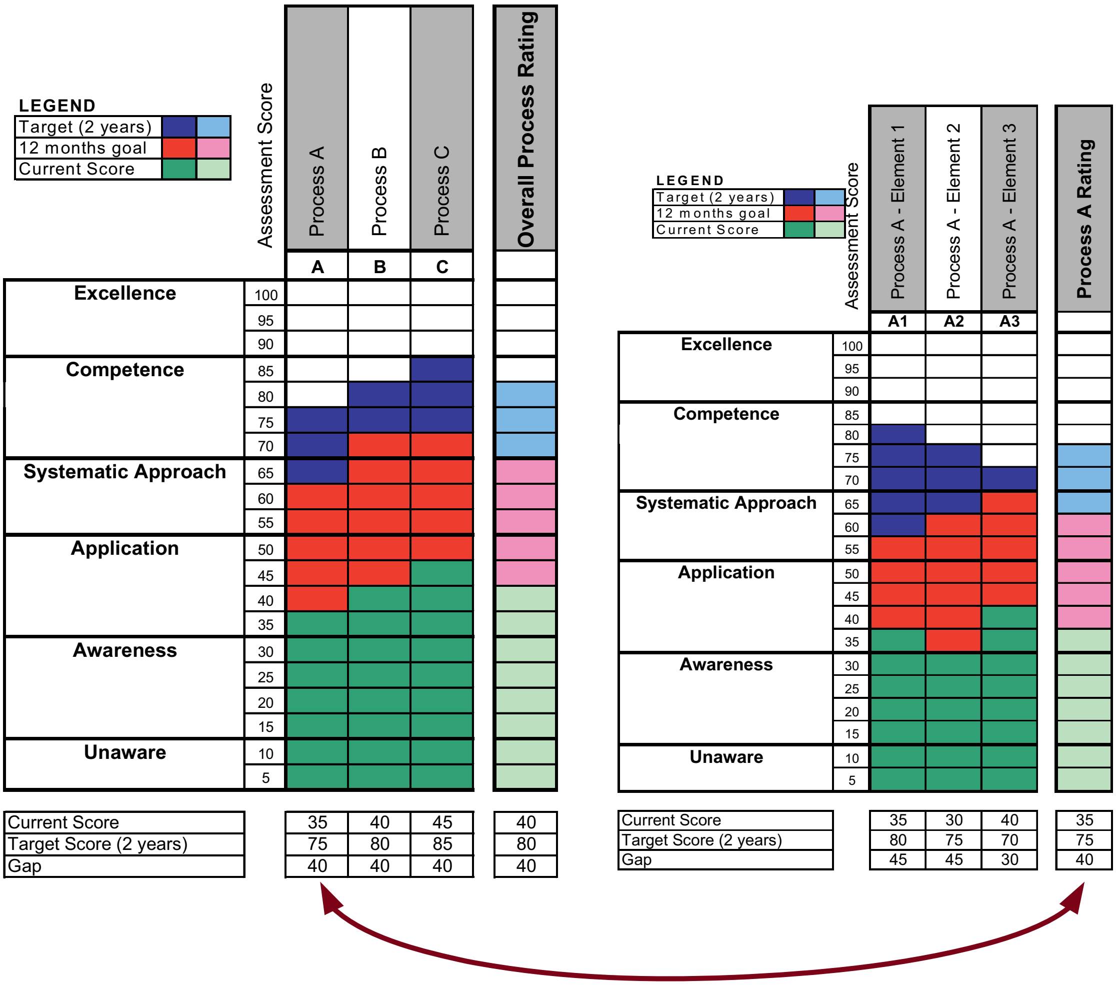

Figure 6 - Example of target score for 12 and 24 months

6 DELIVERY OF THE STRATEGIC ASSET MANAGEMENT FRAMEWORK

An open-learning environment within the organisation is a pre-requisite to the successful implementation of an initiative like SAMF. Based on the complexity of the initiatives resulting from development of the SAMF, the following steps are required to ensure their successful delivery –

- Delivery of a formal SAMF report.
- Briefing on the findings during the SAMF development to the entire organisation. This briefing should include the objectives of the SAMF, information on how the SAMF was developed, the target levels for each process (and the rationale/ objective behind this improvement exercise), expected business environment (during and after the implementation of the improvement initiatives), time frames and the overall impact on the business.
- A program management schedule should be prepared – with individual projects (improvement initiatives) clearly identified. Clear deliverables and expected quality levels of the deliverables must be prescribed.
- During the entire program, change management techniques should be planned and implemented. The change management techniques should focus not only on the implementation phase, but also on the benefits realisation phase (post implementation).
- A steering committee including a program manager and associated project team structure should be set up. Ideally, the implementation team should have a greater representation from the internal staff/ end users of the process.
- Monitoring of the program should ensure that the benefits are being realised during and after implementation.
- It should be possible to monitor the performance of the enhanced/ new processes and such information should be fed back to include in the overall framework.

6.1 Post implementation reviews

Post implementation reviews are critical for ongoing success of the SAMF. It should be remembered that, the development of SAMF is not an end of the journey. This is a never-ending journey and must involve periodic (preferred biennial) assessments of process maturity. This will ensure that best practices are continuously identified (and embraced) and any performance issues are actively addressed through feedback loop.

7 EXPERIENCES AND CONCLUSIONS

The proposed process of development of SAMF has been successfully utilised by a regulated, monopoly utility. It is acknowledged that the process is easy to use, but requires careful planning and adaptation to individual organisation's environment.

Development and implementation of a strategic asset management framework is critical for long-term success of asset intensive organisations. A process for development of the SAMF has been discussed in details, including the key aspects to be applied during implementation of this SAMF. This framework is based on the key concepts as discussed in the International Infrastructure Management Plan [3] and been practically implemented in a regulated monopoly utility.

Strategic Asset Management Framework development could result into useful insights to the business model (and its processes) and is a vital input to strategic business planning exercise. The SAMF development, implementation and continual review will assist organisations to unleash maximum value out of its resources and deliver best returns to its stakeholders.

ISO STANDARDS FOR CONDITION MONITORING

Leith Hitchcock

Reliability Solutions, Pall Corporation QLD, Australia.

Abstract: This paper introduces delegates to the content and requirements of the new, and under development, range of ISO standards relating to condition monitoring. The paper describes the outlined processes for condition monitoring system design and implementation as well as new concepts in the fields of diagnostics and prognostics. The processes outlined also have direct FMEA links to RCM programs and can be used to implement CM programs directly linked to RCM analyses.

This paper also outlines developments in the fields of Training and Accreditation including new and upcoming standards.

Several of the new standards released and under development discussed in this paper are:

ISO 17359, Condition monitoring and diagnostics of machines – General guidelines

ISO 13373, Mechanical vibration and shock - Vibration condition monitoring of machines

ISO 13379, Data interpretation and diagnostic techniques which use information and data related to the condition of a machine.

ISO 13381, Condition monitoring and diagnostics of machines – Prognostics

ISO 18436 Part II, Accreditation of organizations and training and certification of personnel - Part II - General requirements for training and certification – Vibration Analysis

ISO 18436 Sub Parts under development for Oil Analysis and Thermal Imaging

Key Words: RCM, Condition Monitoring, Prognostics, Vibration Analysis, Thermal Imaging, Diagnostics, ISO.

1 INDUSTRY BACKGROUND

Prior to 2002 litigation based on negligence in the condition monitoring business was not largely undertaken due to the lack of standardised procedures, processes, methodologies and associated training and certification requirements and systems available in the public domain that could be used as a basis for argument. This was also compounded by a lack of knowledge within the customer base. This lack of documentation has also resulted in customer contracts with no clearly stated and/or enforceable performance criteria that could be used to form the basis for such litigation.

This situation changed in 2002 with the release of the first of many ISO Standards covering the subject of condition monitoring the most important of which are ISO 17359 Condition monitoring and diagnostics of machines – General guidelines and ISO 18436 Condition monitoring and diagnostics of machines – Accreditation of organisations and training and certification of personnel.

These two documents, and their normative references, outline the processes by which condition monitoring should be performed and also the requirements for training and certification of personnel both of which form a basis for future litigation for negligence given that these documents are now in the public domain as International Standards.

Customers using these documents for the basis of their contracts will also now be able to specify compliance to the ISO processes as mandatory as well as specifying certification standards for personnel supplied. Customers are also becoming highly educated in condition monitoring particularly with the global expansion of such maintenance philosophies as RCM, TPM, Six Sigma and a global drive toward reliability as a focus rather than maintenance cost optimisation hence the requirement for such standards.

2 USE OF STANDARDS

In general the standards being produced can be used in a wide variety of ways including:

- Managing the quality of a delivered service
- Tender or contract compliance conditions
- Evaluation of service providers
- Internal program management
- Risk management
- Insurance management
- Service provider performance evaluation
- Litigation
- Training and education

Given the ease of quoting a standard in a contract document there is a significant risk associated with lack of customer knowledge of condition monitoring principles and techniques. This lack of knowledge coupled with a lack of thorough understanding of the standards requirements may still result in a high risk service provider being selected based on the lowest price basis without regard to risk minimisation. In future far more attention is needed across industry toward Return on Investment (ROI) and risk management approaches to selection and evaluation of service providers to ensure that the service is fit for purpose, with regard to risk of failure, and has the greatest return on investment potential with respect to problem solving rather than just defect detection.

3 GENERAL PROCESS MAP

A general conceptual approach to the overall condition monitoring process is given below in Figure 1 (ISO/CD 13379). An overview of the guideline process from ISO 17359 is shown below in Figure 2.

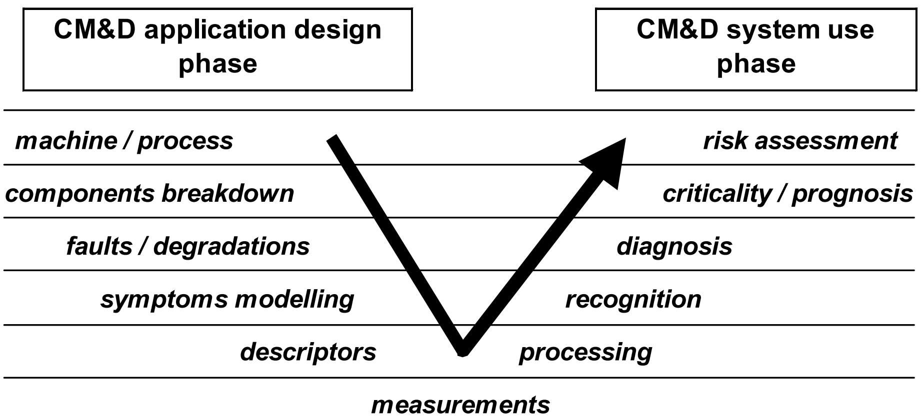

Fig. 1. Conceptual Approach.

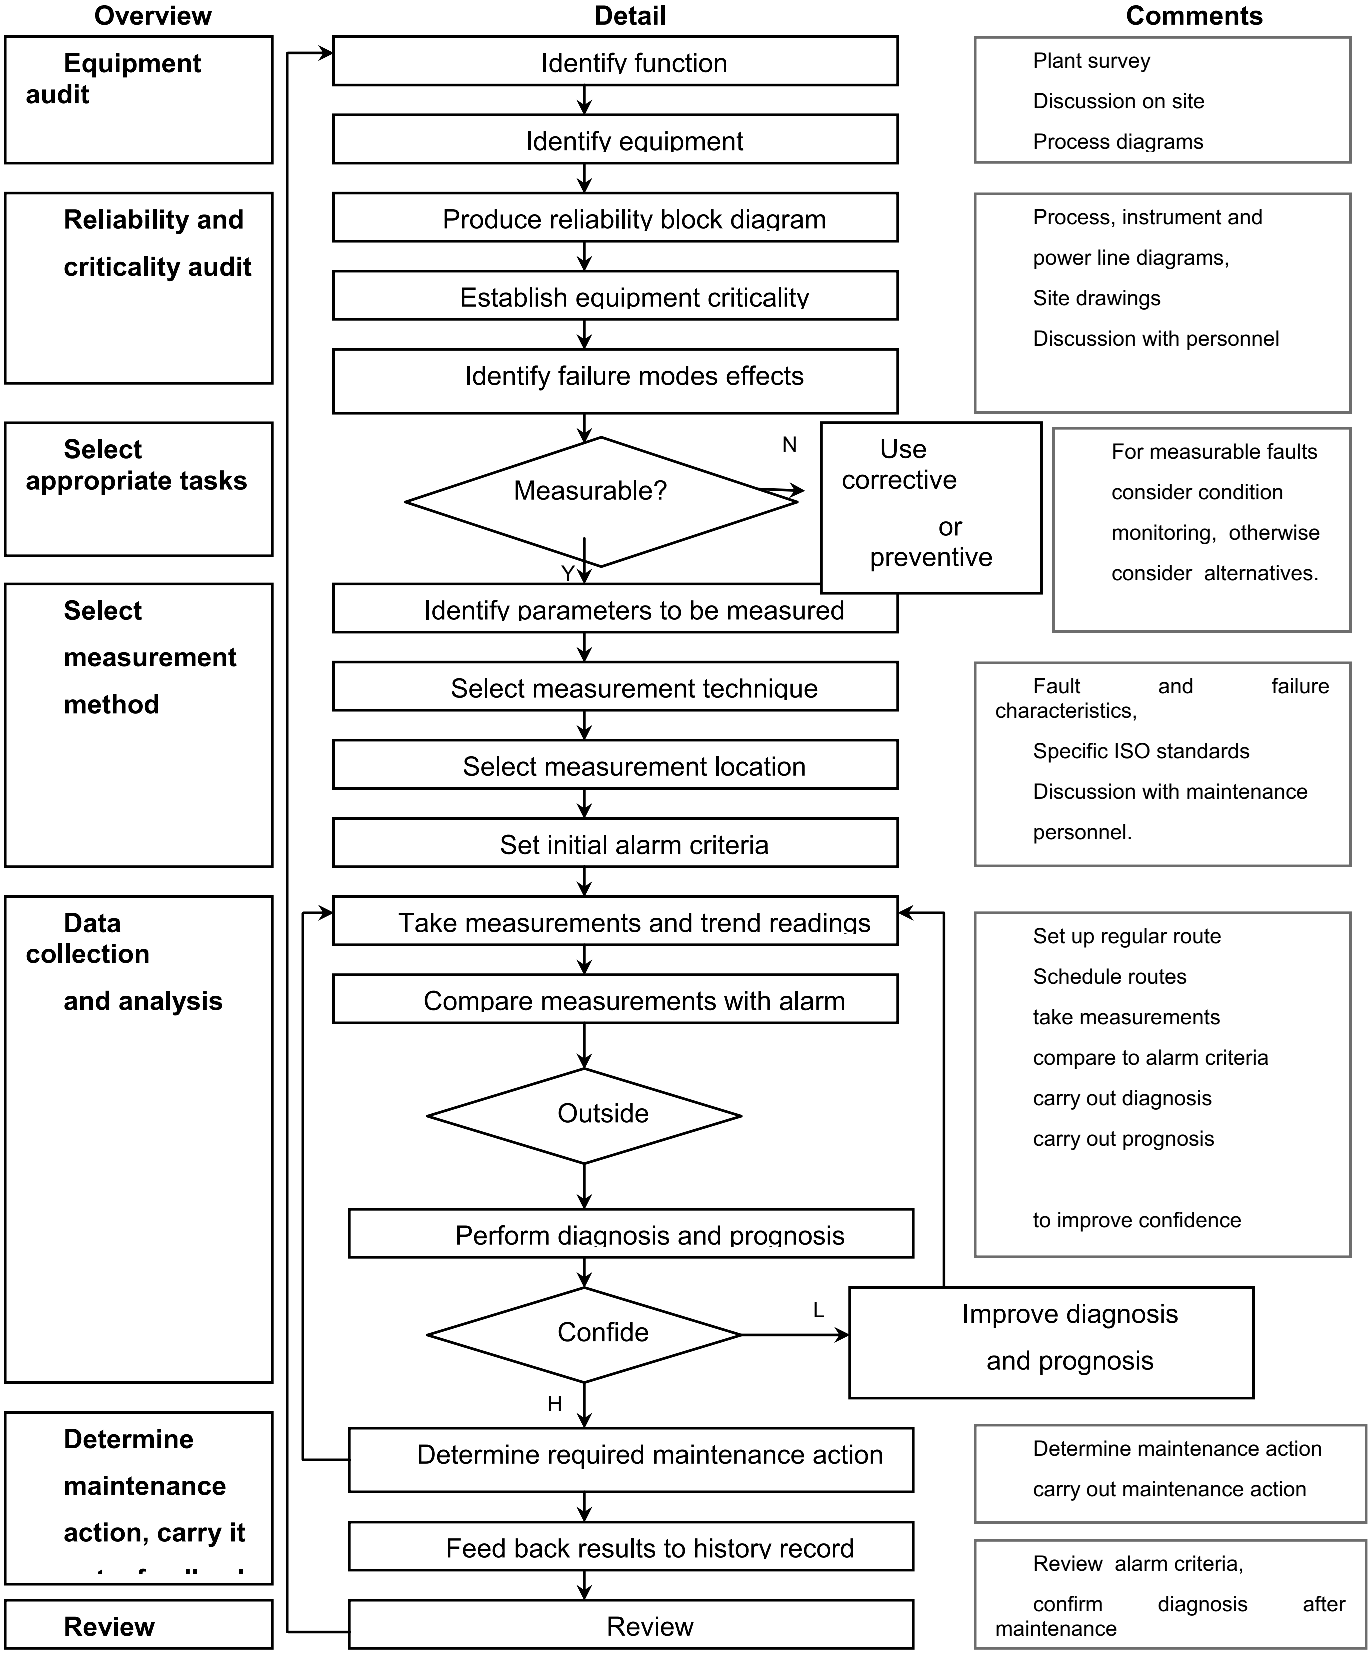

Fig. 2. ISO 17359 General approach diagram extract.

4 SELECTING THE RIGHT CONDITION MONITORING TECHNIQUE (FAILURE MODE SYMPTOMS ANALYSIS (FMSA)) – ISO 13379

4.1 FMSA process

The aim of this process is to select monitoring technologies and strategies that maximise the confidence level in the diagnosis and prognosis of any given failure mode. This methodology is designed to assist with the selection of monitoring techniques that will provide the greatest sensitivity to detection and rate of change of a given symptom. Where the confidence in a technique's sensitivity and resulting diagnosis/prognosis accuracy is questionable then the use of additional techniques for further correlation should be recommended.

This process is essentially a modification of a FMECA process with a focus on the symptoms produced by each identified failure mode and the subsequent selection of the most appropriate detection and monitoring techniques and strategies. This tool should be used in conjunction with an existing FMECA/RCM analysis that has already identified and ranked possible failure modes.

The essential elements of the FMSA process are:

— listing the components involved

— listing the possible failure modes for each component

— listing the effects of each failure mode

— listing the causes of each failure mode

— listing the symptoms produced by each failure mode

— ranking each symptom/monitoring technique combination by a detection rating, severity rating, diagnosis confidence rating and prognosis confidence rating resulting in an overall Monitoring Priority Number (MPN) rating.

— listing the most appropriate monitoring technique

— listing the estimated frequency of monitoring

— listing the most appropriate correlation techniques

— listing the frequency of monitoring for the correlation techniques

When considering monitoring strategies, the following form can also be used:

- A "Failure Mode" produces "Symptoms", which are best detectable by a "Primary Monitoring Technique" resulting in a high diagnosis and prognosis confidence when monitored at a given "Monitoring Frequency".

- Increased diagnosis and prognosis confidence can be gained by using "Correlation Techniques" when monitored at a given "Monitoring Frequency".

5 DIAGNOSIS AND PROGNOSIS PRINCIPLES - ISO 13379 AND ISO/CD 13381

Diagnosis process is generally triggered by anomaly detection. This detection is carried out by making comparison between the present descriptors of a machine, and reference values (generally called baseline values or data) chosen from experience, from the specifications of the manufacturer, from commissioning tests or computed from statistical data (e.g. long term average).

If confidence in the diagnosis and/or prognosis is low, then further verification may be required. If the confidence is high it may be possible to initiate maintenance or corrective action immediately.

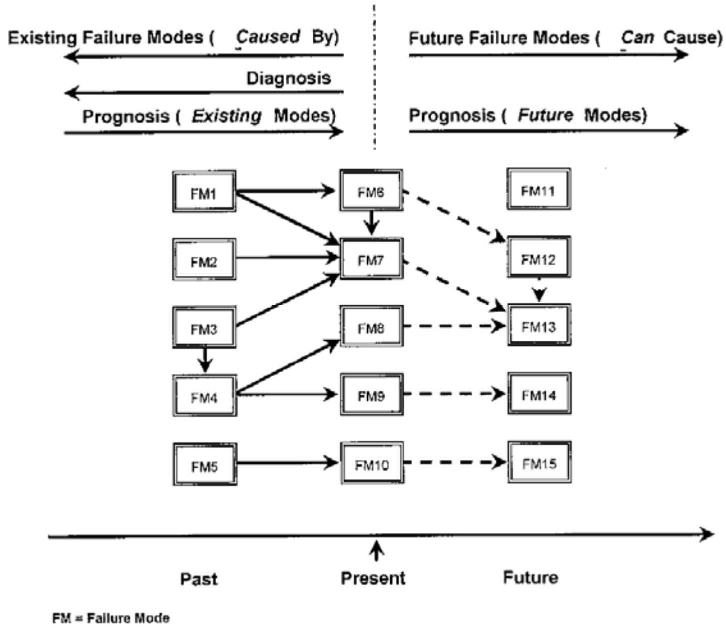

Fig. 3. Causal Tree Relationships for Diagnosis and Prognosis

5.1 Diagnosis and prognosis influence factors

Influence factors are parameters that effect the deterioration rate of a failure mode such as temperature, viscosity, clearance, load, speed, etc. Each influence factor can be considered a symptom of an existing failure mode and in Figure 3 is represented by the solid lines that connect existing failure mode trends. Influence factors also have effects on the progression and initiation of other either existing or future faults (Figure 3).

5.2 Improving diagnosis and/or prognosis confidence

In order to increase the confidence in the diagnosis/prognosis it may be necessary to carry out an iterative verification process as outlined in Figure 4. This process requires additional analysis of data using either the same technology or a different one or both in order to gain further diagnostic or prognostic information.

5.3 Setting alert, alarm and trip (shutdown) limits

The failure definition set point for a parameter/descriptor is the final value that it reaches at the point in time when the item fails. This value is normally determined historically from failure history.

The trip set point, however, is the parameter/descriptor value at which the machine is shut down and is normally less than its failure set point. This value is normally determined from standards, manufacturers' guidelines and experience. This is the value normally used to define the failed condition, however, this value is not normally reflective of the fully failed condition due to its lower set point required to prevent consequential damage or catastrophic failure. Alert and alarm limits are normally set at a value less than the trip set point.

For vibration condition monitoring, information on alarm criteria is contained in ISO/DIS 13373, ISO 10816 and ISO 7919.

Usually this value is determined based on the maintenance lead time required, however, such alert values should be cognisant of confidence level of prognosis, future production requirements, spare parts delivery lead times, maintenance planning lead time required, scope of work required to rectify faults, and trend extrapolation and projection.

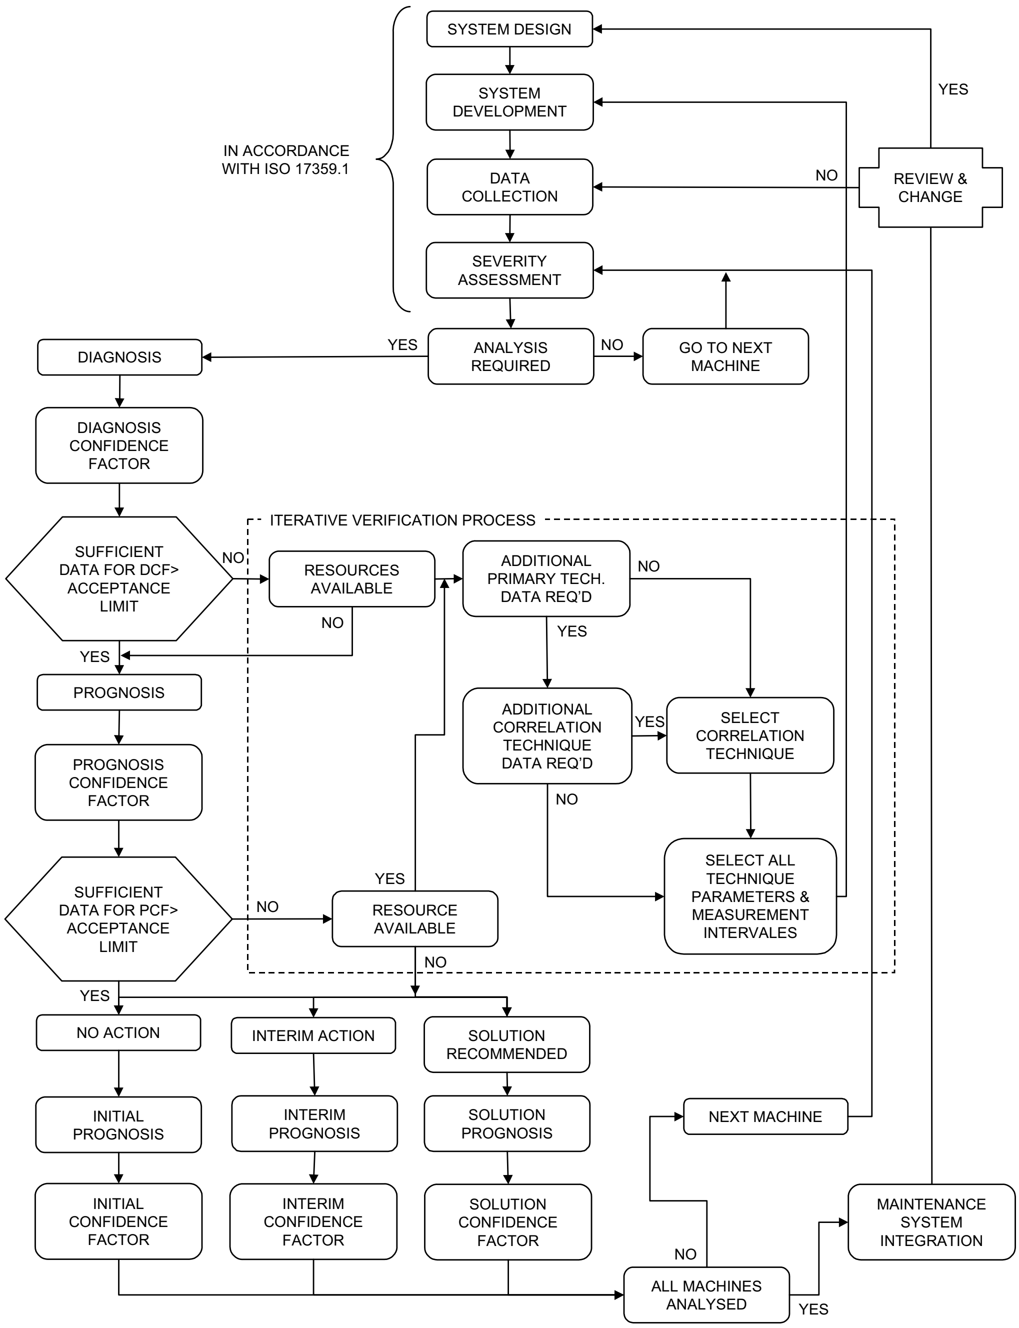

Fig. 4. Expanded Flow Chart for Diagnosis and Prognosis Confidence Level

6 TRAINING AND CERTIFICATION

The second part to running a *low risk* CM program is having qualified, experienced and certified practitioners suited to the level of risk involved in the program. The development of such standards has a global impact and is somewhat controversial given some existing international certification programs and bodies, however, TC108 SC5 has gained full liaison with BSI, BINDT, SAE, ASNT and ICML to ensure that such certification requirements are as aligned as possible to the global requirement.

To this end there are a number of ISO Standards on Training and Accreditation published as follows:

- ISO 18436-1 Condition Monitoring and Diagnostics of Machines – Requirements for Training and Certification of Personnel – Part 1 Requirements for Certifying Bodies and the Certification Process. This is a standard covering the general requirements for the certification process.

- ISO 18436-2 Condition Monitoring and Diagnostics of Machines – Requirements for Training and Certification of Personnel – Part 2 Vibration Analysis. This is a standard outlining the knowledge, experience, and training and examination requirements for a four level certification system for vibration analysts.

There are also several standards under development as follows:

- ISO 18436-3 Condition Monitoring and Diagnostics of Machines – Requirements for Training and Certification of Personnel – Part 3 Requirements for Training Bodies and the Training Process

- ISO 18436-4 Condition Monitoring and Diagnostics of Machines – Requirements for Training and Certification of Personnel – Part 4 Field Technician/Analyst. This is a standard outlining the knowledge, experience, training and examination requirement for a certification system for field based analysts.

- ISO 18436-5 Condition Monitoring and Diagnostics of Machines – Requirements for Training and Certification of Personnel – Part 5 Lubricant Laboratory Technician/Analyst. This is a standard outlining the knowledge, experience, training and examination requirement for a certification system for lubricant laboratory based analysts.

- ISO 18436-8 Condition Monitoring and Diagnostics of Machines – Requirements for Training and Certification of Personnel – Part 8 Thermography. This is a standard outlining the knowledge, experience, and training and examination requirements for a three level certification system for thermographers.

It is important to note that accreditation of Certifying Bodies is for compliance to ISO 18436 Part 1 and does not accredit the certifying organization to the body of knowledge parts. Similarly accreditation of Training Bodies is for compliance to ISO 18436 Part 3 and does not accredit the training material or delivery to the body of knowledge parts.

It also should be understood that the quality of any certification scheme in terms of validity, quality, industrial relevance and integrity is a function of its exam database and the management of such. Customers should be extremely careful with the selection of certification providers with regard to the robustness of their exam question development and management processes and as such their schemes should be thoroughly reviewed before adoption.

7 CONDITION MONITORING PROGRAM REVIEW

The CM process is an on-going process, and techniques which may not have been available, or at the time considered too costly, or too complicated, or unfeasible in some other way, may on review become feasible. Similarly the effectiveness of techniques currently being undertaken in the program should be assessed, and any techniques considered no longer necessary removed.

Similarly, warning and alarm values may need revision, due to changes in the machine such as progressive wear, ageing, modification, operation or duty cycle changes. Measured values and baselines may also change due to maintenance work, including component change, adjustment or duty change.

In certain cases the baseline may need to re-established following such changes. When maintenance actions have been carried out it is also useful to inspect components to confirm that the initial diagnosis or prognosis was correct.

The ISO Standards outlined form a basis for the design, implementation and management of a low risk condition monitoring program and as such are an invaluable resource to both suppliers and customers of condition monitoring services.

8 RECOMMENDATIONS

It is highly recommended that asset owners, service providers, and asset insurers become fully conversant with the knowledge and requirements outlined in the above standards in order to minimise the business risk associated with their activities.

Asset owners who outsource their condition monitoring should use such standards as the basis for evaluating, selecting and managing service providers and contracts. Asset owners with internal programs should use such standards to audit, validate and manage internal programs to ensure they are efficient, effective and are minimum risk.

Service providers should use such standards to design, refine and manage their programs and minimise their business risk.

Insurers should use such standards to audit and validate internal and external programs at customer facilities to ensure premium discounts or rebates and claim payouts are warranted.

9 SUMMARY CONCLUSIONS

It is foreseen that in the future these standards will form the basis for contracts, litigation and prosecution. It is not unrealistic to expect a future contract for condition monitoring services to read :

"The condition monitoring program with be designed in accordance with the requirements of ISO 17359, and where applicable ISO 13373 with the program designed by a person certified to a *minimum* of the second highest level for each technology category applied.

The selection of appropriate techniques shall be in accordance with ISO 13379. The vibration analysis component of the program shall be compliant with ISO 13373, ISO 10816, ISO 10817, ISO 7919, ISO 5348, and any other ISO standards relevant to the technique and application. The thermal imaging component of the program shall be compliant with ISO 18434. The lubricant analysis component of the program shall be compliant with ISO 14830. The performance monitoring based component shall be compliant with ISO 13380.

Diagnostic processes shall be compliant with ISO 13379 and ISO 13373. Prognostics and all reporting requirements shall be in accordance with ISO 13381.

Personnel shall be trained and certified to ISO 18436 with the program managed by a person certified to a *minimum* of the second highest level for each technology category applied.

The program and its compliance to standards will be audited and validated using the above stated standards. The stated standards, and their normative references, shall form the basis of any compliance-based litigation and/or prosecution."

This will become the norm particularly when such certification programs become fully mature and if the consequences of a missed failure include injury or death.

It is not also unrealistic to see a future where one of the key business drivers for standards implementation and compliance is the insurance sector.

As a minimum it should be recognised that standards represent the condensed and refined knowledge of a large group of international experts and as such contain the distilled knowledge of global experts. If for no other reason than education and learning, and a desire to improve, then such standards are a wealth of knowledge for practitioners.

By their very nature the use of such standards can result in the standardised implementation of a highly effective, highly efficient, low risk, optimised condition monitoring program that consistently produces repeatable results in a cost effective manner. Surely this alone is sufficient incentive to use them!

INTEGRATING ROOT CAUSE ANALYSIS METHODOLOGIES

Leith Hitchcock

CPEng CMRP, PALL Corporation

Abstract: Many Root Cause Analysis (RCA) methodologies have specific applications and limitations and in some case for complex machinery investigations they can be combined and enhanced for better results. Typical methodologies that can be combined effectively are Kepner Tregoe, Causal Tree Analysis (Apollo), Fault Tree Analysis, Logic Tree Analysis, Barrier Analysis, and Human Performance Evaluation amongst others.

The difficulty with many RCA methodologies currently available today is that by themselves they may not result in complete and efficient analyses and effectively implemented solutions for complex machinery problems. Most methodologies also need expert facilitation to achieve results. Many methodologies today also have widespread general application yet can be further enhanced for asset specific investigations. Furthermore the can be effectively combined for a more effective and efficient approach.

Using Life Cycle Management principles the concept the all root causes can be classified into one of five categories: Design, Manufacturing, Installation, Operation and Maintenance, can be used to enhance data gathering, problem identification, causal tree selection and management and solution design. This concept is also applicable to both logical (KT) and graphical (CT) methodologies.

Key Words: Fault Tree Analysis, RCA, Fault Tree Analysis, Barrier Analysis, Kepner Tregoe, Life Cycle Management, Solution Design, KT, CT.

1 THE PREPARATORY PHASE

The following flowchart is adapted from Reference 1 and outlined the key sequences in machinery RCA approach:

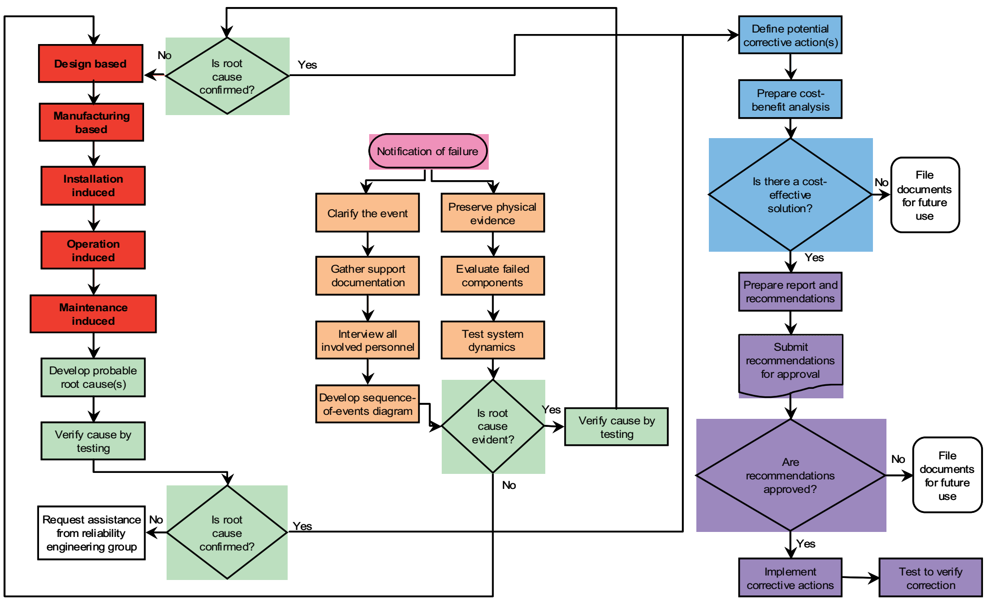

Figure 1. General Machinery Investigation Process (1)

The conceptual refinement is to drive the five basic root cause categories of Design, Manufacturing, Installation, Operation and Maintenance (DMIOM) into the RCA process via specific focussed areas of investigation.

2 THE BASIC TECHNIQUES

The following table is adapted from the US Government's DOE RCA Document[2] and outlines the applications and limitations of some for the generally used techniques:

Method	When to use	Advantages	Disadvantages	Remarks
Cause & Effect Chart Analysis *Fault Tree Analysis* *Logic Tree* *Fishbone Diagram*	Use for multi-faceted problems with long or complex causal factor chain. Fault or Logic Tree can be used when the problem involves logic or control issues.	Provides visual display of analysis process. Identifies probable contributors to the condition. Fault and Logic Tree capable of analysing logic issues with control systems or processes	Time consuming & requires familiarity with process to be effective. Fault and Logic Tree's can be extremely complex	Requires a broad perspective of the event to identify unrelated problems. Helps to identify where deviations occurred from acceptable methods. May need specialists in control systems and logic for Fault or Logic Tree methods.
Change Analysis	Use when cause is obscure. Especially useful in evaluating equipment failures.	Simple 4 step process.	Limited value because of the danger of accepting wrong, "obvious" answer.	A singular problem technique that can be used in support of a larger investigation. All Root Causes may not be identified.
Barrier Analysis	Use to identify barrier & equipment failures & procedural or administrative problems.	Provides systematic approach.	Requires familiarity with process to be effective.	This process is based on the MORT Hazard / Target concept.
Management Oversight & Risk Tree Analysis (MORT)	Use when there is a shortage of experts to ask the right questions & whenever the problem is a recurring one. Helpful in solving programmatic problems.	Can be used with limited prior training. Provides a list of questions for specific control & Management factors.	May only identify areas of cause, not specific causes.	If this process fails to identify problem areas, seek additional help or use Cause & Effect analysis.
Human Performance Evaluation	Use whenever people have been identified as being involved in the problem cause.	Thorough analysis. Looks at systemic and human aspects to failure.	None if the process is closely followed.	Requires training.
Kepner-Tregoe Problem Solving & Decision Making	Use for major concerns where all aspects need thorough analysis. Can be used as a general framework.	Highly structured approach, focuses on all aspects of the occurrence & problem resolution. Disciplined solution development process.	More comprehensive than may be needed.	Requires training.

Table 2. Method Applicability Table [2]

3 USING KEPNER-TREGOE AS A FRAMEWORK

Although the Kepner-Tregoe (KT) [3] methodology is comprehensive this degree of detail is often required for complex or extensive machinery failure investigations and warranty claim work. Using KT as a framework allows facilitators to better acquire and prepare information prior to carrying out such methodologies as Causal Tree[3] or Fault Tree[4]. This is important when the sequence of events, failure mechanism relationships and failure mode interrelationships must be understood in detail. Proper data acquisition prior to commencing the RCA also improves the processes effectiveness and efficiency.

A diagrammatic process is detailed below in Figure 2 detailing how KT can be used as a framework with other graphical techniques inserted for more detail failure mechanism/logic analysis.

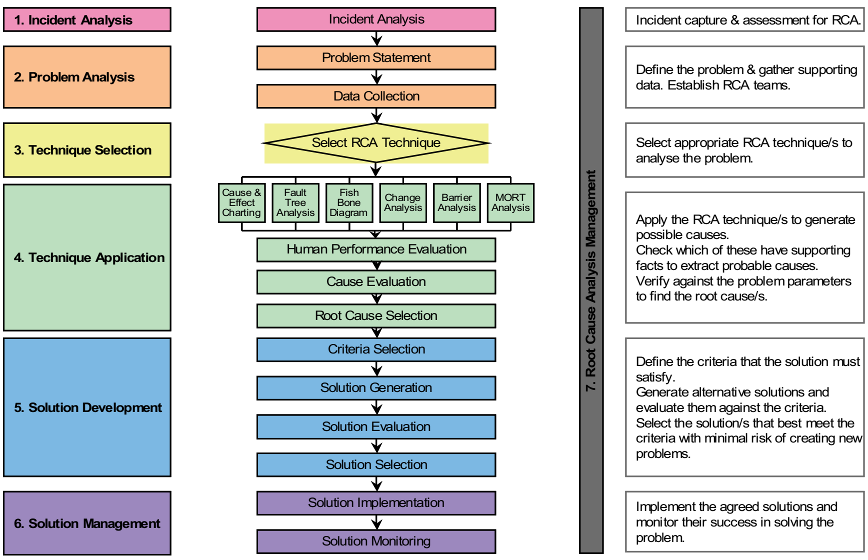

Fig. 3. A diagrammatic approach to using KT as a framework for RCA methodology integration.

The KT methodology, however, can be further improved by driving the DMIOM concept through the data acquisition, problem analysis, and solution design areas of RCA. One way to do this is to carry out the question challenge for each DMIOM category. An additional improvement is to expand the data acquisition/problem analysis phase with the basic elements from the change analysis methodology to give an additional "deviation" and "effect/consequence" dimension to the analysis as can be seen below in Table 2.

For each DMIOM category	*IS*	*IS NOT*	*Deviation*	*Effect/ Consequence*
Identity (WHAT)				
Location (WHERE)				
Timing (WHEN)				
Extent (SIGNIFICANCE)				

Answer the following questions and fill in the chart:

IS…

Identity - What item specifically has trouble? What is wrong with it?
Location - Where on the item did it happen? Where was the item located?
Timing - When did it happen - time, before / after, point in cycle?
Extent - When it happens how much is affected? Any pattern?

IS NOT…

Identity - Are there similar items? How are they affected?
Location - What parts are unaffected? Are others having trouble?
Timing - What are other likely times? Is it happening then too?
Extent - Is some portion consistently not involved? Is this usual?

Table 2. The expanded KT methodology with DMIOM category and change analysis embedded.

4 HUMAN ERROR

Human Performance Evaluation has a key role in linking solutions to DMIOM categories where there is human involvement. In the case of machinery failure human error is prevalent and in order to make solutions permanent a focus on the systemic and human dimensions needs to be carried out.

A systematic view of human error is outlined in Figure 4, which details the key areas for investigation into human and systemic error.

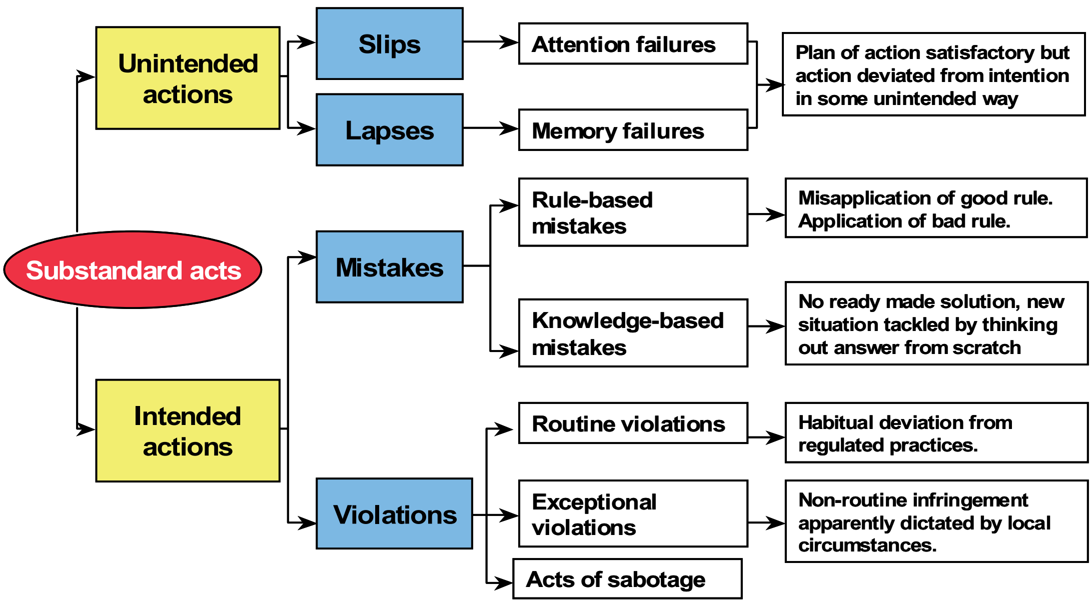

Figure 4. Human Error Sources

The analysis of human error as part of an asset RCA provides a necessary link to Incident/Accident investigation techniques used in health, safety, and environmental incident investigations where such techniques as Barrier Analysis [(2&5)] and MORT [(2&6)] are used.

5 MODIFYING CAUSAL TREE METHODS

Causal Tree analysis can often become difficult if a complex problem is not initially broken down into separate areas of analysis. This in itself poses a problem from a facilitation viewpoint in that sometimes the process can end up with several teams investigating the same fault tree. The classic example of this from a machinery viewpoint is "lubrication failure".

The author first used a matrix system in 1990 to regain control over a complex turbine investigation with great success. The system basically splits a complex investigation into several logical areas of analysis and each area is given a sequential number. The causal tree sheets (when using the Apollo method (7) for example) are then numbered and each fault tree is laid over an alphanumeric matrix such that each individual failure mode (Post-it note) can be identified using sheet number and Cartesian coordinate.

When simultaneous analyses are carried out the facilitator ensures that when a common cause is found it is only analysed once from either one fault tree or as a separate tree. Whenever this tree is referenced the initiating cause is marked with "TO Sheet X, Row Y, Column Z)" and the analysis tree is referenced "FROM Sheet A, Row B, Column C". The reason for this becomes clear when as the analysis progresses key failure modes become referenced multiple times. A failure mode that receives multiple references is either a Root Cause or a Significant Contributing Cause and must be dealt with by the solution. Quite often these multiple reference failure modes become the focus for quick fixes or interim solutions as they themselves influence multiple other failure mechanisms, as is the case for "lubrication failure" in machines investigations.

Further modifications can be made by incorporating "and, or, if" logic indicators on the causal tree branches, however, this can cause unnecessary complication of the process. This process is useful particularly in the case of conditional "if" review where an event wont take place until a preceding condition has been met.

6 CONCLUSION

Like any maintenance activity the different root cause analysis methodologies should be viewed as tools in a toolbox and as such any RCA program should not rely on just one method in isolation but rather have expertise in several key methodologies that can be deployed to suit the type of RCA required.

This concept of deploying a task oriented method is the general principle behind the US Governments DOE document.

When such techniques are used for machinery root cause analysis investigations users should consider further refinements as outlined in this paper in order improve the effectiveness and efficiency of investigations. Such processes and modification should, however, be based on the criticality of the failed asset, the risk associated with its failure, and the return on investments expected from the RCA.

MAINTAINING KNOWLEDGE ASSETS

Karl Matthews [a] and Howard Harris [b]

[a] *School of Management, University of South Australia; Principal Consultant of CBDConsultancy.com*

[b] *School of Management, University of South Australia*

Abstract: The importance of organisational information and knowledge in developing advantage and sustaining business competitiveness is becoming more widely recognised. Various standards have recently been developed to assist businesses create, store, access and reuse their knowledge. These standards include ISO 5037 Knowledge Management, ISO 9001 Quality Management, ISO 4801 Health and Safety, ISO 14000 Environmental Management and ISO 15489 Records Management. The management of knowledge, and the requirements of the standards, has led to the development of new management systems specifically designed to assist maintain organisational knowledge assets. However, it is considered that unless these new systems are implemented effectively they will not succeed in assisting managers maintain information and knowledge assets. This paper discusses this modern issue of information and knowledge asset maintenance. It includes a case study and taxonomy of the issues that influence the implementation of new management systems. These will provide insights into practical implementation issues and how they can be overcome. Ultimately, it is through better implementation of information and knowledge management systems that managers can better maintain their knowledge assets. The objective of this paper is to refine models that assist managers maintain organisational knowledge assets.

Key Words: Knowledge, Wisdom, Asset, Maintenance, Management, Change, Implementation, Agility

1 THE EVOLUTION OF KNOWLEDGE ASSETS

Over the 800 lifetimes of human existence, only during the last 6 have we benefited from the printed word. Only in the last two has anyone used an electric motor, and the overwhelming majority of all the material goods we currently use in daily life today have been developed within the present lifetime [1]. It is considered that the evolution of human knowledge has been a significant enabler to the technology development that has occurred over the last two 'lifetimes'.

This knowledge forms a significant part of organisational asset capital, being the most powerful engine of production and thus an asset requiring management [2]. Human knowledge is considered to be an Intangible Intellectual Capital Asset Resource [3]. By simple definition, an asset is a resource controlled by an enterprise as a result of past events and from which future economic benefits are expected to flow to the enterprise [4]. Intellectual capital assets (including knowledge) are as invisible as the roots of a tree, however these roots form a proportion of the entity and significantly affect its future performance [5]. The asset of Intellectual Capital is traditionally defined as having three parts being the human aspects, intra-organisational structures and the external environment [6].

According to Ahonen (2000), intangible assets can be divided into two classes, namely generative and commercially exploitable intangibles, which enable intellectual capital based value creation. The commercially exploitable intangibles consist, for example, of production, immaterial property rights, customer capital, demand and management. These commercially exploitable intangibles can be acquired or self generated through generative intangibles such as human capital, internal structures and external structures. These generative intangibles describe the capacity of a firm to produce commercially exploitable intangibles [7]. Knowledge assets therefore exist in both classes.

There are two different kinds of knowledge, that is, tacit and explicit [9]. Tacit knowledge resides in a person's mind and may include aspects of culture, or 'ways of doing things' [10]. It is personal and unarticulated, therefore, difficult to describe, communicate and share with others. It includes lessons learned, know-how, judgment, rules of thumb, and intuition [11]. Explicit knowledge is recorded as information in a document, image, film clip or some other medium [10]. It is clearly formulated or defined, easily expressed without ambiguity or vagueness, and codified and stored in information systems [11].

In Nonaka and Takeuchi (1995) the interaction between tacit and explicit knowledge has been expressed by means of the SECI model, which consists of four different modes of knowledge conversion: socialisation, externalisation, combination and internalization. Knowledge creation is a spiralling process in which different modes of knowledge conversion follow on each other. This process is called the epistemological level of knowledge creation. The SECI process is shown in Figure 1. This epistemological spiral of the SECI process expands both horizontally and vertically across the organisation, into new ontological levels. These two dimensions constitute knowledge creation [8].
